Privacy-Preserving Machine Learning

Manuel V. Loureiro

Version 2026-10-26

Table of contents

Preface **1**
How this book is organized . . . 1

I. Prerequisites **2**
Who this part is for . . . 3
The common thread . . . 3
How to read this part . . . 4
Notation . . . 5
What you will be able to do . . . 6

1. Probability distributions **7**
1.1. Why this matters . . . 7
1.2. Toolkit: what to know for each distribution . . . 8
1.3. Bernoulli and binomial . . . 11
1.4. Poisson . . . 12
1.5. Exponential . . . 15
1.6. Laplace . . . 19
1.7. Normal . . . 22
1.8. Comparing a density with its shifted copy . . . 27
1.9. Code: check the facts by simulation . . . 30
1.10. References . . . 30
1.11. Cheat sheet . . . 31

2. Concentration inequalities **32**
2.1. Why this matters . . . 32
2.2. Toolkit: five facts every derivation uses . . . 33
2.3. Markov and Chebyshev . . . 36
2.4. The Chernoff method . . . 38
2.5. Sub-Gaussian variables and Hoeffding . . . 42
2.6. Gaussian and Laplace tails . . . 47
2.7. McDiarmid and Azuma . . . 52
2.8. Code: check every bound by simulation . . . 55
2.9. References . . . 56
2.10. Cheat sheet . . . 56

3. Divergences **58**
3.1. Why this matters . . . 58
3.2. Toolkit: three facts every derivation uses . . . 60
3.3. KL divergence . . . 62

3.4. Rényi divergence . . . 66
3.5. Two Gaussians with equal variance, by hand . . . 72
3.6. Two Laplace distributions with shifted location . . . 74
3.7. Total variation . . . 77
3.8. Hockey-stick divergence . . . 81
3.9. f-divergences . . . 84
3.10. The data-processing inequality . . . 87
3.11. Pinsker's inequality . . . 90
3.12. Code: check every divergence by computation and simulation . . . 93
3.13. References . . . 95
3.14. Cheat sheet . . . 95

4. Hypothesis testing **97**
4.1. Why this matters . . . 97
4.2. Toolkit: four facts every derivation uses . . . 98
4.3. Simple-versus-simple testing . . . 100
4.4. The Neyman–Pearson lemma . . . 103
4.5. Trade-off functions and ROC curves . . . 107
4.6. The Gaussian trade-off curve . . . 109
4.7. The Laplace trade-off curve . . . 112
4.8. Best advantage equals total variation . . . 115
4.9. ROC summaries: why AUC hides the low-FPR regime . . . 118
4.10. The Bayesian view . . . 121
4.11. Estimating error rates from finite trials . . . 122
4.12. Code: check every result by computation and simulation . . . 127
4.13. References . . . 128
4.14. Cheat sheet . . . 128

5. Information theory **130**
5.1. Why this matters . . . 130
5.2. Toolkit: three facts every derivation uses . . . 131
5.3. Shannon entropy . . . 133
5.4. Mutual information . . . 138
5.5. Channels and capacity . . . 141
5.6. Min-entropy and guessing . . . 143
5.7. Conditional min-entropy and min-entropy leakage . . . 145
5.8. Shannon leakage versus min-entropy leakage . . . 149
5.9. Fano's inequality . . . 152
5.10. Code: check every formula numerically . . . 155
5.11. References . . . 156
5.12. Cheat sheet . . . 156

6. Optimization **158**
6.1. Why this matters . . . 158
6.2. Toolkit: five facts every derivation uses . . . 159
6.3. Convexity, Lipschitz continuity and smoothness . . . 162
6.4. Gradient descent and SGD . . . 166
6.5. SGD for convex Lipschitz objectives . . . 170

6.6. Strongly convex objectives . . . 173
6.7. Gradient noise and minibatches . . . 175
6.8. Non-convex objectives: convergence to stationary points . . . 179
6.9. Sensitivity of regularized ERM . . . 184
6.10. Code: check every bound by simulation . . . 188
6.11. References . . . 189
6.12. Cheat sheet . . . 189

7. Algorithmic stability and generalization **191**
7.1. Why this matters . . . 191
7.2. Toolkit: five facts every derivation uses . . . 192
7.3. Risk, empirical risk and the gap . . . 195
7.4. Uniform stability and the expected gap . . . 196
7.5. High probability: the Bousquet–Elisseeff bound . . . 200
7.6. Regularized ERM is stable . . . 203
7.7. SGD is stable if you stop early . . . 208
7.8. An unstable algorithm: 1-nearest neighbour . . . 210
7.9. Overfitting is memorization of individual records . . . 214
7.10. Choosing what to measure after looking . . . 216
7.11. Code: check every bound by simulation . . . 220
7.12. References . . . 221
7.13. Cheat sheet . . . 221

8. Cryptography basics **223**
8.1. Why this matters . . . 223
8.2. Toolkit: five facts every derivation uses . . . 224
8.3. Security parameter, adversaries and negligible functions . . . 226
8.4. Computational indistinguishability and the hybrid argument . . . 230
8.5. Concrete versus asymptotic security . . . 233
8.6. Pseudorandom generators and functions . . . 234
8.7. Encryption: perfect secrecy and IND-CPA . . . 240
8.8. The simulation paradigm . . . 243
8.9. Learning with errors . . . 245
8.10. Code: check the numbers by simulation . . . 250
8.11. References . . . 251
8.12. Cheat sheet . . . 252

II. Threat models and attacks **254**
Who this part is for . . . 255
The common thread . . . 255
How to read this part . . . 257
Notation . . . 257
What you will be able to do . . . 258

9. Threat models and privacy games **260**
9.1. Why this matters . . . 260
9.2. Toolkit: three facts every derivation uses . . . 261

9.3. Threat models . . . 265
9.4. Privacy games . . . 269
9.5. Advantage, total variation and the trade-off curve . . . 273
9.6. Average case and worst case . . . 276
9.7. Code: check every number by computation and simulation . . . 279
9.8. References . . . 280
9.9. Cheat sheet . . . 281

10. Membership inference **283**
10.1. Why this matters . . . 283
10.2. Toolkit: three facts every derivation uses . . . 285
10.3. The loss attack and the generalization gap . . . 287
10.4. Shadow models . . . 289
10.5. LiRA: a likelihood-ratio test per example . . . 293
10.6. Evaluating attacks: TPR at a low FPR . . . 298
10.7. Why outliers are most exposed . . . 302
10.8. The full-size pipeline: LiRA on CIFAR-10 . . . 306
10.9. Code: run every attack on the running example . . . 307
10.10. References . . . 309
10.11. Cheat sheet . . . 309

11. Attribute inference and model inversion **311**
11.1. Why this matters . . . 311
11.2. Toolkit: three facts every derivation uses . . . 313
11.3. The attribute inference game . . . 314
11.4. The imputation baseline . . . 317
11.5. Model inversion: the MAP attack . . . 319
11.6. Confidence masking . . . 325
11.7. Code: the game on a toy model . . . 328
11.8. References . . . 329
11.9. Cheat sheet . . . 330

12. Property inference **331**
12.1. Why this matters . . . 331
12.2. Toolkit: three facts every derivation uses . . . 333
12.3. The property-inference game . . . 335
12.4. Why a property leaks when no record does . . . 337
12.5. Shadow models and meta-classifiers . . . 341
12.6. Permutation invariance . . . 346
12.7. Code: check every result by computation and simulation . . . 349
12.8. References . . . 350
12.9. Cheat sheet . . . 351

13. Memorization and training-data extraction **353**
13.1. Why this matters . . . 353
13.2. Toolkit: three facts every derivation uses . . . 354
13.3. Verbatim, approximate, discoverable, extractable . . . 357
13.4. Duplication and model size: the copies a string needs . . . 359

13.5. Canaries and the exposure metric . . . 363
13.6. Extraction without the prefix: generate, rank, verify . . . 368
13.7. Code: check every number by computation and simulation . . . 372
13.8. References . . . 373
13.9. Cheat sheet . . . 374

14. Gradient inversion **376**
14.1. Why this matters . . . 376
14.2. Toolkit: three facts every derivation uses . . . 378
14.3. Exact recovery from a fully connected layer . . . 380
14.4. Label recovery from the last layer . . . 383
14.5. Deep Leakage from Gradients . . . 386
14.6. Batches and averaging . . . 389
14.7. Code: check every attack by computation . . . 394
14.8. References . . . 395
14.9. Cheat sheet . . . 396

15. Linkage and re-identification **398**
15.1. Why this matters . . . 398
15.2. Toolkit: three facts every derivation uses . . . 399
15.3. Quasi-identifiers and the linkage attack . . . 401
15.4. Pseudonyms and hashed identifiers . . . 405
15.5. How many people are unique? A birthday calculation . . . 407
15.6. Sparse, high-dimensional data: the Netflix attack . . . 412
15.7. Does releasing a sample protect? . . . 418
15.8. Code: check every formula by simulation . . . 422
15.9. References . . . 423
15.10. Cheat sheet . . . 424

16. Syntactic anonymity and how it breaks **426**
16.1. Why this matters . . . 426
16.2. Toolkit: three facts every derivation uses . . . 427
16.3. k-anonymity . . . 429
16.4. Homogeneity, background knowledge and l-diversity . . . 434
16.5. Skewness, similarity and t-closeness . . . 437
16.6. The composition attack . . . 440
16.7. Code: anonymize, then attack . . . 444
16.8. References . . . 445
16.9. Cheat sheet . . . 446

17. Reconstruction attacks **448**
17.1. Why this matters . . . 448
17.2. Toolkit: three facts every derivation uses . . . 449
17.3. The exponential attack . . . 451
17.4. The linear-programming decoder . . . 454
17.5. Least squares under worst-case and random error . . . 458
17.6. The Fundamental Law of Information Recovery . . . 462
17.7. Attacking a deployed query system . . . 467

17.8. Reconstructing a census block . . . 471
17.9. Code: check every attack by computation and simulation . . . 474
17.10. References . . . 475
17.11. Cheat sheet . . . 476

III. Differential privacy foundations **478**
Who this part is for . . . 479
The common thread . . . 479
How to read this part . . . 480
Notation . . . 481
What you will be able to do . . . 482

18. The definition of differential privacy **484**
18.1. Neighbouring datasets . . . 484
18.2. Pure and approximate differential privacy . . . 485
18.3. Randomized response . . . 488
18.4. Divergence forms and the privacy loss . . . 490
18.5. The hypothesis-testing interpretation . . . 493
18.6. Bound on the membership advantage . . . 494
18.7. The Bayesian interpretation . . . 497
18.8. Why δ must be much smaller than 1/n . . . 499
18.9. What differential privacy does not protect . . . 501
18.10. Is it a privacy violation? . . . 502
18.11. Code . . . 503
18.12. Summary . . . 504
18.13. References . . . 505

19. Post-processing, group privacy and composition **507**
19.1. Post-processing . . . 507
19.2. Group privacy . . . 511
19.3. Basic sequential composition . . . 513
19.4. Parallel composition . . . 519
19.5. What composes and what doesn't . . . 520
19.6. Code . . . 522
19.7. Summary . . . 523
19.8. References . . . 523

20. The Laplace and Gaussian mechanisms **525**
20.1. Sensitivity . . . 525
20.2. The Laplace mechanism . . . 527
20.3. The Gaussian mechanism: classic calibration . . . 532
20.4. The exact privacy profile of the Gaussian mechanism . . . 535
20.5. Laplace against Gaussian in many dimensions . . . 538
20.6. Code . . . 540
20.7. Summary . . . 541
20.8. References . . . 542

21. Advanced and optimal composition **544**
21.1. The privacy loss of a composition . . . 544
21.2. Advanced composition . . . 548
21.3. The worst mechanism . . . 551
21.4. Optimal composition . . . 553
21.5. Adaptive composition . . . 556
21.6. Code . . . 558
21.7. Summary . . . 559
21.8. References . . . 560

22. Selection: exponential mechanism, report-noisy-max, sparse vector **562**
22.1. The exponential mechanism . . . 562
22.2. Utility of the exponential mechanism . . . 564
22.3. Applications of the exponential mechanism . . . 566
22.4. Report-noisy-max . . . 570
22.5. Gumbel noise: report-noisy-max is the exponential mechanism . . . 572
22.6. The sparse vector technique . . . 574
22.7. When the sparse vector technique goes wrong . . . 576
22.8. Code . . . 579
22.9. Summary . . . 580
22.10. References . . . 581

23. Query release and private multiplicative weights **583**
23.1. Linear queries as inner products . . . 583
23.2. Noise on every answer . . . 585
23.3. Multiplicative weights and its regret bound . . . 586
23.4. From regret to a mistake bound . . . 588
23.5. Private multiplicative weights . . . 590
23.6. Online private multiplicative weights . . . 594
23.7. SmallDB: the exponential mechanism over small datasets . . . 596
23.8. Code . . . 598
23.9. Summary . . . 598
23.10. References . . . 599

24. Beyond global sensitivity **601**
24.1. Local sensitivity, and why it leaks . . . 601
24.2. Smooth sensitivity . . . 604
24.3. Admissible noise for smooth sensitivity . . . 606
24.4. Propose-test-release . . . 609
24.5. Inverse sensitivity . . . 611
24.6. Stability-based release . . . 612
24.7. Subsample-and-aggregate . . . 614
24.8. Clipping . . . 615
24.9. Code . . . 618
24.10. Summary . . . 619
24.11. References . . . 620

25. Discrete and floating-point-safe mechanisms **621**
25.1. Floating-point Laplace breaks differential privacy . . . 621
25.2. The snapping mechanism . . . 623
25.3. An exact coin with an exponential bias . . . 624
25.4. The discrete Laplace mechanism . . . 627
25.5. The discrete Gaussian mechanism . . . 631
25.6. Sampling the discrete Gaussian exactly . . . 636
25.7. Code . . . 638
25.8. Summary . . . 639
25.9. References . . . 640

26. Local, shuffle and distributed trust models **641**
26.1. Central and local differential privacy . . . 642
26.2. The price of local privacy . . . 644
26.3. Frequency estimation . . . 648
26.4. Large and unknown domains . . . 650
26.5. Estimating a mean . . . 652
26.6. Collecting every day . . . 654
26.7. The shuffle model . . . 656
26.8. Distributed noise . . . 658
26.9. Code . . . 661
26.10. Summary . . . 661
26.11. References . . . 663

27. Lower bounds: what privacy costs **665**
27.1. Packing: pure DP pays the logarithm of the number of candidates . . . 666
27.2. Sample complexity: how many records privacy costs . . . 671
27.3. Fingerprinting: the $\sqrt{d}$ lower bound for approximate DP . . . 674
27.4. Tracing attacks: the lower bound is a membership inference attack . . . 679
27.5. Dinur–Nissim as a lower bound . . . 681
27.6. Code . . . 684
27.7. Summary . . . 685
27.8. References . . . 686

28. Private mean estimation **688**
28.1. Bounded data . . . 689
28.2. Gaussian data with a known range . . . 691
28.3. Coarse then fine . . . 693
28.4. Many dimensions: shrinking balls . . . 697
28.5. Heavy tails: clip into the data . . . 700
28.6. Code . . . 703
28.7. Summary . . . 704
28.8. References . . . 705

IV. Privacy accounting **707**
Who this part is for . . . 708
The common thread . . . 708

The running example . . . 710
How to read this part . . . 710
Notation . . . 710
What you will be able to do . . . 712

29. Rényi differential privacy **713**
29.1. Why this matters . . . 713
29.2. Toolkit: four facts from Part 1 . . . 715
29.3. Rényi differential privacy . . . 716
29.4. RDP curves of the basic mechanisms . . . 719
29.5. Composition adds curves . . . 722
29.6. Post-processing and group privacy . . . 726
29.7. The moments accountant is RDP in disguise . . . 729
29.8. From RDP to (ε, δ) . . . 731
29.9. Code: check every curve and every conversion . . . 735
29.10. References . . . 736
29.11. Cheat sheet . . . 737

30. From Rényi DP to (ε, δ) and to tests **739**
30.1. Why this matters . . . 739
30.2. Toolkit: four facts every derivation uses . . . 740
30.3. Where Mironov's conversion loses . . . 742
30.4. The improved conversion . . . 744
30.5. RDP as a constraint on tests . . . 748
30.6. Choosing the order . . . 752
30.7. The slack no conversion removes . . . 755
30.8. Code: check every conversion by computation . . . 758
30.9. References . . . 760
30.10. Cheat sheet . . . 760

31. Concentrated differential privacy **762**
31.1. Why this matters . . . 762
31.2. Toolkit: four facts used below . . . 763
31.3. The definition of zCDP . . . 764
31.4. Pure DP implies zCDP . . . 768
31.5. From zCDP to (ε, δ) . . . 773
31.6. Group privacy . . . 775
31.7. Approximate zCDP . . . 778
31.8. Subsampling, and truncated CDP . . . 780
31.9. Code: check every number . . . 785
31.10. References . . . 786
31.11. Cheat sheet . . . 786

32. f-DP and Gaussian differential privacy **789**
32.1. Why this matters . . . 789
32.2. Toolkit: three facts every derivation uses . . . 790
32.3. f-DP . . . 792
32.4. Gaussian differential privacy . . . 796

32.5. Duality with (ε, δ) . . . 798
32.6. Composition . . . 801
32.7. The central limit theorem for composition . . . 803
32.8. The subsampled Gaussian and DP-SGD . . . 808
32.9. RDP as a lossy summary of the curve . . . 811
32.10. Code: check every result by computation and simulation . . . 815
32.11. References . . . 816
32.12. Cheat sheet . . . 816

33. Amplification by subsampling **818**
33.1. Why this matters . . . 818
33.2. Toolkit: three facts every derivation uses . . . 819
33.3. Amplification for (ε, δ)-DP under Poisson sampling . . . 821
33.4. The sampling scheme must match the neighbouring relation . . . 824
33.5. RDP of the Poisson-subsampled Gaussian . . . 830
33.6. Small q and the moments accountant . . . 835
33.7. The running example: DP-SGD . . . 838
33.8. No tight amplification theorem for every mechanism . . . 841
33.9. Code: check every number by computation . . . 843
33.10. References . . . 844
33.11. Cheat sheet . . . 845

34. Numerical accounting with privacy loss distributions **848**
34.1. Why this matters . . . 848
34.2. Toolkit: three facts the derivations reuse . . . 850
34.3. The privacy loss distribution . . . 851
34.4. Composition is convolution . . . 854
34.5. Discretization: pessimistic and optimistic . . . 856
34.6. Composition by FFT . . . 860
34.7. The subsampled Gaussian . . . 863
34.8. The running example: DP-SGD . . . 867
34.9. Code . . . 870
34.10. References . . . 871
34.11. Cheat sheet . . . 872

35. Amplification by shuffling and by iteration **874**
35.1. Why this matters . . . 874
35.2. Toolkit: three facts every derivation uses . . . 876
35.3. Shuffled binary randomized response, exactly . . . 877
35.4. The clone bound for any local randomizer . . . 881
35.5. Amplification by iteration . . . 886
35.6. Hidden state: privacy that stops growing . . . 891
35.7. An exact example: noisy GD on a quadratic . . . 894
35.8. Code: check every number by computation . . . 897
35.9. References . . . 898
35.10. Cheat sheet . . . 899

36. Adaptive composition: filters, odometers and individual accounting **901**
36.1. Why this matters . . . 901
36.2. Toolkit: stopping a supermartingale . . . 903
36.3. Why adaptively chosen parameters break the usual theorems . . . 905
36.4. Filters for pure differential privacy . . . 908
36.5. The Rényi filter . . . 913
36.6. Odometers . . . 917
36.7. Individual privacy accounting in DP-SGD . . . 920
36.8. Code: filters, odometers and per-record spend . . . 924
36.9. References . . . 925
36.10. Cheat sheet . . . 926

Appendices **1226**

A. How much noise to add **1226**
A.1. What differential privacy promises, and the privacy loss . . . 1227
A.2. Sensitivity: how much one person can move the answer . . . 1230
A.3. Laplace noise: scale Δ_1/ε gives ε-DP . . . 1232
A.4. Randomized response: one bit, ε-DP . . . 1234
A.5. The exponential mechanism: choosing the best candidate . . . 1238
A.6. Gaussian noise, the classic formula . . . 1241
A.7. Gaussian noise, the exact calibration . . . 1244
A.8. How ε, δ, σ and the sensitivity trade off . . . 1247
A.9. All the recipes in one table . . . 1255
A.10. Code . . . 1255

A.11. References 1256

B. Composing private releases **1258**
B.1. Basic composition: the budgets add 1259
B.2. Advanced composition: $\sqrt{k}$ instead of k 1263
B.3. Gaussian releases: k of them are one 1268
B.4. Rényi DP: a summary of the loss that adds 1271
B.5. Comparing the four accountants 1275
B.6. Code 1277
B.7. References 1278

C. Accounting for DP-SGD **1279**
C.1. Clipping gives the sum a sensitivity 1280
C.2. One noisy step is a Gaussian mechanism 1282
C.3. Random batches make each step cheaper 1284
C.4. The Rényi curve of a sampled Gaussian step 1287
C.5. From batch, noise and epochs to the final ε 1292
C.6. Code 1296
C.7. References 1297

D. What ε means, and converting between definitions **1299**
D.1. What ε means for any test 1300
D.2. What ε means for an attacker's belief 1304
D.3. From Rényi DP to (ε, δ) 1307
D.4. From zero-concentrated DP to (ε, δ) 1311
D.5. Gaussian DP and its exact (ε, δ) curve 1313
D.6. Summary 1315
D.7. Code 1316
D.8. References 1317

E. Sums, limits and counting **1318**
E.1. A sum's distribution, found by convolution 1318
E.2. Stirling's formula and the peak of a binomial 1323
E.3. The central limit theorem, by swapping one term at a time 1327
E.4. The length of a normal vector stays near $\sqrt{d}$ 1333
E.5. The difference of two Laplace variables 1335
E.6. Code 1338
E.7. References 1340

F. Tail bounds, tests and divergences **1342**
F.1. Bernstein's inequality: the variance sets the width 1342
F.2. Chernoff's exponent is exact, for tails and for tests 1345
F.3. The Clopper–Pearson limits exist and are unique 1353
F.4. Rényi divergence tends to KL at order 1 1356
F.5. Perspective functions are jointly convex 1359
F.6. A noisy count has an increasing likelihood ratio 1363
F.7. Code 1366
F.8. References 1367

G. Optimization and estimation **1368**
G.1. Convexity three ways, and the linear rate of gradient descent . . . 1368
G.2. The gradient of a convex smooth function is co-coercive . . . 1373
G.3. No gradient method beats $RL/\sqrt{T}$ on every convex Lipschitz function . . . 1374
G.4. The 1-nearest-neighbour error tends to $\mathbb{E}[2p(1-p)]$ . . . 1378
G.5. Fitted parameters are approximately Gaussian, and one record moves them by its gradient . . . 1381

N. Auditing, reconstruction and adaptive analysis **1534**
N.1. One-run auditing: correct guesses are dominated by a binomial 1535
N.2. Private answers stay accurate with high probability 1540
N.3. The Ladder: a leaderboard that rarely changes cannot be overfitted 1548
N.4. Unbiased reconstruction has a floor set by Rényi DP of order 2 1551
N.5. Code 1555
N.6. References 1556

O. Glossary **1557**

P. Index **1561**

Preface

This is the full edition of *Privacy-Preserving Machine Learning*: every result is derived step by step. Two companions share its parts and chapter files: the exercise book, with a worked solution for every exercise, and the practitioner edition, which states the same results without proofs and shows how to use them with real libraries. A separate course in differential privacy teaches the subject one topic per chapter, with complete proofs and little else.

The figures and the numbers quoted in the text are produced by each chapter's script, in the repository's `code/` directory, one folder per part.

How this book is organized

The book has five parts, each building on the ones before it.

1. **Prerequisites** collects the mathematics: distributions, concentration, divergences and hypothesis testing, then information theory, optimization and stability, and the basics of cryptography.
2. **Threat models and attacks** shows how models and data leak before any defence is introduced. It first attacks trained models, from one bit of membership up to whole training inputs, then attacks released data, from records with names removed to records hidden in crowds to aggregate statistics alone.
3. **Differential privacy foundations** defines the guarantee those attacks call for, builds its mechanisms, composes them, and ends with what privacy costs.
4. **Privacy accounting** tracks the guarantee through many steps of training, as accurately as possible.
5. **Differential privacy in machine learning** trains models with the guarantee: where the noise goes, how the knobs of noisy, clipped gradient descent trade privacy for accuracy, what else spends the budget, who pays for the noise, which ε to choose, and how to audit the result.

The appendices hold a glossary of acronyms and an index. The exercises, with a worked solution for each, are in the exercise book, a companion website, and each chapter ends with a link to its page there.

Part I.

Prerequisites

This part collects the mathematics the rest of the book stands on. It contains no new ideas about privacy. Everything here is standard probability, statistics, optimization, information theory and cryptography, and you may have met most of it before. What is different is the selection and the angle: each topic is chosen because a later part needs it, and each is developed only as far as that need goes, but always with full derivations.

Who this part is for

You are expected to know undergraduate calculus and linear algebra, the basics of probability (random variables, expectation, variance, independence, conditional probability), and enough machine learning to recognise a loss function, a training set and stochastic gradient descent. You should be able to read short Python programs that use NumPy. Nothing beyond that is assumed. Every inequality, divergence or definition that the later parts rely on is stated and derived here, so you can check each step for yourself instead of taking it on trust.

If you already know a topic well, skim its cheat sheet and try its exercises in the exercise book. If they go smoothly, move on.

The common thread

Later parts study algorithms whose output is random, and keep asking the same few questions about them. How far is a random output from its expected value? How different are the output distributions on two slightly different inputs, and how would anyone tell them apart? How much does a trained model depend on a single training record? How much does an observation reveal about something hidden, and what can an observer with limited computing power learn from it? Each chapter of this part supplies the vocabulary and tools for one of these questions (Table 1).

Table 1.: The chapters of this part, the question each one answers, and the earlier chapters it uses.

Chapter	The question it answers	Builds on
Probability distributions	Which few distributions model counts, waiting times and additive noise, and what are their moments and tails?	—
Concentration inequalities	How far can a random quantity be from its mean, and with what probability?	1
Divergences	How different are two probability distributions, as a single number?	1, 2
Hypothesis testing	Given one observation, how well can you tell which of two distributions produced it?	1, 2, 3

Chapter	The question it answers	Builds on
Information theory	How much does an observation tell you about a hidden value, on average and for a single best guess?	3
Optimization	How fast does (stochastic) gradient descent converge, and how far does the minimizer move when one record changes?	1, 2
Algorithmic stability and generalization	Why does a model that depends little on each training record generalize?	2, 6
Cryptography basics	What does it mean that an efficient observer learns nothing it was not supposed to learn?	2, 3, 4

Two ideas run through all eight chapters. The first is the **likelihood ratio** $p(x)/q(x)$: how many times more likely an observation is under one distribution than under another. Divergences are averages of functions of it, the best test thresholds it, and mutual information is a divergence in disguise. The second is the **effect of one input**: how much one record shifts an average, a minimizer, a loss or a test statistic. Concentration inequalities bound it for sums, stability bounds it for learning algorithms, and the sensitivity of regularized empirical risk minimization makes it a concrete number. Watch for both as you read. Most of the later parts are built from them.

How to read this part

Order. Read chapters 1 to 4 in order, since each one uses the previous ones. Together they form the core of this part: tail bounds, then a number for how different two distributions are, then what that number means for anyone trying to tell them apart. Chapter 5, information theory, continues that thread: it measures how much an observation reveals, on average and for a single best guess. Then read chapters 6 and 7, which go together: how training moves when one record changes, and why that matters for generalization. Chapter 8 is used by three later chapters: chapter 9 on threat models uses its security games and advantage, chapter 15 on linkage uses its birthday bound, and chapter 26 on trust models builds secure aggregation from its secret sharing. A planned later part on cryptographic approaches will use all of it. You can defer it until you reach chapter 9.

Structure of a chapter. Every chapter follows the same shape, so you always know where to look:

- **Why this matters** states the question the chapter answers, the one idea that organizes it, and a table of its results and where each is used.
- **Toolkit** collects the few facts that the derivations share, each proved once.

- **One section per result**, each with the same arc: the context, the statement, a step-by-step derivation that names the fact used at each step, an interpretation that says when the result is tight and when it is loose, a worked example with real numbers, and two *check yourself* questions with their answers.
- **Code** runs a script that checks every quoted number by exact computation or simulation.
- **References** and a one-table **Cheat sheet** close the chapter.

The exercises, each with a worked solution, are collected in the exercise book, a companion website. Each chapter ends with a link to its exercises.

Abstract steps are made concrete. Where a derivation takes an abstract step, such as writing a probability as the expectation of an indicator or changing the distribution an expectation is taken under, the text works the step out on a small case first, usually a die or a coin with a table of every outcome. If a step feels like a trick, look for that table. It is there to show that the step is just bookkeeping.

Run the code. Each chapter has a script in `code/` that reproduces every number and figure in its text. From the repository root, run, for example,

```
uv run python code/part01-prerequisites/concentration.py
```

The scripts use fixed random seeds, so your output matches the tables in the text. Change the parameters and watch how the bounds respond. That is the quickest way to develop a feel for how loose each bound is.

Notation

The chapters share the conventions in Table 2. Where a chapter departs from them, it says so at its start.

Table 2.: Notation shared by the chapters of this part.

Symbol	Meaning
$\Pr[A]$, $\mathbb{E}[X]$, $\mathrm{Var}(X)$	Probability, expectation, variance
$\mathbf{1}[A]$	Indicator of the event A: 1 if A happens, 0 otherwise
$\mathcal{N}(\mu, \sigma^2)$, $\mathrm{Lap}(b)$	Normal distribution with mean μ and variance σ^2; Laplace distribution with scale b
P, Q and p, q	Two distributions and their probability mass functions or densities
ln, $\log_2$	Natural logarithm (in nats); base-2 logarithm (in bits), used in information theory
$\lVert \cdot \rVert$	Euclidean norm, $\lVert x \rVert = \lVert x \rVert_2$
$D = (z_1, \dots, z_n)$, $z = (x, y)$	A dataset of n records; a labelled record with features x and label y

Symbol	Meaning
$\theta \in \mathbb{R}^d$, $\ell(\theta; z)$	Model parameters of dimension d; the loss of θ on the record z
$\mathcal{L}(\theta; D)$, $\mathcal{L}_{\mathcal{D}}(\theta)$	Empirical risk on D; population risk under the data distribution $\mathcal{D}$
η, T	Learning rate; number of steps
L, β, λ	Lipschitz, smoothness and strong convexity constants

What you will be able to do

By the end of this part you should be able to do each of the following on paper:

- derive exponential tail bounds for sums of independent variables, and for normal and Laplace noise;
- compute the Kullback–Leibler (KL), Rényi, total-variation and hockey-stick divergences between two normal or two Laplace distributions, and explain why processing data cannot increase any of them;
- derive the optimal test between two distributions and its trade-off curve between the two kinds of error;
- prove convergence rates for stochastic gradient descent, and bound how far a regularized minimizer moves when one training record is replaced;
- prove that a uniformly stable algorithm generalizes;
- compute entropy, mutual information and min-entropy leakage, and say when the last two disagree;
- state a security definition as a game between two worlds, and prove a simple scheme secure with a hybrid argument or a simulator.

Each of these is a result derived in one of the chapters that follow.

1. Probability distributions

1.1. Why this matters

A handful of distributions do almost all the work in this book. Counts of events (errors, successes, records drawn into a batch) are binomial, and Poisson when the events are rare. Additive noise is usually normal or Laplace. Every later chapter — concentration, divergences, hypothesis testing — is stated in terms of these few families. So you need to know each one well: its density, mean, variance, moment generating function (MGF), tails, and how it relates to the others.

The idea that ties the chapter together is that these families are not a zoo of unrelated formulas. They are built from one another. A binomial is a sum of coin flips. A Poisson is a binomial with many trials and a small success probability. An exponential is the waiting time for the first event in that same Poisson setting. A Laplace is two exponentials placed back to back. A normal is what any sum of many small independent pieces looks like. Because each family is built from simpler ones, its mean, variance and MGF can be computed from the pieces, and that is how this chapter derives them.

This chapter covers five families (Table 1.1):

Table 1.1.: The five families in this chapter, what each models, and the fact about it that later chapters use.

Family	Models	Key fact for later
Bernoulli and binomial	One yes/no outcome; the count of successes in n trials	Mean and variance add over independent trials
Poisson	Counts of rare events	Its MGF $e^{\mu(e^{\lambda}-1)}$ drives the Chernoff bound
Exponential	Waiting times; a building block	A difference of two exponentials is Laplace
Laplace	Symmetric noise with exponential tails	Its log density is piecewise linear, so shifted copies differ by a bounded factor
Normal	Sums of many small effects; symmetric noise with light tails	Closed under sums; a d-dimensional normal vector has norm $\approx \sigma\sqrt{d}$

A last section puts the normal and the Laplace side by side and asks how different a density is from a copy of itself moved sideways. That comparison is where the next chapters begin.

Each section follows the same arc: context, definition, derivations of the moments, interpretation, an example from machine learning, and a self-check.

1.2. Toolkit: what to know for each distribution

For every family below you will meet the same three summaries: its moments, its moment generating function and its tail. This section says what each one is, why it is worth computing, and the few rules for working with it.

1.2.1. Moments: where the distribution sits and how wide it is

The **mean** $\mathbb{E}[X]$ is the centre of mass of the distribution: the long-run average of many independent draws. The **variance** measures how far draws typically land from the mean. It squares each draw's distance from the mean, so that distances on either side count the same, and averages. Expanding the square $(X-\mathbb{E}X)^2 = X^2 - 2X\,\mathbb{E}X + (\mathbb{E}X)^2$ and averaging each term gives a second form that is often easier to compute, "mean of the square minus square of the mean":

$$\operatorname{Var}(X) = \mathbb{E}\big[(X-\mathbb{E}X)^2\big] = \mathbb{E}[X^2] - (\mathbb{E}X)^2. \tag{1.1}$$

Its square root, the **standard deviation**, is in the same units as X, so it is the number to compare with the mean. For a fair die, $\mathbb{E}X = (1+\cdots+6)/6 = 3.5$ and $\mathbb{E}X^2 = (1+4+\cdots+36)/6 = 91/6$, so $\operatorname{Var} X = 91/6 - 3.5^2 = 35/12 \approx 2.92$ and the standard deviation is about 1.71.

Three rules cover almost every calculation in this chapter. The first is that the mean of a sum is the sum of the means, $\mathbb{E}[X+Y] = \mathbb{E}X + \mathbb{E}Y$, always, even when X and Y are dependent. The reason is that an expectation is a weighted sum over outcomes, and a weighted sum of $X+Y$ splits into the weighted sum of X plus the weighted sum of Y.

The second rule says what scaling does to the spread: $\operatorname{Var}(cX) = c^2 \operatorname{Var}(X)$. Multiplying X by c multiplies every deviation $X - \mathbb{E}X$ by c, and squaring the deviation turns that into c^2.

The third rule is that variances add when the variables are independent: $\operatorname{Var}(X+Y) = \operatorname{Var} X + \operatorname{Var} Y$. To see where independence enters, expand the square in the definition. In general $\operatorname{Var}(X+Y) = \operatorname{Var} X + \operatorname{Var} Y + 2\operatorname{Cov}(X,Y)$, where the cross term is the **covariance** $\operatorname{Cov}(X,Y) = \mathbb{E}[XY] - \mathbb{E}X\,\mathbb{E}Y$. Independence makes $\mathbb{E}[XY] = \mathbb{E}X\,\mathbb{E}Y$, so the covariance vanishes and only the two variances remain.

The second and third rules together give the $1/\sqrt{n}$ law. The average of n independent copies of X is their sum times $1/n$. The sum has variance $n\operatorname{Var}(X)$ by the third rule, and multiplying by $1/n$ divides that by n^2 by the second, so the average has variance $n\operatorname{Var}(X)/n^2 = \operatorname{Var}(X)/n$. Its standard deviation is therefore the standard deviation of one draw divided by $\sqrt{n}$.

1.2.2. The moment generating function

The mean and variance summarize a distribution by two numbers. The moment generating function summarizes it by a whole function, and that function turns out to be the right tool for sums of independent variables and for tails. The idea is to average not X itself but an exponential of it, $e^{\lambda X}$, for a number λ of your choice. The **moment generating function** (MGF) of X is

$$M_X(\lambda) = \mathbb{E}[e^{\lambda X}]. \tag{1.2}$$

Here λ is a real number that *you* choose. It is not a parameter of the distribution; it is a dial. For each setting of the dial you get one number, $\mathbb{E}[e^{\lambda X}]$, and the MGF is the whole function $\lambda \mapsto M_X(\lambda)$. With $\lambda > 0$, the weight $e^{\lambda X}$ grows exponentially in X, so large values of X dominate the average; the larger λ, the further into the right tail it looks. With $\lambda < 0$ it looks at the left tail instead. At $\lambda = 0$ every weight is $e^0 = 1$, so $M_X(0) = 1$ for every distribution.

A concrete case: where e^λ comes from. Take a coin $X \sim \text{Bern}(p)$, which is 1 with probability p and 0 otherwise. To compute $\mathbb{E}[e^{\lambda X}]$, list each outcome, the value $e^{\lambda X}$ takes there, and its probability (Table 1.2).

Table 1.2.: The MGF of a coin, outcome by outcome. The factor e^λ is just $e^{\lambda x}$ evaluated at $x = 1$.

Outcome x	$\Pr[X = x]$	$e^{\lambda x}$
0	$1 - p$	$e^{\lambda \cdot 0} = 1$
1	p	$e^{\lambda \cdot 1} = e^\lambda$

An expectation is the value at each outcome times its probability, added up, so

$$M_X(\lambda) = (1-p) \cdot 1 + p \cdot e^\lambda = 1 + p(e^\lambda - 1). \tag{1.3}$$

So the e^λ in the Bernoulli, binomial and Poisson MGFs is nothing mysterious: it is the weight $e^{\lambda x}$ of the outcome $x = 1$. For a count k the weight is $e^{\lambda k} = (e^\lambda)^k$, which is why e^λ keeps reappearing for the counting distributions. With $p = 0.3$ and $\lambda = 1$, for instance, $M_X(1) = 0.7 + 0.3e \approx 1.52$.

Why it "generates" moments. The k-th **moment** of X is $\mathbb{E}X^k$; the mean is the first. The MGF contains all of them, and the way to see this is to expand the exponential in its power series, $e^u = 1 + u + u^2/2! + u^3/3! + \cdots$, with $u = \lambda X$, and take the expectation of each term separately (the first rule of Section 1.2.1, extended to many terms):

$$M_X(\lambda) = \mathbb{E}\Big[1 + \lambda X + \frac{\lambda^2 X^2}{2!} + \frac{\lambda^3 X^3}{3!} + \cdots\Big] = 1 + \lambda\,\mathbb{E}X + \frac{\lambda^2}{2!}\mathbb{E}X^2 + \cdots. \tag{1.4}$$

The k-th moment $\mathbb{E}X^k$ is $k!$ times the coefficient of λ^k, and differentiating k times at $\lambda = 0$ picks it out, because differentiation kills the lower powers of λ and setting $\lambda = 0$ kills the higher ones: $M_X'(0) = \mathbb{E}X$, $M_X''(0) = \mathbb{E}X^2$. For the coin, expanding e^λ the same way gives $1 + p(e^\lambda - 1) = 1 + p\lambda + p\lambda^2/2! + \cdots$, so every moment equals p, as it must, since $X^k = X$ when $X \in \{0, 1\}$.

The log-MGF gives mean and variance directly. The derivatives of M_X give the raw moments $\mathbb{E}X$ and $\mathbb{E}X^2$, and the variance then needs a subtraction. Taking the logarithm first does the subtraction for you, and it will also turn products of MGFs into sums. Let

$\psi_X(\lambda) = \ln M_X(\lambda)$. The chain rule gives $\psi' = M'/M$, and the quotient rule applied to M'/M gives $\psi'' = M''/M - (M'/M)^2$. At 0, where $M = 1$, $M' = \mathbb{E}X$ and $M'' = \mathbb{E}X^2$,

$$\psi_X'(0) = \mathbb{E}X, \qquad \psi_X''(0) = \mathbb{E}X^2 - (\mathbb{E}X)^2 = \operatorname{Var} X. \tag{1.5}$$

The derivatives of ψ_X at 0 are called the **cumulants** of X: the first is the mean, the second the variance, and the higher ones measure finer features of the shape. For the Poisson below, ψ turns out so simple that both derivatives can be read off in one line.

Sums become products. The main reason to use MGFs is that adding independent variables multiplies their MGFs. The exponential turns the sum into a product, and independence lets the expectation of that product split. If X and Y are independent, then

$$M_{X+Y}(\lambda) = \mathbb{E}[e^{\lambda X}e^{\lambda Y}] = \mathbb{E}[e^{\lambda X}]\,\mathbb{E}[e^{\lambda Y}] = M_X(\lambda)M_Y(\lambda). \tag{1.6}$$

The first step is $e^{a+b} = e^a e^b$; the second uses independence, which lets the expectation of a product split into a product of expectations. In log form, $\psi_{X+Y} = \psi_X + \psi_Y$. This is how you get the binomial MGF from the Bernoulli one without touching the probability table, and it is the starting point of every exponential tail bound in Concentration inequalities.

The MGF pins down the distribution. If two distributions have the same MGF on an interval around 0, they are the same distribution. This is a standard theorem of probability (it is proved in Blitzstein & Hwang, listed in the references); its proof needs more analysis than this book uses, so take it as given. You can check each sum this chapter identifies without it: Section E.1 in the appendices derives every one directly, by integrating or summing over the ways the two values can add up. We use it to identify sums: compute the MGF of $X + Y$ as a product, recognise it as the MGF of a known family, and conclude that $X + Y$ belongs to that family ("the sum of independent Poissons is Poisson"). The MGF can be infinite for some λ, and for heavy-tailed distributions it is infinite for every $\lambda > 0$; the identification needs it finite near 0.

1.2.3. Tails: how fast large values become rare

The **tail** of X is $\Pr[X \geq t]$ as a function of t, for t well above the mean. The mean and variance describe the bulk of the distribution; the tail describes the rare, large outcomes, which are what a worst-case guarantee has to control. What matters is the *shape* of the decay, and three shapes recur. Evaluate each at $t = 5$. A polynomial decay such as $1/t^2$ gives $1/25 = 0.04$. An exponential decay such as e^{-t} gives e^{-5}, about 6.7×10^{-3}. A Gaussian decay such as $e^{-t^2/2}$ gives $e^{-12.5}$, about 3.7×10^{-6}.

The gap widens quickly as t grows, because the exponent of the Gaussian decay grows like t^2 while that of the exponential grows like t. Exponential tails are those of the exponential and Laplace families below; Gaussian tails are those of the normal.

The tail and the MGF are tied together, and the link is a one-line argument. Fix $\lambda > 0$. Whenever $X \geq t$, the weight $e^{\lambda X}$ is at least $e^{\lambda t}$, and it is never negative, so averaging gives $M_X(\lambda) = \mathbb{E}[e^{\lambda X}] \geq e^{\lambda t}\Pr[X \geq t]$. Rearranged, $\Pr[X \geq t] \leq M_X(\lambda)e^{-\lambda t}$. So if $M_X(\lambda)$ is finite for some $\lambda > 0$, the tail decays at least exponentially in t. Concentration inequalities turns this into explicit bounds by choosing λ well. Which decay a distribution has decides which concentration inequalities apply to it.

1.3. Bernoulli and binomial

1.3.1. Context

The simplest random quantity is a yes/no outcome: a test record is misclassified or not, a coin lands heads or not, a record is included in a sample or not. Count the yeses over n independent trials and you get a binomial. Every estimated rate in machine learning — accuracy, error rate, false-positive rate — is a binomial count divided by n.

1.3.2. Definitions

$X \sim \text{Bern}(p)$ takes value 1 with probability p and 0 with probability $1-p$.

$S \sim \text{Bin}(n, p)$ is the number of ones in n independent $\text{Bern}(p)$ trials. The probability of exactly k ones is the number of ways to place k ones among n trials, times the probability of any one such placement. That gives the probability mass function (PMF), the table of probabilities of each count,

$$\Pr[S = k] = \binom{n}{k} p^k (1-p)^{n-k}, \qquad k = 0, 1, \ldots, n. \tag{1.7}$$

Derivation of the PMF. Any particular sequence with exactly k ones has probability $p^k(1-p)^{n-k}$, because the trials are independent and the probability of a sequence is the product of the probabilities of its entries: p for each one and $1-p$ for each zero. There are $\binom{n}{k}$ such sequences — choose which k positions hold the ones — and they are disjoint events, so their probabilities add.

1.3.3. Moments

Bernoulli. $\mathbb{E}X = 1 \cdot p + 0 \cdot (1-p) = p$. Since $X^2 = X$, $\mathbb{E}X^2 = p$, so $\text{Var}\, X = p - p^2 = p(1-p)$. The MGF, computed outcome by outcome in Table 1.2, is $M_X(\lambda) = (1-p) + pe^{\lambda} = 1 + p(e^{\lambda} - 1)$.

Binomial. Rather than work with the PMF, write the count as a sum of the trials, $S = X_1 + \cdots + X_n$ with independent Bernoullis, and apply the rules of the Toolkit to the sum. The mean of a sum is the sum of the n means, each p. The trials are independent, so the variances add, n times $p(1-p)$. And the MGF of an independent sum is the product of n identical Bernoulli MGFs. Together,

$$\mathbb{E}S = np, \qquad \text{Var}\, S = np(1-p), \qquad M_S(\lambda) = \left(1 + p(e^{\lambda} - 1)\right)^n. \tag{1.8}$$

No sums over the PMF are needed: decomposing into simple pieces is almost always easier than computing with the PMF directly.

1.3.4. Interpretation

The variance $p(1-p)$ is a downward parabola in p that is zero at $p=0$ and $p=1$, so it is largest halfway between, at $p=\frac{1}{2}$, where it is $\frac{1}{2}\cdot\frac{1}{2}=\frac{1}{4}$, and small near 0 or 1. A rate near 0 is therefore estimated much more precisely than one near $\frac{1}{2}$. Bounds that use only the fact that each trial lies between 0 and 1, such as Hoeffding's inequality in Concentration inequalities, cannot see this difference, and it matters later.

The estimated rate $\hat{p}=S/n$ is the count scaled by $1/n$. By the scaling rules of Section 1.2.1 it has mean $np/n=p$ and variance $np(1-p)/n^2=p(1-p)/n$, so its standard deviation is $\sqrt{p(1-p)/n}$. Precision improves like $1/\sqrt{n}$: four times the data halves the error, since $\sqrt{4}=2$.

1.3.5. Example: estimating a classifier's error rate

A classifier makes an error on each test record independently with probability $p=0.05$. On $n=2{,}000$ test records the error count is $\mathrm{Bin}(2000, 0.05)$, with mean $2000\times0.05=100$ and standard deviation $\sqrt{2000\times0.05\times0.95}\approx9.7$. Divided by n, that standard deviation is about $9.7/2000\approx0.005$ of the rate, so the measured error rate is typically within about ±0.5 percentage points of the true 5%. At $p=0.001$ the count has mean 2 and standard deviation $\sqrt{2000\times0.001\times0.999}\approx1.4$: the *relative* error, $1.4/2$, is now about 70%, and a single test set can easily show 0 errors (that happens with probability $0.999^{2000}\approx e^{-2}$, about one test set in seven).

1.3.6. Check yourself

- Why is $\mathrm{Var}(X_1+\cdots+X_n)=n\,\mathrm{Var}(X_1)$ wrong if the X_i are copies of the same variable? *(Then the sum is nX_1, whose variance is $n^2\,\mathrm{Var}\,X_1$. Independence is what makes variances add.)*
- What is $\Pr[S=0]$ for $\mathrm{Bin}(n,p)$, and roughly how large must n be before you expect to see at least one success? *($(1-p)^n\approx e^{-np}$, using $1-p\approx e^{-p}$ for small p; this is small only once np is around 1 or more, so you need n on the order of $1/p$.)*

1.4. Poisson

1.4.1. Context

When n is large and p is small, the binomial depends on n and p only through the mean $\mu=np$, as the limit below shows. The limit is the Poisson distribution: the law of rare events. It describes the number of errors in a large test set with a tiny error rate, the number of rare tokens in a document, or the size of a minibatch when each of many records is included independently with small probability.

1.4.2. Definition

$N \sim \text{Poisson}(\mu)$ for $\mu > 0$ counts events whose expected number is μ. It takes values $k = 0, 1, 2, ...$ with

$$\Pr[N = k] = e^{-\mu}\frac{\mu^k}{k!}. \tag{1.9}$$

The factor $e^{-\mu}$ makes the probabilities add up to 1, since $\sum_k \mu^k/k! = e^{\mu}$ is the power series of the exponential.

1.4.3. The Poisson limit of the binomial

Hold the expected count μ fixed and let the number of trials grow, so each trial has success probability $p = \mu/n$. Put that into the binomial PMF for a fixed count k, write $\binom{n}{k} = n(n-1)\cdots(n-k+1)/k!$, and group the result into four factors, each of which has a simple limit as $n \to \infty$:

$$\binom{n}{k}\left(\frac{\mu}{n}\right)^k\left(1-\frac{\mu}{n}\right)^{n-k} = \underbrace{\frac{n(n-1)\cdots(n-k+1)}{n^k}}_{\to 1}\cdot\frac{\mu^k}{k!}\cdot\underbrace{\left(1-\frac{\mu}{n}\right)^n}_{\to e^{-\mu}}\cdot\underbrace{\left(1-\frac{\mu}{n}\right)^{-k}}_{\to 1}. \tag{1.10}$$

The first factor is a product of k fractions $n/n, (n-1)/n, ...$, each tending to 1, and there are only k of them. The middle factor does not depend on n. The third is the classic limit that defines e: its logarithm is $n\ln(1-\mu/n)$, and since $\ln(1-u) \approx -u$ for small u, that is close to $n\cdot(-\mu/n) = -\mu$. The last factor has a fixed exponent $-k$ and a base tending to 1. The limit is $e^{-\mu}\mu^k/k!$. Figure 1.1 shows the convergence: at $n = 10$ the binomial is visibly narrower than the Poisson, while at $n = 100$ they almost coincide.

1.4.4. Moments via the MGF

The MGF is the sum, over all counts k, of the weight $e^{\lambda k}$ times the probability of k. Gathering the powers of k into $(\mu e^{\lambda})^k$ leaves the power series of the exponential, evaluated at μe^{λ}:

$$M_N(\lambda) = \sum_{k\geq 0} e^{\lambda k}e^{-\mu}\frac{\mu^k}{k!} = e^{-\mu}\sum_{k\geq 0}\frac{(\mu e^{\lambda})^k}{k!} = e^{-\mu}e^{\mu e^{\lambda}} = \exp\left(\mu(e^{\lambda}-1)\right). \tag{1.11}$$

So the log-MGF is $\psi_N(\lambda) = \mu(e^{\lambda}-1)$. Its derivatives are all μe^{λ}, which equals μ at $\lambda = 0$. Since $\psi'(0)$ is the mean and $\psi''(0)$ the variance (Section 1.2.2),

$$\mathbb{E}N = \operatorname{Var} N = \mu. \tag{1.12}$$

Sums. Take independent $N_1 \sim \text{Poisson}(\mu_1)$ and $N_2 \sim \text{Poisson}(\mu_2)$. The MGF of the sum is the product of the two MGFs, and multiplying two exponentials adds their exponents, which gives $\exp((\mu_1+\mu_2)(e^{\lambda}-1))$. That is the Poisson MGF with mean $\mu_1+\mu_2$, and since the MGF pins down the distribution, $N_1 + N_2 \sim \text{Poisson}(\mu_1+\mu_2)$.

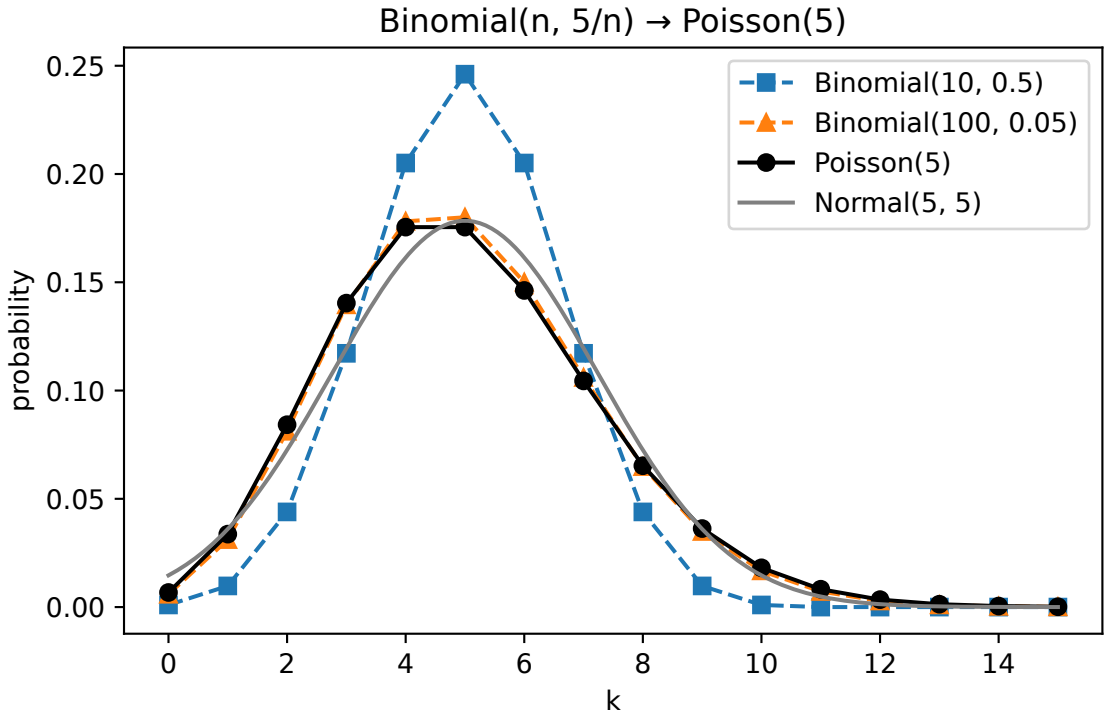

Figure 1.1.: $\mathrm{Bin}(n, 5/n)$ for $n = 10$ and 100, against Poisson(5) and its normal approximation.

1.4.5. Interpretation

Mean equals variance. The standard deviation is $\sqrt{\mu}$, so the spread relative to the mean, $\sqrt{\mu}/\mu = 1/\sqrt{\mu}$, shrinks only once you expect many events. With $\mu = 4$ the standard deviation is 2, so a count of 0 or 8, two standard deviations from the mean, is unremarkable.

The Poisson MGF bounds the Bernoulli MGF. The inequality $1 + x \le e^x$ holds for every x: the exponential is convex, and $1 + x$ is its tangent line at 0, which a convex curve always lies above. Apply it with $x = p(e^\lambda - 1)$:

$$M_{\mathrm{Bern}(p)}(\lambda) = 1 + p(e^\lambda - 1) \le \exp(p(e^\lambda - 1)) = M_{\mathrm{Poisson}(p)}(\lambda). \tag{1.13}$$

Now take independent Bernoullis with probabilities $p_1, \dots, p_n$ and mean $\mu = p_1 + \cdots + p_n$. The MGF of their sum is the product of their MGFs, each at most $\exp(p_i(e^\lambda - 1))$, and the product of those is $\exp(\mu(e^\lambda - 1))$. So the MGF of any sum of independent Bernoullis with mean μ is at most the Poisson(μ) MGF. This one-line inequality is the first step of the Chernoff bound in Concentration inequalities, which bounds the tail of a count through its MGF, as in Section 1.2.3.

Right tail. Count data are right-skewed: the count cannot go below 0 but can run far above the mean. For large k, $\Pr[N = k]$ decays like $(e\mu/k)^k$. To see this, use the bound $k! \ge (k/e)^k$ (it follows from $e^k = \sum_j k^j/j! \ge k^k/k!$), which gives $\Pr[N = k] \le e^{-\mu}\mu^k(e/k)^k \le (e\mu/k)^k$. Written as $e^{-k\ln(k/(e\mu))}$, the exponent grows like $k \ln k$, so the decay is faster than any exponential e^{-ck}, but slower than the $e^{-k^2/(2\mu)}$ of a normal with the same variance.

1.4.6. Example: minibatch sizes under independent sampling

Some training procedures form a minibatch by including each of $n = 60{,}000$ records independently with probability $q = 0.01$. The batch size is $\text{Bin}(60000, 0.01)$: many trials, each unlikely, so it is very close to Poisson(600), with mean $60000 \times 0.01 = 600$ and standard deviation $\sqrt{600}$, about 24.5. Batch sizes between 550 and 650, about two standard deviations either side, are typical; Concentration inequalities shows how unlikely anything outside $600 \pm 20\%$ is.

1.4.7. Check yourself

- Using only the MGF, show that $\mathbb{E}[N(N-1)] = \mu^2$. *(Differentiate M_N twice at 0 to get $\mathbb{E}N^2 = \mu^2 + \mu$, then subtract $\mathbb{E}N$.)*
- The binomial variance $np(1-p)$ tends to μ under the Poisson limit. Which factor disappears, and why? *($(1-p) \to 1$ because $p = \mu/n \to 0$.)*

1.5. Exponential

1.5.1. Context

The Poisson counts how many rare events land in a fixed window. Turn the question around: starting now, *how long* until the first one? A model in production makes a rare error, a cache entry is evicted, a request arrives. The answer is the exponential distribution, and it comes out of the same construction as the Poisson: chop time into many short slots, give each slot a small, independent chance of holding an event, and let the slots shrink. For us it is mainly a building block: the Laplace distribution is two exponentials glued back to back, and the simplest exponential-type tail bounds are calculations with it.

1.5.2. Derivation: the waiting time in the Poisson limit

Fix a scale $b > 0$, which will turn out to be the average waiting time. Split each unit of time into n slots of width $1/n$. As the slots get finer, each one must get less likely to hold an event, or the number of events per unit of time would blow up. So choose the per-slot probability to keep the expected number of events per unit of time at $1/b$, whatever n is. With n slots per unit of time, that means each slot holds an event independently with probability

$$p = \frac{1}{bn}, \tag{1.14}$$

since then $np = 1/b$. This is the Poisson setup: in the Poisson limit we held the mean $\mu = np$ fixed and let $n \to \infty$, and here we hold the mean *rate* $1/b$ fixed in the same way.

1. **The wait in slots is geometric.** Let G be the index of the first slot that holds an event. $G > j$ means the first j slots are all empty, each with probability $1 - p$. The slots are independent, so these probabilities multiply:

$$\Pr[G > j] = (1-p)^j, \qquad j = 0, 1, 2, ... \tag{1.15}$$

Table 1.3 lists the first few outcomes. This is the **geometric distribution**: the number of coin flips up to and including the first head.

Table 1.3.: The waiting time G, in slots, until the first event. Each row is one outcome. $G > j$ exactly when the first j slots are empty.

j	Slots $1, \dots, j$ when $G = j$	$\Pr[G = j]$	$\Pr[G > j]$
1	event	p	$1-p$
2	empty, event	$(1-p)p$	$(1-p)^2$
3	empty, empty, event	$(1-p)^2 p$	$(1-p)^3$
j	$j-1$ empty, then event	$(1-p)^{j-1}p$	$(1-p)^j$

2. **Convert slots to time.** Each slot lasts $1/n$, so the first event happens at time $T_n = G/n$. Time t covers $\lfloor nt \rfloor$ whole slots (the floor $\lfloor \cdot \rfloor$ rounds down to a whole number), so $T_n > t$ means those slots are all empty:

$$\Pr[T_n > t] = \Pr[G > \lfloor nt \rfloor] = \left(1 - \frac{1}{bn}\right)^{\lfloor nt \rfloor}. \tag{1.16}$$

3. **Let the slots shrink.** The goal is to bring this into the form $(1-\mu/m)^m$, whose limit $e^{-\mu}$ we already know from the Poisson limit. Two rewrites do it. Write the exponent as $nt - r$, where $0 \le r < 1$ is the fractional part of nt, and write $\frac{1}{bn}$ as $\frac{t/b}{nt}$, which is the same number. Then

$$\left(1 - \frac{1}{bn}\right)^{\lfloor nt \rfloor} = \underbrace{\left(1 - \frac{t/b}{nt}\right)^{nt}}_{\to e^{-t/b}} \cdot \underbrace{\left(1 - \frac{1}{bn}\right)^{-r}}_{\to 1}. \tag{1.17}$$

The first factor is the limit $(1-\mu/m)^m \to e^{-\mu}$ with $\mu = t/b$ and $m = nt$ slots. The second has a bounded exponent and a base tending to 1. So the limiting waiting time T satisfies

$$\Pr[T > t] = e^{-t/b}, \qquad t \ge 0. \tag{1.18}$$

4. **Differentiate to get the density.** The probability that the wait is at most t is $\Pr[T \le t] = 1 - e^{-t/b}$, and a density is the derivative of this function, here $\frac{1}{b}e^{-t/b}$.

The same answer from the Poisson count. The first event comes after t exactly when no event falls in $[0, t]$. The number of events in $[0, t]$ is a count over $\lfloor nt \rfloor$ independent slots, $\mathrm{Bin}(\lfloor nt \rfloor, \frac{1}{bn})$, with mean about t/b; by the Poisson limit it tends to $\mathrm{Poisson}(t/b)$, and $\Pr[\mathrm{Poisson}(t/b) = 0] = e^{-t/b}$. Counting events in a window gives a Poisson count, and waiting for the first event gives an exponential time. Both come from the same slots.

1.5.3. Definition

$Y \sim \mathrm{Exp}(b)$ with *scale* $b > 0$ has the density just derived,

$$f(y) = \frac{1}{b} e^{-y/b}, \qquad y \ge 0. \tag{1.19}$$

(Some texts use the rate $1/b$ instead. NumPy's `rng.exponential(b)` uses the scale.)

Figure 1.2 shows the limit for $b = 2$. With one slot per unit of time, each slot holds an event with probability $p = 1/(2 \cdot 1) = \frac{1}{2}$, so $\Pr[T_n > t] = (\frac{1}{2})^{\lfloor t \rfloor}$ is a staircase that halves at every integer. With five slots it already hugs $e^{-t/2}$. At $t = 4$ the script gives $\Pr[T_n > 4] = 0.0625$, 0.1216 and 0.1347 for $n = 1, 5, 100$, against $e^{-2} = 0.1353$. The first two follow from the formula of step 2: $(\frac{1}{2})^4 = 0.0625$, and with $n = 5$, $p = 0.1$ and $(0.9)^{20} = 0.1216$.

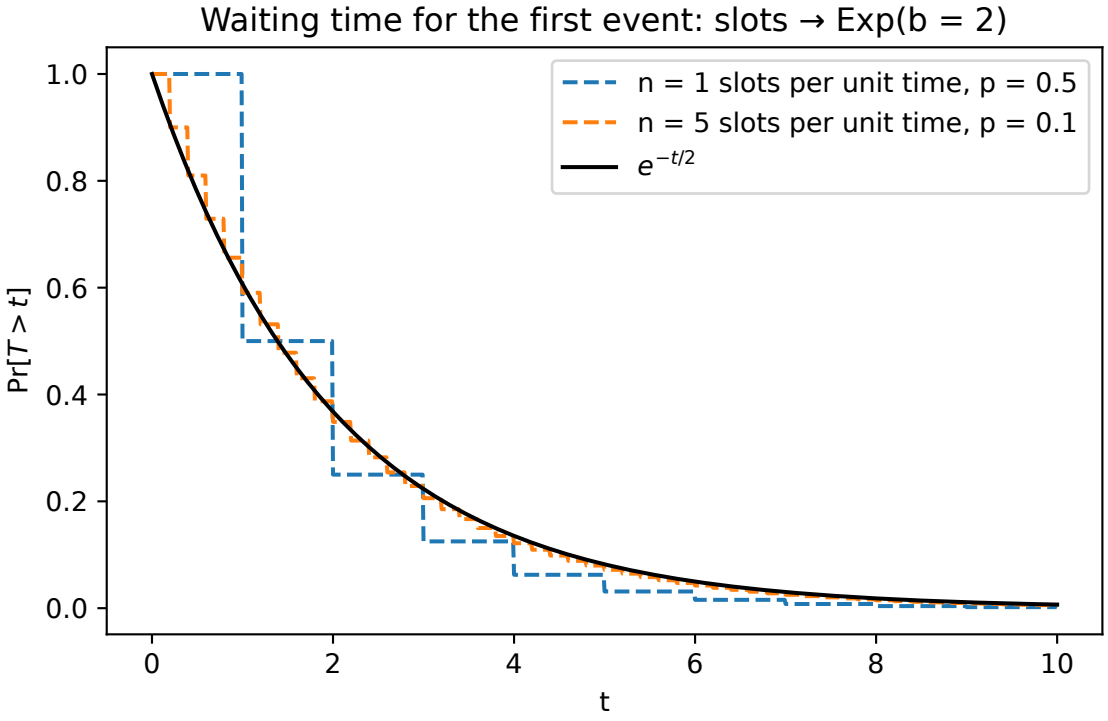

Figure 1.2.: $\Pr[T_n > t]$ for the slotted waiting time with $b = 2$ and $n = 1$ or 5 slots per unit of time, against the exponential tail $e^{-t/2}$.

1.5.4. Moments and tail

Everything about the exponential follows from its density by short integrals.

The **tail** is the area under the density to the right of t: $\Pr[Y \geq t] = \int_t^\infty \frac{1}{b} e^{-y/b}\,\mathrm{d}y = e^{-t/b}$, which is Equation 1.18 again.

The **mean** is easiest from the tail. A non-negative variable can be written as $Y = \int_0^\infty \mathbf{1}[Y \geq t]\,\mathrm{d}t$, where $\mathbf{1}[\cdot]$ is 1 when the condition holds and 0 otherwise: the integrand is 1 for t from 0 up to Y, so the integral is the length Y. Taking expectations turns each indicator into a probability, $\mathbb{E}Y = \int_0^\infty \Pr[Y \geq t]\,\mathrm{d}t = \int_0^\infty e^{-t/b}\,\mathrm{d}t = b$. So b is indeed the average wait.

The **second moment** uses the Gamma integral $\int_0^\infty y^k e^{-y/b}\,\mathrm{d}y = k!\,b^{k+1}$. Substituting $u = y/b$ turns it into $b^{k+1}\int_0^\infty u^k e^{-u}\,\mathrm{d}u$, and integrating by parts k times reduces the last integral to $k!$. With $k = 2$ and the factor $\frac{1}{b}$ from the density, $\mathbb{E}Y^2 = 2b^2$, so $\operatorname{Var} Y = 2b^2 - b^2 = b^2$.

The **MGF** multiplies the density by $e^{\lambda y}$, which combines the two exponents into $-(1/b-\lambda)y$. As long as $\lambda < 1/b$ that exponent is negative and the integral converges:

$$M_Y(\lambda) = \frac{1}{b}\int_0^\infty e^{-(1/b-\lambda)y}\,\mathrm{d}y = \frac{1}{1-b\lambda}. \tag{1.20}$$

For $\lambda \geq 1/b$ the exponent is zero or positive, the integrand does not shrink, and the integral diverges. The MGF exists only on part of the line: the hallmark of an exponential, rather than Gaussian, tail.

1.5.5. Interpretation: memorylessness

The exponential forgets how long you have waited. Given that you have already waited s without an event, the chance of waiting at least t more is the same as the chance of waiting t from scratch. In symbols, the conditional probability is the ratio of the two tails,

$$\Pr[Y \geq s+t \mid Y \geq s] = e^{-(s+t)/b}/e^{-s/b} = e^{-t/b} = \Pr[Y \geq t]. \tag{1.21}$$

Having already waited s tells you nothing about the remaining wait. The derivation explains why: the slots after time s are independent of the empty slots before it, so the wait starts afresh. The geometric distribution is memoryless for the same reason. The exponential is also the only continuous distribution with this property: memorylessness says the tail $g(t) = \Pr[Y \geq t]$ satisfies $g(s+t) = g(s)g(t)$, and the only decreasing functions with that property are exponentials $e^{-t/b}$.

1.5.6. Example: time to a model's first error

A deployed classifier serves 50 requests per second and misclassifies each one independently with probability 10^{-4}. Each request is a slot, so errors arrive at rate $50 \times 10^{-4} = 0.005$ per second, and the time to the first error is approximately $\mathrm{Exp}(b)$ with $b = 1/0.005 = 200$ seconds. A 10-minute window is 600 seconds, so the probability of a clean window is $e^{-600/200} = e^{-3} \approx 0.050$. The exact slotted answer is $(1-10^{-4})^{30000}$, one factor for each of the $50 \times 600 = 30{,}000$ requests, which agrees to three decimals because p is tiny. Memorylessness says that after 10 error-free minutes, the expected wait for the first error is still 200 seconds.

1.5.7. Check yourself

- Show that $\mathbb{E}Y^k = k!\,b^k$ by differentiating the MGF k times. *($M^{(k)}(\lambda) = k!\,b^k(1-b\lambda)^{-k-1}$, which is $k!\,b^k$ at $\lambda = 0$.)*
- The slotted wait has $\mathbb{E}T_n = \mathbb{E}G/n = b$ for every n, and $\mathrm{Var}\,T_n = (1-p)b^2$. Which factor disappears in the limit, and why? *($(1-p) \to 1$ because $p = 1/(bn) \to 0$, just as for the binomial variance under the Poisson limit. The script's samples give variances 2.001, 3.596 and 3.984 for $n = 1, 5, 100$, against $b^2 = 4$.)*

1.6. Laplace

1.6.1. Context

The Laplace distribution is symmetric noise with exponential tails. Compared with a normal of the same variance it puts more mass near zero *and* more mass far out. In machine learning it appears as the noise model behind absolute-error loss: assuming Laplace noise and maximizing the likelihood gives least-absolute-deviation regression, just as normal noise gives least squares. In later parts it is one of the two standard noise distributions.

1.6.2. Definition

The Laplace density is an exponential density on each side of a centre μ, mirrored, with each side carrying half the probability. $X \sim \mathrm{Lap}(\mu, b)$ with location μ and scale $b > 0$ has density

$$f(x) = \frac{1}{2b} e^{-|x-\mu|/b}. \tag{1.22}$$

We write $\mathrm{Lap}(b)$ for $\mathrm{Lap}(0, b)$. The cumulative distribution function (CDF), the probability $\Pr[X \le x]$, comes from integrating the density up to x. Left of the centre only the left half contributes, and right of it you subtract the remaining right tail from 1: the CDF is $\frac{1}{2}e^{(x-\mu)/b}$ for $x < \mu$ and $1 - \frac{1}{2}e^{-(x-\mu)/b}$ for $x \ge \mu$.

1.6.3. Moments and tail

Take $\mu = 0$. The density takes the same value at x and $-x$, so the size $|X|$ collects the density from both sides: its density is $2 \cdot \frac{1}{2b} e^{-x/b} = \frac{1}{b} e^{-x/b}$ on $x \ge 0$, which is the $\mathrm{Exp}(b)$ density. So $|X| \sim \mathrm{Exp}(b)$, and everything follows from the exponential.

The tail of $|X|$ is the exponential tail, $\Pr[|X| \ge t] = e^{-t/b}$. The event $|X| \ge t$ is made of two equally likely pieces, $X \ge t$ and $X \le -t$, because the density is mirror-symmetric about 0, so one side alone has half of it: $\Pr[X \ge t] = \frac{1}{2}e^{-t/b}$. The mean absolute deviation is the exponential mean, $\mathbb{E}|X| = b$.

For the variance, note that $X^2 = |X|^2$, so $\mathbb{E}X^2$ is the exponential second moment $2b^2$. The mean is 0 by symmetry, so $\operatorname{Var} X = 2b^2$. Turned around, a Laplace variable with variance σ^2 has scale $b = \sigma/\sqrt{2}$.

For the MGF, split the integral at 0 into the two exponential halves. On the right, $\frac{1}{2b}\int_0^\infty e^{\lambda x - x/b}\,\mathrm{d}x = \frac{1}{2b} \cdot \frac{1}{1/b - \lambda}$, which needs $\lambda < 1/b$; the left half is the same with $-\lambda$ in place of λ, which needs $\lambda > -1/b$. So for $|\lambda| < 1/b$, putting the two fractions over the common denominator $1/b^2 - \lambda^2$,

$$M_X(\lambda) = \frac{1}{2b}\left(\frac{1}{1/b - \lambda} + \frac{1}{1/b + \lambda}\right) = \frac{1}{1 - b^2\lambda^2}. \tag{1.23}$$

1.6.4. A Laplace variable is a difference of exponentials

The Laplace is two exponentials back to back, which suggests building it by subtracting one exponential from another: the positive one supplies the right half, the negated one the left half. The MGF confirms it. Let $Y_1, Y_2 \sim \mathrm{Exp}(b)$ be independent. Negating a variable flips the dial, $\mathbb{E}[e^{\lambda(-Y_2)}] = M_{Y_2}(-\lambda)$, and the MGF of an independent sum is the product, so the MGF of $Y_1 - Y_2$ is

$$M_{Y_1}(\lambda)\, M_{Y_2}(-\lambda) = \frac{1}{1-b\lambda} \cdot \frac{1}{1+b\lambda} = \frac{1}{1-b^2\lambda^2}, \tag{1.24}$$

which is the Laplace MGF. Since the MGF pins down the distribution, $Y_1 - Y_2 \sim \mathrm{Lap}(b)$. The script checks this numerically: over a million samples, the empirical CDF of $\mathrm{Exp}(1) - \mathrm{Exp}(1)$ is within 0.0006 of the Lap(1) CDF everywhere on $[-5, 5]$ (Figure 1.3).

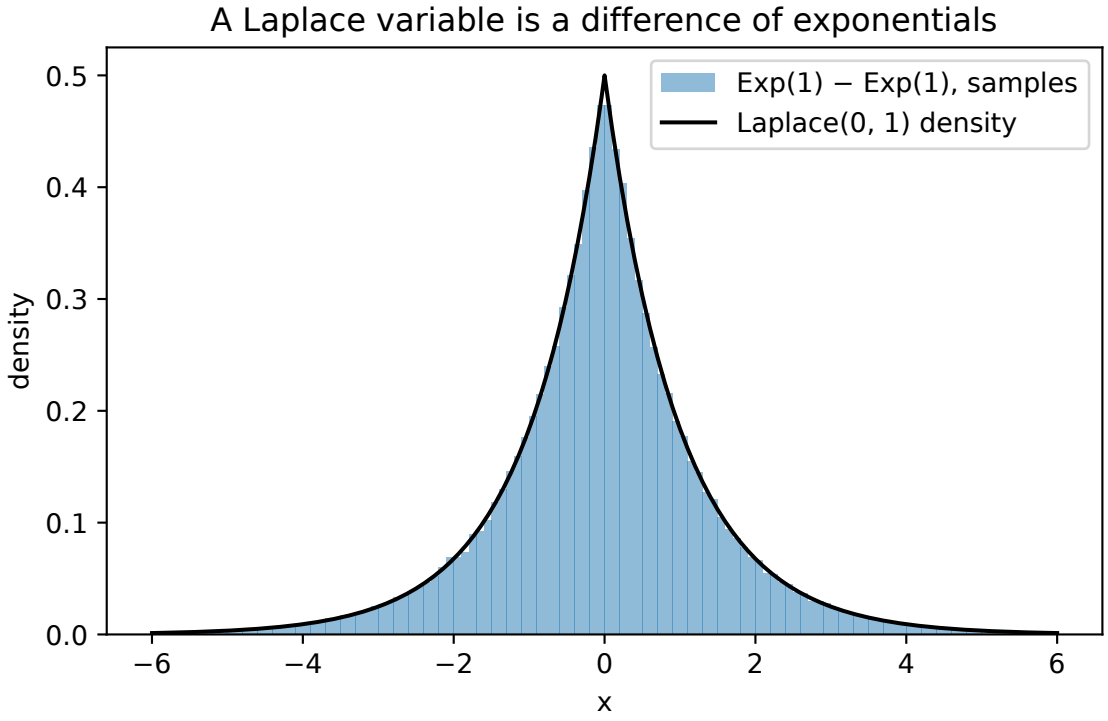

Figure 1.3.: Histogram of $\mathrm{Exp}(1) - \mathrm{Exp}(1)$ samples against the $\mathrm{Lap}(0, 1)$ density.

1.6.5. Interpretation: Laplace against normal

Put a Laplace and a normal side by side with the same variance, here 2, which means a normal with $\sigma = \sqrt{2}$ and a Laplace with $b = 1$ (Figure 1.4, left). The Laplace has a sharp peak at 0 and fatter tails. On a log scale (right) the difference is structural. Taking the logarithm of each density removes the exponential and leaves its exponent, plus a constant: the normal log density is a parabola, $-x^2/(2\sigma^2)$, while the Laplace log density is two straight lines, $-|x|/b$. Far out, a parabola always falls below a line, so the normal's tails are much lighter.

The same fact explains why the Laplace MGF exists only for $|\lambda| < 1/b$. Inside the MGF integral the weight $e^{\lambda x}$ multiplies the density, so the exponents add: $\lambda x - |x|/b$. For large positive x that

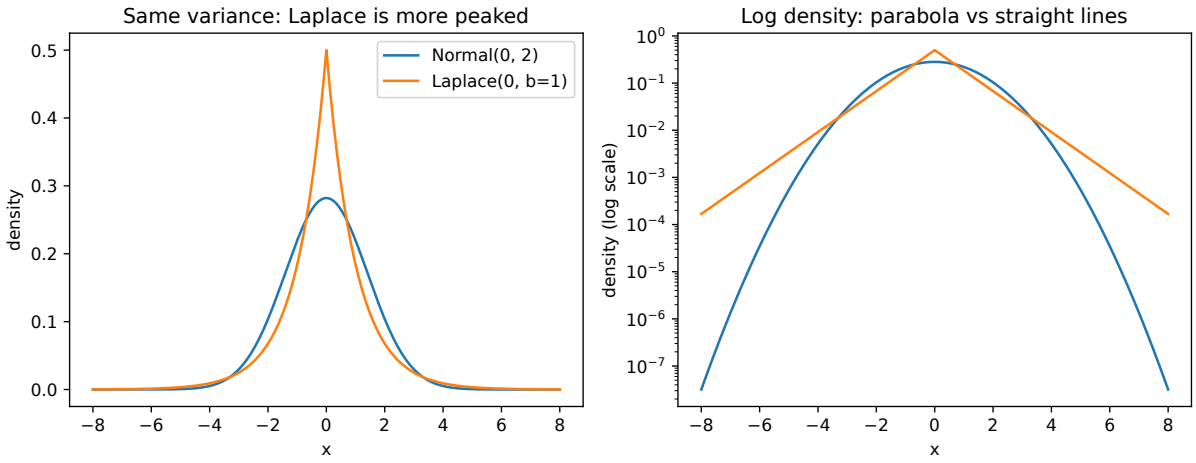

Figure 1.4.: Normal and Laplace densities with variance 2, on linear and log scales.

is $(\lambda - 1/b)x$, which goes to $-\infty$, and keeps the integral finite, only when $\lambda < 1/b$; the left side needs $\lambda > -1/b$. A quadratic decay $-x^2/(2\sigma^2)$ beats the linear term λx for every λ, which is why the normal MGF is finite everywhere.

1.6.6. Example: absolute-error regression

Suppose $y_i = \theta^\top x_i + \xi_i$, with parameters θ and independent noise $\xi_i \sim \mathrm{Lap}(b)$. The likelihood of the data is the product of the n Laplace densities of the residuals $y_i - \theta^\top x_i$, and its logarithm is the sum of their log densities, $-n \ln(2b) - \frac{1}{b}\sum_i |y_i - \theta^\top x_i|$. Only the second term depends on θ, and it enters with a minus sign, so the maximum-likelihood θ minimizes the sum of absolute errors. With no features this estimates the location by the *median*: moving a candidate location m to the right lowers the absolute error of every point above m and raises it for every point below, so the sum stops decreasing exactly when half the points are on each side. The median is far less sensitive to outliers than the mean, because moving one extreme point further out does not change which point is in the middle. That insensitivity is the same heavy-tail property seen in the figure: under a Laplace model, large residuals are not surprising enough to dominate the fit.

1.6.7. Check yourself

- If $X \sim \mathrm{Lap}(b)$, what is $\Pr[|X| \geq 3b]$, and what is the corresponding probability for a normal with the same variance? *($e^{-3b/b} = e^{-3} \approx 0.050$; for the normal, $\sigma = \sqrt{2}b$, so $3b$ is $3/\sqrt{2}$ standard deviations and $\Pr[|Z| \geq 3/\sqrt{2}] \approx 0.034$. The Laplace wins this far out, and the gap grows quickly.)*
- Derive $\mathbb{E}|X| = b$ from the exponential. *($|X| \sim \mathrm{Exp}(b)$.)*

1.7. Normal

1.7.1. Context

The normal distribution appears whenever many small independent effects add up — that is the central limit theorem (CLT) — and it is the default model for measurement noise, weight initialization and random projections. It is the light-tailed counterpart of the Laplace: closed under sums and scalings, with an MGF that is finite everywhere and a tail that decays like $e^{-t^2/2}$.

1.7.2. Definition

The normal density is the bell curve: its logarithm is a downward parabola centred at the mean μ, with width set by the standard deviation σ. $X \sim \mathcal{N}(\mu, \sigma^2)$ has density

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-(x-\mu)^2/(2\sigma^2)}. \tag{1.25}$$

Standardization: subtracting the mean and dividing by the standard deviation gives $Z = (X - \mu)/\sigma \sim \mathcal{N}(0, 1)$, the standard normal, with density φ and CDF Φ. So $\Phi(t)$ is the probability that a standard normal is below t, and every normal probability reduces to it: $\Pr[X \le x] = \Phi((x-\mu)/\sigma)$. There is no closed form for Φ. In code, use the complementary error function erfc that every maths library provides, through $\Phi(x) = \frac{1}{2}\operatorname{erfc}(-x/\sqrt{2})$. It stays accurate far into the tail, where computing a small tail as $1 - \Phi$ by subtraction would lose all its digits.

1.7.3. MGF and moments

The MGF integrates $e^{\lambda x}$ against the density, so the two exponents add, and the trick is to recognize the sum as another normal density. Take $\mu = 0$ first. Completing the square in the combined exponent gives $\lambda x - \frac{x^2}{2\sigma^2} = -\frac{(x-\lambda\sigma^2)^2}{2\sigma^2} + \frac{\lambda^2\sigma^2}{2}$. The first term is the exponent of a normal density centred at $\lambda\sigma^2$, which integrates to 1 against the normalizer $\frac{1}{\sigma\sqrt{2\pi}}$, so only the factor $e^{\lambda^2\sigma^2/2}$ survives. A mean μ adds the constant μ to X, which multiplies $e^{\lambda X}$ by $e^{\lambda\mu}$. So

$$M_X(\lambda) = e^{\mu\lambda + \sigma^2\lambda^2/2}. \tag{1.26}$$

Then $\psi(\lambda) = \mu\lambda + \sigma^2\lambda^2/2$ gives $\psi'(0) = \mu$ and $\psi''(0) = \sigma^2$. Because ψ is a quadratic, its third and higher derivatives are zero, so all higher cumulants (the higher derivatives of the log-MGF at 0, Section 1.2.2) are zero.

1.7.4. Sums and linear maps

Scaling and adding independent normals gives another normal. The MGF shows it: scaling X_i by a_i evaluates its MGF at $a_i\lambda$, and adding independent variables multiplies MGFs, which adds the exponents. For independent $X_i \sim \mathcal{N}(\mu_i, \sigma_i^2)$, the MGF of $\sum_i a_i X_i$ is therefore $\exp(\lambda \sum_i a_i\mu_i +$

$\frac{\lambda^2}{2}\sum_i a_i^2\sigma_i^2$). That is the normal MGF with mean $\sum_i a_i\mu_i$ and variance $\sum_i a_i^2\sigma_i^2$, and since the MGF pins down the distribution,

$$\sum_i a_i X_i \sim \mathcal{N}\Big(\sum_i a_i\mu_i,\ \sum_i a_i^2\sigma_i^2\Big). \tag{1.27}$$

Among distributions with finite variance, the normal is the only one for which every linear combination of independent copies stays in the same family, up to location and scale (a classical result of Lévy on what are called stable distributions). The Laplace, for instance, fails: the sum of two independent Lap(b) variables has MGF $1/(1-b^2\lambda^2)^2$, which is not a Laplace MGF.

1.7.5. The normal in many dimensions

$X \sim \mathcal{N}(0, \sigma^2 I_d)$ means the d coordinates are independent $\mathcal{N}(0,\sigma^2)$; I_d is the $d \times d$ identity matrix. Two facts are used constantly.

Rotation invariance. The noise looks the same in every direction, so a question about one direction is a one-dimensional question. To see it, project X onto a unit vector u, one with $\sum_i u_i^2 = 1$. The projection $\langle u, X\rangle = \sum_i u_i X_i$ is a linear combination of independent normals, so by the rule above $\langle u, X\rangle \sim \mathcal{N}(0, \sigma^2\sum_i u_i^2) = \mathcal{N}(0,\sigma^2)$, whatever the direction u.

The norm concentrates at $\sigma\sqrt{d}$. The squared length $\|X\|^2 = \sum_i X_i^2$ is a sum of d independent terms, so its mean and variance are d times those of one term. Write $X_i = \sigma Z$ with Z standard normal. Then $\mathbb{E}X_i^2 = \sigma^2$, and $\operatorname{Var} X_i^2 = \sigma^4(\mathbb{E}Z^4 - (\mathbb{E}Z^2)^2) = \sigma^4(3-1) = 2\sigma^4$. The value $\mathbb{E}Z^4 = 3$ comes from the MGF: $e^{\lambda^2/2} = 1 + \lambda^2/2 + \lambda^4/8 + \cdots$, and the coefficient of λ^4 times $4!$ is $24/8 = 3$. So

$$\mathbb{E}\|X\|^2 = d\sigma^2, \qquad \operatorname{Var}\|X\|^2 = 2d\sigma^4, \qquad \frac{\|X\|^2}{d\sigma^2} = 1 \pm O\Big(\frac{1}{\sqrt{d}}\Big). \tag{1.28}$$

The last statement divides by the mean: the ratio has mean 1 and standard deviation $\sqrt{2d\sigma^4}/(d\sigma^2) = \sqrt{2/d}$, and $O(1/\sqrt{d})$ means "at most a constant times $1/\sqrt{d}$". In high dimension a normal vector is almost never near the origin: it lives on a thin shell of radius $\sigma\sqrt{d}$. The script measures $\|X\|/\sqrt{d}$ for $\sigma = 1$ (Table 1.4 and Figure 1.5):

Table 1.4.: Mean and standard deviation of $\|X\|/\sqrt{d}$ over 2,000 draws of $X \sim \mathcal{N}(0, I_d)$.

d	1	10	100	1,000	10,000
mean of $\|X\|/\sqrt{d}$	0.802	0.977	0.998	1.000	1.000
std of $\|X\|/\sqrt{d}$	0.611	0.220	0.069	0.022	0.007

The standard deviation falls like $1/\sqrt{2d}$. That is half the $\sqrt{2/d}$ found for the squared norm, because taking a square root halves small relative deviations: $\sqrt{1+e} \approx 1 + e/2$. At $d = 10{,}000$, for instance, $1/\sqrt{20000} \approx 0.007$. At $d = 1$ the mean is $\mathbb{E}|Z| = 2\int_0^\infty z\varphi(z)\,\mathrm{d}z = 2/\sqrt{2\pi} = \sqrt{2/\pi} \approx 0.798$.

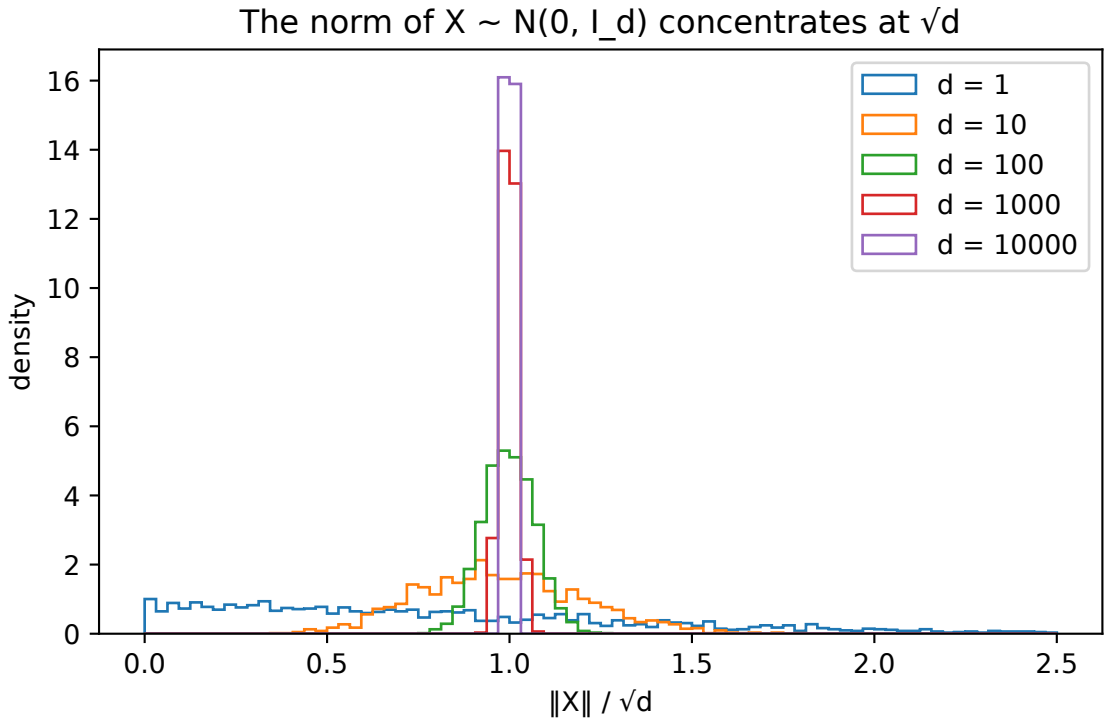

Figure 1.5.: Histograms of $\|X\|/\sqrt{d}$ for $X \sim \mathcal{N}(0, I_d)$ and d from 1 to 10,000.

1.7.6. The central limit theorem

Take a sum of n independent draws from the same distribution, with mean μ and finite variance σ^2. By the rules of Section 1.2.1 the sum has mean $n\mu$ and standard deviation $\sigma\sqrt{n}$. Subtract the first and divide by the second, and the result always has mean 0 and variance 1. The central limit theorem says more: whatever the distribution of each draw, the *shape* of this standardized sum approaches the standard normal. In symbols, if $X_1, X_2, \ldots$ are independent and identically distributed with mean μ and finite variance σ^2, then

$$\frac{X_1 + \cdots + X_n - n\mu}{\sigma\sqrt{n}} \to \mathcal{N}(0,1) \quad \text{in distribution,} \tag{1.29}$$

which means that its CDF approaches Φ at every point. The theorem holds whatever the shape of the X_i, and the best way to see this is to start from a distribution that looks nothing like a normal. Take $X_i \sim \text{Exp}(1)$, so $\mu = \sigma^2 = 1$. One draw is badly skewed: it can't go below 0, its density is highest at 0, and it has a long right tail. The sum $S_n = X_1 + \cdots + X_n$ has a known density, the Gamma$(n, 1)$ density $x^{n-1}e^{-x}/(n-1)!$ (its MGF is $(1-\lambda)^{-n}$, the product of n exponential MGFs), so you can watch the standardized sum $(S_n - n)/\sqrt{n}$ change shape as n grows (Figure 1.6).

At $n = 1$ it is the exponential itself, shifted to mean 0. The hard wall at $z = (0-1)/1 = -1$ is the constraint $X \geq 0$. At $n = 2$ the wall moves to $(0-2)/\sqrt{2} = -\sqrt{2}$, and the peak rounds off, because two draws are rarely both near 0. At $n = 5$ the bump is in the right place but leans left, with a longer right tail. At $n = 30$ the curve is close to $\mathcal{N}(0, 1)$, though a small lean to the left remains.

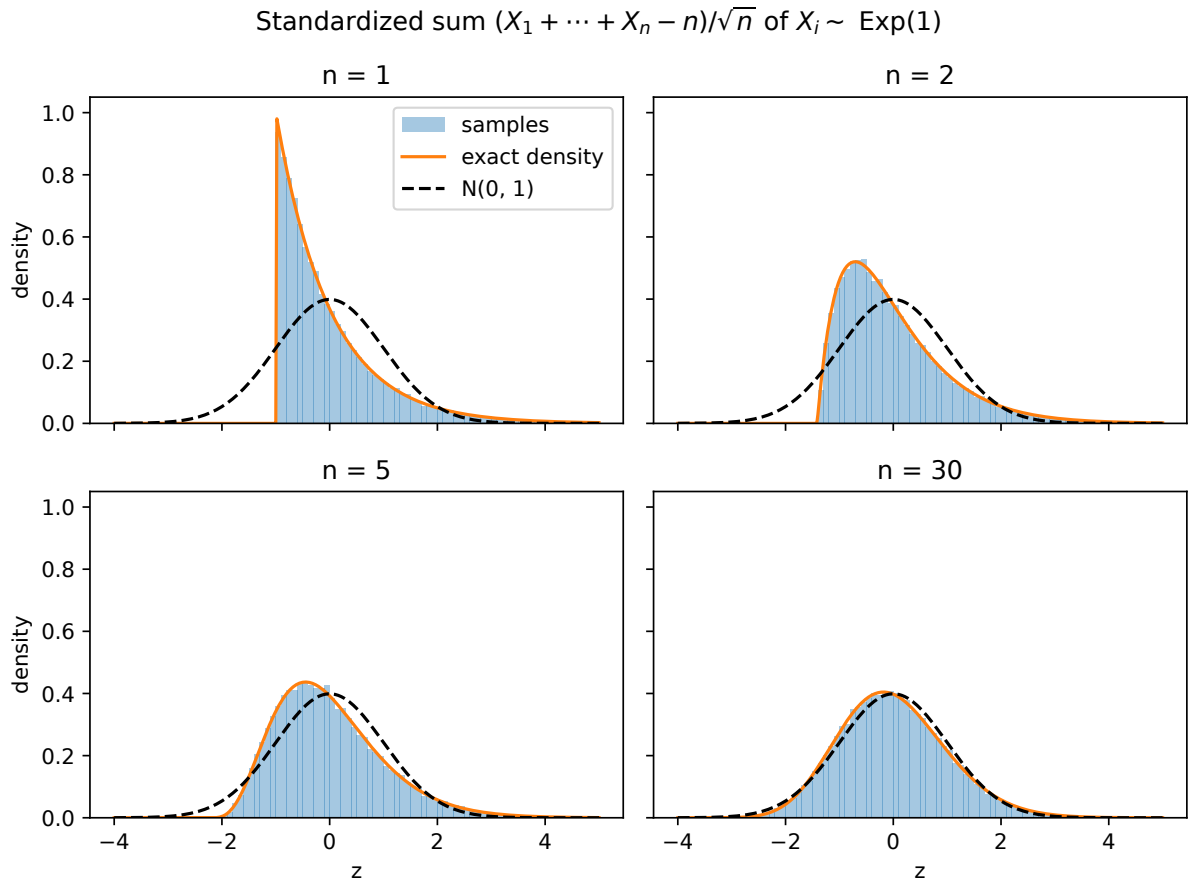

Figure 1.6.: The standardized sum of n independent Exp(1) variables for $n = 1, 2, 5, 30$: histogram of 50,000 simulated sums, the exact density from Gamma$(n, 1)$, and the $\mathcal{N}(0, 1)$ density. The skewed exponential becomes a normal step by step.

The leftover lean is measured by the **skewness** $\mathbb{E}[(X-\mu)^3]/\sigma^3$, the average cubed deviation in units of the standard deviation. Cubing keeps the sign, so a long right tail makes it positive; it is 0 for every normal, which is symmetric. The third central moment, like the variance, adds over independent terms: expand $\mathbb{E}[(\sum_i (X_i-\mu))^3]$, and every cross term contains some $\mathbb{E}[X_i-\mu]=0$ as a factor. For Exp(1) the third central moment is 2: with $\mathbb{E}Y^k = k!$, it is $\mathbb{E}Y^3 - 3\mathbb{E}Y^2 + 3\mathbb{E}Y - 1 = 6-6+3-1=2$. So S_n has third central moment $2n$ and standard deviation $\sqrt{n}$, and its skewness is $2n/n^{3/2} = 2/\sqrt{n}$. The skewness falls, but only like $1/\sqrt{n}$. The largest gap between the CDF of the standardized sum and the normal CDF, which the script computes exactly from the Gamma CDF, falls at the same rate (Table 1.5).

Table 1.5.: How far the standardized sum of n Exp(1) variables is from $\mathcal{N}(0,1)$. The CDF gap is the maximum of $|F_n(z)-\Phi(z)|$ over $z \in [-5,5]$ in steps of 0.01.

n	Skewness $2/\sqrt{n}$	Largest CDF gap to $\mathcal{N}(0,1)$
1	2.000	0.1587
2	1.414	0.0945
5	0.894	0.0596
30	0.365	0.0243

Multiply each gap by $\sqrt{n}$ and you get 0.159, 0.134, 0.133 and 0.133: the product settles to a constant, so the error decays like $1/\sqrt{n}$. This rate holds in general. The Berry–Esseen theorem bounds the gap by $c\,\mathbb{E}|X-\mu|^3/(\sigma^3\sqrt{n})$ for a universal constant $c < 0.48$ (Shevtsova, 2011). Section E.3 in the appendices proves the central limit theorem itself, with a slower rate, by swapping one term at a time for a normal one. The numerator is a third moment, like the skewness, so the more skewed the summands, the more terms you need.

This is also why the normal curve in Figure 1.1 fits so well: Poisson(5) is a sum of five independent Poisson(1) variables, since Poisson means add, so the CLT already applies to it. A common rule of thumb is that the normal approximation to a binomial is reasonable once $np(1-p) \gtrsim 10$. The CLT is a statement about the *bulk*. In the far tails, where worst-case guarantees operate, it can be badly wrong, because the gap it controls is an absolute error of order $1/\sqrt{n}$, far larger than the tiny tail probabilities themselves; that is the job of the concentration inequalities in the next chapter.

1.7.7. Example: noise in high dimension

Add $\mathcal{N}(0, \sigma^2 I_d)$ noise to a model with $d = 10^6$ parameters and $\sigma = 0.01$. The noise vector has norm about $\sigma\sqrt{d} = 0.01 \times 1000 = 10$, almost surely within a fraction of a percent of that: the relative standard deviation is $1/\sqrt{2d} = 1/\sqrt{2\times 10^6}$, under 0.1%. Yet by rotation invariance its projection onto any fixed unit vector is only $\mathcal{N}(0, 0.01^2)$. Large in norm, small in every direction: both facts come from rotation invariance and norm concentration.

1.7.8. Check yourself

- If $X \sim \mathcal{N}(0, \sigma^2 I_d)$ and u, v are orthogonal unit vectors, are $\langle u, X\rangle$ and $\langle v, X\rangle$ independent? *(Yes. They are jointly normal with covariance $\sigma^2\langle u, v\rangle = 0$, and for jointly normal variables*

zero covariance means independence, which Section E.1 proves by rotation.)

- Why does the mean of $\|X\|/\sqrt{d}$ approach 1 from below? *(Jensen's inequality says that for a concave function g, such as the square root, $\mathbb{E}g(Y) \leq g(\mathbb{E}Y)$. With $Y = \|X\|^2$ this gives $\mathbb{E}\|X\| \leq \sqrt{\mathbb{E}\|X\|^2} = \sqrt{d}$.)*

1.8. Comparing a density with its shifted copy

1.8.1. Context

You take a noisy measurement $x = \mu + X$ of an unknown value μ: a sensor reading, a timing measurement, or a statistic computed from a random sample. The noise X has density f centred at 0. Suppose μ can only be one of two values, 0 or s. The number $s \in \mathbb{R}$ is the **shift**, the distance between the two candidate values. It is fixed and known, and it may be positive or negative.

Each candidate gives x its own density. If $\mu = 0$, then $x = X$, with density $f(x)$. If $\mu = s$, then $x = s + X$, with density $f(x - s)$: the same curve, moved sideways by s.

The second claim is the step to check. The CDF of $s + X$ at a point t is $\Pr[s + X \leq t] = \Pr[X \leq t - s] = F(t - s)$, where F is the CDF of X, and differentiating in t gives the density $f(t - s)$. So $f(x - s)$ is the graph of f moved right by s: its value at x is the value f had at $x - s$. With $s = 1$, for instance, $f(x - 1)$ at $x = 1$ equals $f(0)$, so the shifted copy has its peak at 1.

To decide between the two candidates from one observation x, compare the two densities at x. Their ratio $f(x)/f(x - s)$ says how many times more likely x is under $\mu = 0$ than under $\mu = s$. Taking its logarithm turns the ratio into a difference, and since both densities below are exponentials of something, it leaves just the difference of the exponents. That logarithm is the **log ratio**

$$L(x) = \ln \frac{f(x)}{f(x - s)} = \ln f(x) - \ln f(x - s). \tag{1.30}$$

It is positive when x favours $\mu = 0$, negative when x favours $\mu = s$, and zero when x says nothing.

The question this section answers is: **how large can $|L(x)|$ get?** If it is bounded, no single observation can make one candidate much more likely than the other. If it is unbounded, some observations settle the question almost for certain. The normal and the Laplace give opposite answers. Later parts compare distributions in exactly this way, and the next chapters build on it: divergences average the log ratio over x, and hypothesis testing uses it to decide.

1.8.2. Statement

The answer follows from the shapes of the two log densities. A normal log density is a parabola, and the difference of a parabola and the same parabola shifted is a straight line, which grows without bound. A Laplace log density is a pair of straight lines with slopes $\pm 1/b$, and the difference of two such shapes can never exceed what the shift moves it, $|s|/b$. For any shift $s \in \mathbb{R}$, if f is the $\mathcal{N}(0, \sigma^2)$ density, then

$$L(x) = \frac{s^2 - 2sx}{2\sigma^2}, \tag{1.31}$$

which is linear in x and unbounded. If f is the Lap(b) density, then

$$L(x) = \frac{|x-s|-|x|}{b}, \qquad |L(x)| \le \frac{|s|}{b} \quad \text{for every } x. \tag{1.32}$$

1.8.3. Derivation

Normal. Start from the normal density with $\mu = 0$, $f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-x^2/(2\sigma^2)}$.

1. *Write the shifted density.* Replace x by $x - s$: $f(x-s) = \frac{1}{\sigma\sqrt{2\pi}} e^{-(x-s)^2/(2\sigma^2)}$. The constant in front is the same; only the exponent changes.
2. *Take the ratio.* The constants cancel, and $e^a/e^c = e^{a-c}$:

$$\frac{f(x)}{f(x-s)} = \frac{e^{-x^2/(2\sigma^2)}}{e^{-(x-s)^2/(2\sigma^2)}} = \exp\left(\frac{(x-s)^2 - x^2}{2\sigma^2}\right). \tag{1.33}$$

3. *Take the logarithm.* Since $\ln e^c = c$, the log ratio is the exponent: $L(x) = \dfrac{(x-s)^2 - x^2}{2\sigma^2}$.
4. *Expand the square.* $(x-s)^2 = x^2 - 2sx + s^2$, and the x^2 cancels against $-x^2$, leaving $L(x) = \dfrac{s^2 - 2sx}{2\sigma^2}$.

The x^2 terms cancel because both densities have the same curvature; what is left is linear in x, with slope $-s/\sigma^2$. A line with nonzero slope has no bound, so $|L(x)| \to \infty$ as $|x| \to \infty$.

Laplace. Start from $f(x) = \frac{1}{2b} e^{-|x|/b}$.

1. *Write the shifted density.* $f(x-s) = \frac{1}{2b} e^{-|x-s|/b}$.
2. *Take the ratio and the logarithm,* as for the normal: the constants cancel and the log leaves the difference of exponents, $L(x) = -\dfrac{|x|}{b} + \dfrac{|x-s|}{b} = \dfrac{|x-s|-|x|}{b}$.
3. *Bound it from above.* The triangle inequality $|a+c| \le |a| + |c|$ says that the size of a sum is at most the sum of the sizes. With $a = x$, $c = -s$ it gives $|x-s| \le |x| + |s|$, so $|x-s| - |x| \le |s|$.
4. *Bound it from below.* The same inequality with $a = x - s$, $c = s$ gives $|x| \le |x-s| + |s|$, so $|x-s| - |x| \ge -|s|$.
5. *Combine.* $\big||x-s|-|x|\big| \le |s|$, so $|L(x)| \le |s|/b$ for every x, and the ratio of the two densities never exceeds $e^{|s|/b}$.

The bound is reached, not just approached. For $s > 0$ and any $x \le 0$, $|x-s|-|x| = (s-x)-(-x) = s$; for any $x \ge s$, it is $(x-s) - x = -s$. Between 0 and s the log ratio falls linearly from s/b to $-s/b$.

Table 1.6 puts numbers on both formulas for $s = 1$, $\sigma = 1$ and $b = 1$, where they read $L(x) = (1-2x)/2$ and $L(x) = |x-1| - |x|$.

Table 1.6.: The log ratio $L(x)$ of a density and its copy shifted by $s = 1$, for $\mathcal{N}(0, 1)$ and Lap(1), at a few observations x.

x	-2	0	0.5	1	3	10
Normal, $L(x) = (1 - 2x)/2$	2.5	0.5	0	-0.5	-2.5	-9.5
Laplace, $L(x) = \lvert x - 1\rvert - \lvert x\rvert$	1	1	0	-1	-1	-1

Both vanish at the midpoint $x = 0.5$, where the two candidates are equally plausible. Far out they part ways. At $x = 10$ the normal log ratio is -9.5, so the observation is $e^{9.5} \approx 13{,}360$ times more likely under $\mu = 1$ than under $\mu = 0$. The Laplace never says more than $e^1 \approx 2.72$ times, however far out x is (Figure 1.7).

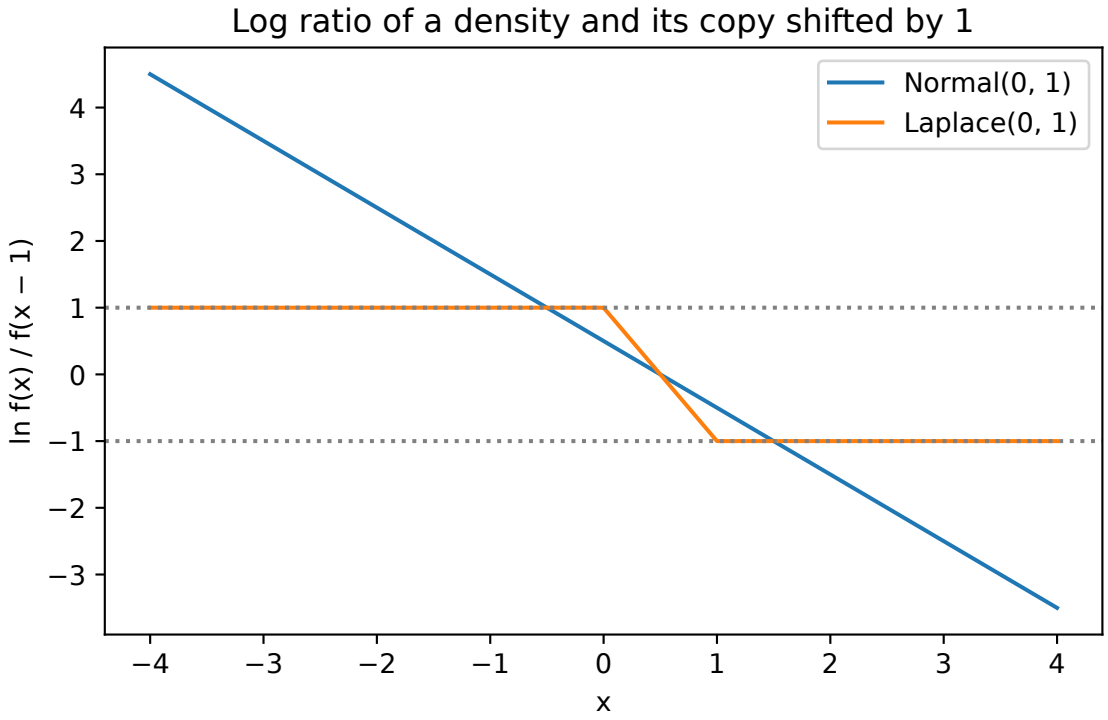

Figure 1.7.: Log ratio $L(x)$ of a density and its copy shifted by $s = 1$, for the standard normal and Lap(1).

1.8.4. Interpretation

For the Laplace, the two copies are within a fixed factor of each other everywhere. For the normal, they are close in the bulk, but the ratio is unbounded in the tails — where, however, there is very little probability. How to make "very little probability" precise is the subject of the next three

chapters: concentration bounds it, divergences summarize it, and hypothesis testing says what an observer can do with it.

1.8.5. Check yourself

- For the normal, at which x is $L(x) = 0$, and why is that point natural? *($x = s/2$, the midpoint, where the two densities cross.)*
- Under $x \sim \mathcal{N}(0, \sigma^2)$, what is the distribution of $L(x)$? *(It is linear in a normal, so normal: mean $s^2/(2\sigma^2)$, variance $(s/\sigma^2)^2\sigma^2 = s^2/\sigma^2$.)*

1.9. Code: check the facts by simulation

The script code/distributions.py draws every figure in this chapter and checks the formulas against simulation. Each probability function and each simulated quantity is a small typed function; the script calls them once for the tables and loops them over parameters for the figures. From the repository root:

```
uv run python code/part01-prerequisites/distributions.py
```

Table 1.7 compares each formula with 1,000,000 samples:

Table 1.7.: Mean and variance from the formulas against 1,000,000 samples (seed 0).

Distribution	Mean (formula / sample)	Variance (formula / sample)
Bern(0.3)	0.300 / 0.301	0.210 / 0.210
Bin(20, 0.3)	6.000 / 6.001	4.200 / 4.198
Poisson(4)	4.000 / 3.998	4.000 / 4.001
Exp(2)	2.000 / 2.001	4.000 / 4.019
Lap(0, 2)	0.000 / −0.000	8.000 / 7.993
$\mathcal{N}(1, 3^2)$	1.000 / 1.002	9.000 / 8.977

The formulas in each row are the ones derived above: $p(1-p)$, $np(1-p)$, μ, b^2, $2b^2$ and σ^2. Every sample value is within a few thousandths of its formula, which is the sampling error you expect from a million draws. The other four checks are reported in their sections above: the slotted waiting time, the difference of exponentials, the norm of a normal vector, and the convergence of standardized exponential sums to the normal. tests/test_distributions.py checks that the output still matches.

1.11. Cheat sheet

Table 1.8 collects the facts above.

Table 1.8.: Summary of the five families: density, moments, MGF and tail.

Distribution	Density or PMF	Mean	Variance	MGF	Tail
Bern(p)	$p^x(1-p)^{1-x}$, $x \in \{0,1\}$	p	$p(1-p)$	$1 + p(e^\lambda - 1)$	—
Bin(n,p)	$\binom{n}{k}p^k(1-p)^{n-k}$	np	$np(1-p)$	$(1 + p(e^\lambda - 1))^n$	Chernoff, see chapter 2
Poisson(μ)	$e^{-\mu}\mu^k/k!$	μ	μ	$e^{\mu(e^\lambda - 1)}$	$\approx (e\mu/k)^k$
Exp(b)	$\frac{1}{b}e^{-y/b}$, $y \ge 0$	b	b^2	$\frac{1}{1-b\lambda}$, $\lambda < \frac{1}{b}$	$e^{-t/b}$
Lap(μ,b)	$\frac{1}{2b}e^{-\lvert x-\mu\rvert/b}$	μ	$2b^2$	$\frac{e^{\mu\lambda}}{1-b^2\lambda^2}$, $\lvert\lambda\rvert < \frac{1}{b}$	$\Pr[\lvert X-\mu\rvert \ge t] = e^{-t/b}$
$\mathcal{N}(\mu,\sigma^2)$	$\frac{1}{\sigma\sqrt{2\pi}}e^{-(x-\mu)^2/(2\sigma^2)}$	μ	σ^2	$e^{\mu\lambda+\sigma^2\lambda^2/2}$	$\Pr[X-\mu \ge t] \le \frac{1}{2}e^{-t^2/(2\sigma^2)}$

Relationships

- Bin($n, \mu/n$) $\to$ Poisson(μ) as $n \to \infty$.
- Geom($\frac{1}{bn}$)$/n \to$ Exp(b) as $n \to \infty$: the waiting time for the first event in the same slots as the Poisson limit.
- Bin(n,p) $\approx \mathcal{N}(np, np(1-p))$ in the bulk when $np(1-p) \gtrsim 10$.
- Exp(b) $-$ Exp(b) $\sim$ Lap(b), and $\lvert$Lap(b)$\rvert \sim$ Exp(b).
- Independent Poissons add to a Poisson, and independent normals add to a normal.
- CLT: $(S_n - n\mu)/(\sigma\sqrt{n}) \to \mathcal{N}(0,1)$ for any i.i.d. summands with finite variance. The CDF error is $O(1/\sqrt{n})$ and grows with the skewness (Berry–Esseen).
- $\mathcal{N}(0, \sigma^2 I_d)$ has norm $\approx \sigma\sqrt{d}$ and is $\mathcal{N}(0,\sigma^2)$ along every unit direction.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

2. Concentration inequalities

2.1. Why this matters

Randomness enters machine learning everywhere: the sample you trained on, the minibatches you drew, the test set you evaluated on, and later in this book, noise that is added on purpose. In every case the question is the same: **how far can a random quantity be from what you expect, and with what probability?** Concentration inequalities answer it. Treat them as tools for that one job, not as a list to memorize.

The whole subject is one idea, applied with more and more information about the random variable. To bound the chance that a variable lands far out, you compare it with something whose average you know, and the more you know, the sharper the comparison. If you know only the mean, you get Markov's inequality, and the tail can only be shown to decay like $1/t$, where t is how far out you look. If you also know the variance, the average squared distance from the mean, you get Chebyshev's inequality and a decay like $1/t^2$. If you know the **moment generating function (MGF)** $\mathbb{E}[e^{\lambda X}]$, which averages an exponential of the variable and so feels every moment at once, you get the Chernoff bound, which decays exponentially in t. When that MGF is no larger than a normal distribution's, the variable is called **sub-Gaussian** and its tail decays like a normal's, as e^{-t^2}; Hoeffding's inequality is the special case of bounded variables, which are always sub-Gaussian. Finally, when the quantity is not a sum of independent terms but a function of many inputs, or a running total whose steps depend on the past (a martingale), McDiarmid's and Azuma's inequalities give the same exponential bounds as long as each input or step can move the result only a bounded amount.

Table 2.1 lists where each one shows up:

Table 2.1.: The inequalities in this chapter and where each is typically used.

Inequality	Typical use
Markov	The base step inside every other proof
Chebyshev	Quick variance-based error bars
Chernoff	Counts of events: error counts, sampled batch sizes, rare outcomes
Hoeffding	Confidence intervals for averages of bounded quantities; generalization bounds
Gaussian tail	How large normal noise can be
Laplace tail	How large Laplace noise can be; maxima over many draws
McDiarmid	Functions of many independent inputs, such as an empirical risk; stability

Inequality	Typical use
Azuma	Sums whose terms are chosen adaptively, based on the past

The distributions used here (binomial, Poisson, Laplace, normal) and their MGFs are derived in Probability distributions. This chapter restates each fact where it uses it, so you do not need that chapter open.

2.2. Toolkit: five facts every derivation uses

Each section below follows the same arc: the question the bound answers, the statement, a derivation, an interpretation, an example, and a self-check. The derivations reuse five facts. We prove them once here.

2.2.1. Fact 1 — Probability is the expectation of an indicator

The probability of an event is the average of a variable that is 1 when the event happens and 0 when it does not. Write $\mathbf{1}[A]$ for that 0/1 variable, the **indicator** of the event A, and $\mathbb{E}$ for the expectation (the probability-weighted average). Then

$$\Pr[A] = \mathbb{E}[\mathbf{1}[A]]. \tag{2.1}$$

This matters because it turns probabilities into averages, and averages respect inequalities: any pointwise inequality between a random variable and an indicator becomes a probability bound after taking expectations. Markov's inequality and the union bound are both this move. Because everything later depends on it, here it is slowly, with a die.

Step 1: an indicator is a 0/1 random variable. For an event A, $\mathbf{1}[A]$ equals 1 on outcomes where A happens and 0 elsewhere. Roll a fair die and let A = "the roll is at least 5" (Table 2.2):

Table 2.2.: The indicator of the event "roll at least 5" on each outcome of a fair die.

Roll	1	2	3	4	5	6
$\mathbf{1}[A]$	0	0	0	0	1	1

The average of that row is 2/6, which is exactly $\Pr[A]$. Averaging a 0/1 variable counts the fraction of outcomes where the event happens.

Step 2: if one variable is never larger, its average is never larger. If $Y \le Z$ on *every* outcome, then $\mathbb{E}[Y] \le \mathbb{E}[Z]$: you are averaging two rows of numbers where each entry of the first is at most the matching entry of the second.

Step 3: put them together. Take X = the roll and compare $5 \cdot \mathbf{1}[X \ge 5]$ with X itself, outcome by outcome (Table 2.3):

Table 2.3.: Outcome-by-outcome comparison of $5 \cdot \mathbf{1}[X \geq 5]$ with the die roll X.

Roll	1	2	3	4	5	6	Average
$5 \cdot \mathbf{1}[X \geq 5]$	0	0	0	0	5	5	$5\Pr[X \geq 5]$
X	1	2	3	4	5	6	3.5

Every entry in the top row is at most the one below it. Where the event fails, the top is 0 and $X \geq 0$. Where it holds, the top is 5 and $X \geq 5$ by definition of the event. So the averages are ordered: $5\Pr[X \geq 5] \leq 3.5$, and dividing by 5 gives $\Pr[X \geq 5] \leq 0.7$. The true value is $2/6 = 1/3$; the bound is weak, but it is correct and used nothing except the mean. Figure 2.1 shows the comparison.

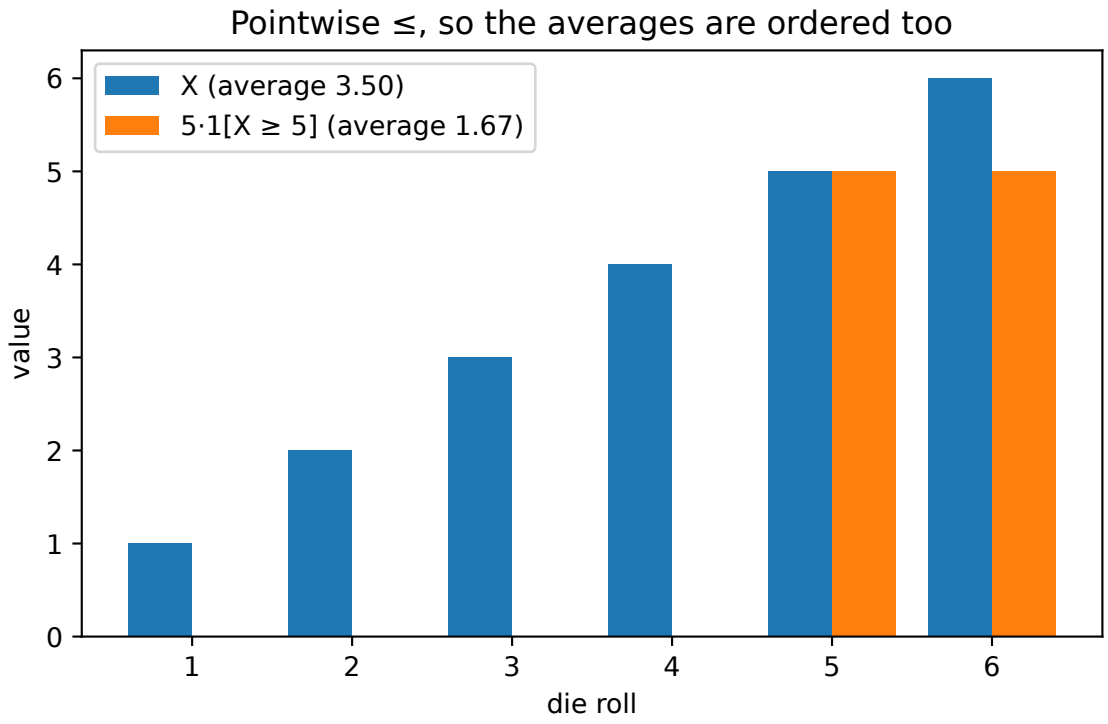

Figure 2.1.: The scaled indicator $5 \cdot \mathbf{1}[X \geq 5]$ never exceeds the die roll X, so its average never exceeds 3.5.

The pattern for bounding Pr[event]: write it as the average of an indicator, find a variable that is at least as large as that indicator on every outcome and whose average you know, and average both sides.

2.2.2. Fact 2 — Union bound

The chance that at least one of several events happens is at most the sum of their separate chances. Adding the chances can only overcount, never undercount, because an outcome that lies in several

events gets counted several times. In symbols, for events $A_1, \dots, A_k$,

$$\Pr[A_1 \cup \cdots \cup A_k] \le \sum_i \Pr[A_i]. \tag{2.2}$$

To prove it, use Fact 1 and compare indicators outcome by outcome: $\mathbf{1}[\cup_i A_i] \le \sum_i \mathbf{1}[A_i]$. On an outcome where none of the events happens, both sides are 0. On an outcome where at least one happens, the left side is 1 and the right side counts how many of the events happen, which is at least 1. The right side can be larger than 1 on outcomes that lie in several events at once: that double counting is the only slack. Taking expectations of both sides turns each indicator into a probability and gives the bound.

You will use it whenever you need k estimates, k steps or k hypotheses to all behave at once. If each one fails with probability at most β/k, all of them succeed together except with probability at most $k \cdot \beta/k = \beta$. In the exponential bounds of this chapter, asking for failure probability β/k instead of β replaces $\ln(1/\beta)$ by $\ln(k/\beta) = \ln k + \ln(1/\beta)$, so the cost of controlling k things is an extra $\ln k$ inside every exponential bound.

2.2.3. Fact 3 — $1 + x \le e^x$ for every real x

The straight line $1 + x$ touches the curve e^x at $x = 0$ (both equal 1 there and both have slope 1) and stays below it everywhere else. The reason is that e^x is **convex**: its second derivative e^x is positive, so the curve bends upward, away from any tangent line, on both sides of the point of contact. A convex function therefore lies above all its tangents, and $1 + x$ is its tangent at 0.

You will use it to turn a sum into an exponential. In the Chernoff bound it turns $1 + p(e^\lambda - 1)$ into $\exp(p(e^\lambda - 1))$, by taking $x = p(e^\lambda - 1)$. A product of such factors then becomes a single exponential whose exponent is a sum, which is far easier to optimize.

2.2.4. Fact 4 — MGFs multiply under independence

The moment generating function of a random variable X is the average of $e^{\lambda X}$, viewed as a function of a number λ that you choose:

$$M_X(\lambda) = \mathbb{E}[e^{\lambda X}]. \tag{2.3}$$

With $\lambda > 0$ the weight $e^{\lambda X}$ grows exponentially in X, so large values of X dominate the average, and the larger λ, the further into the right tail it looks. That is why the MGF is the right object for tail bounds.

The MGF of a sum of independent variables is the product of their MGFs. The reason is that $e^{\lambda(X+Y)} = e^{\lambda X} e^{\lambda Y}$, and when X and Y are independent so are $e^{\lambda X}$ and $e^{\lambda Y}$; the average of a product of independent variables is the product of their averages, so

$$\mathbb{E}[e^{\lambda(X+Y)}] = \mathbb{E}[e^{\lambda X}]\,\mathbb{E}[e^{\lambda Y}]. \tag{2.4}$$

Scaling is just as simple. Multiplying X by a constant c is the same as multiplying the dial λ by c, because $\mathbb{E}[e^{\lambda(cX)}] = \mathbb{E}[e^{(c\lambda)X}]$, so $M_{cX}(\lambda) = M_X(c\lambda)$.

You will use it to reduce a sum of n variables to n one-variable calculations, one MGF per term.

2.2.5. Fact 5 — Inverting a tail bound

A tail bound answers "how likely is a deviation of size t?". In practice you usually want the reverse: "how large a deviation must I allow so that it is exceeded with probability at most β?". That number is the **width** at failure probability β, and you get it by setting the bound equal to β and solving for t.

Concretely, suppose the deviation V satisfies $\Pr[V \geq t] \leq e^{-g(t)}$ for an increasing function g. The bound is at most β exactly when $g(t) \geq \ln(1/\beta)$, that is, when $t \geq g^{-1}(\ln(1/\beta))$. So with probability at least $1 - \beta$,

$$V < g^{-1}(\ln(1/\beta)). \tag{2.5}$$

For example, the Gaussian-shaped bound with $g(t) = t^2/(2\sigma^2)$ gives $t^2/(2\sigma^2) = \ln(1/\beta)$, so $V < \sigma\sqrt{2\ln(1/\beta)}$. Every "width at failure probability β" in this chapter is this step.

2.3. Markov and Chebyshev

2.3.1. Context

You have a random estimate and want the crudest answer to "how far can it be from the truth?", using as little as possible about its distribution. Markov uses only the mean, and Chebyshev uses only the variance. Both are weak. But every stronger bound in this chapter is Markov applied to a better function, so the derivation pattern matters more than the bounds themselves.

2.3.2. Markov's inequality

A non-negative variable cannot often be much larger than its mean, because those large values alone would already pull the average up. If $X \geq 0$ were at least a with probability p, those outcomes would contribute at least ap to the mean, so $ap \leq \mathbb{E}[X]$. For $X \geq 0$ and $a > 0$:

$$\Pr[X \geq a] \leq \frac{\mathbb{E}[X]}{a}. \tag{2.6}$$

Derivation. This is the die argument of Fact 1, with a general a in place of 5.

1. Compare X with a scaled indicator: $a\,\mathbf{1}[X \geq a] \leq X$ pointwise. If $X \geq a$, the left side is a, which is at most X. If $X < a$, the left side is 0, which is at most X because $X \geq 0$. This is the only place non-negativity is used.
2. Take expectations, which preserve $\leq$ (Fact 1, Step 2). The average of the indicator is a probability (Fact 1), so $a\Pr[X \geq a] \leq \mathbb{E}[X]$.
3. Divide both sides by $a > 0$.

Tightness. You cannot do better with only the mean. Write μ for the mean and take the variable that puts all its mass on two points: $X = a$ with probability μ/a and 0 otherwise. Its mean is $a \cdot \mu/a = \mu$, and $\Pr[X \geq a] = \mu/a$ exactly, so Markov's bound holds with equality.

2.3.3. Generalized Markov

Markov's inequality applies to any non-negative variable, so you can apply it to a transformed version of X instead of X itself. If g is non-negative and strictly increasing, then $X \geq t$ and $g(X) \geq g(t)$ are the same event, because an increasing function keeps the order. Applying Markov to the non-negative variable $g(X)$ at the level $a = g(t)$ gives

$$\Pr[X \geq t] = \Pr[g(X) \geq g(t)] \leq \frac{\mathbb{E}[g(X)]}{g(t)}. \tag{2.7}$$

The rest of this chapter is a search for good g. A fast-growing g makes the threshold $g(t)$ in the denominator huge compared with typical values of $g(X)$, so the bound gets small; the price is that $\mathbb{E}[g(X)]$ also grows, and you must be able to compute or bound it. $g(x) = x^2$ gives Chebyshev, and $g(x) = e^{\lambda x}$ gives Chernoff.

2.3.4. Chebyshev's inequality

The variance σ^2 is the average squared distance from the mean μ. A large deviation $|X - \mu| \geq t$ makes the squared distance at least t^2, and if that happened often, the average squared distance would exceed σ^2. So the probability of a deviation of t or more is at most σ^2/t^2. For X with mean μ and variance σ^2:

$$\Pr[|X - \mu| \geq t] \leq \frac{\sigma^2}{t^2}. \tag{2.8}$$

Derivation.

1. Turn the two-sided event into an event about a non-negative variable: $|X - \mu| \geq t$ holds exactly when $(X - \mu)^2 \geq t^2$, since squaring preserves the order of non-negative numbers.
2. Apply Markov to $Y = (X - \mu)^2$, which is non-negative and has mean σ^2 by the definition of the variance, at the level $a = t^2$: $\Pr[Y \geq t^2] \leq \mathbb{E}[Y]/t^2 = \sigma^2/t^2$.

Means of samples. Averaging n independent samples shrinks the variance by a factor of n. Two rules give this. Variances add for independent terms, because the cross terms (covariances) in the expansion of the square vanish, so a sum of n terms has variance $n\sigma^2$. And $\mathrm{Var}(cX) = c^2 \operatorname{Var} X$, because every deviation is multiplied by c and then squared, so dividing the sum by n divides its variance by n^2. Together, the mean $\bar{X}$ has $\mathrm{Var}(\bar{X}) = n\sigma^2/n^2 = \sigma^2/n$. Chebyshev then gives $\Pr[|\bar{X} - \mu| \geq t] \leq \sigma^2/(nt^2)$. To turn this into a width, set the bound equal to β and solve for t, as in Fact 5: $\sigma^2/(nt^2) = \beta$ gives $t = \sigma/\sqrt{n\beta}$. So with probability at least $1 - \beta$, $|\bar{X} - \mu| < \sigma/\sqrt{n\beta}$.

2.3.5. Interpretation: the price of knowing only the variance

How wide must an error bar be to fail with probability at most β? With only the variance known, solving $\sigma^2/t^2 = \beta$ gives $t = \sigma/\sqrt{\beta}$. With a Gaussian-type tail $e^{-t^2/(2\sigma^2)}$, Fact 5 gives $t = \sigma\sqrt{2\ln(1/\beta)}$. Table 2.4 compares the two, in units of σ. For instance, at $\beta = 0.05$, $1/\sqrt{0.05} = 4.5$, while $\ln(1/0.05) = \ln 20 \approx 3.0$ gives $\sqrt{2 \times 3.0} = 2.4$.

Table 2.4.: Width needed to reach failure probability β, in units of σ, with only the variance known (Chebyshev) and with a Gaussian-type tail.

β	Chebyshev, $1/\sqrt{\beta}$	Gaussian-type, $\sqrt{2\ln(1/\beta)}$
0.05	4.5	2.4
10^{-3}	31.6	3.7
10^{-6}	1,000	5.3

The Chebyshev width grows like a power of $1/\beta$, the Gaussian-type width only like the square root of a logarithm. Polynomial bounds are fine for a quick 95% error bar. They are useless when the failure probability must be tiny, as it usually must be in security and in the later parts of this book, often 10^{-5} or smaller.

2.3.6. Example: the error of Laplace noise

A measurement is corrupted by additive noise from the **Laplace distribution** $\mathrm{Lap}(b)$, which has density $\frac{1}{2b}e^{-|x|/b}$: symmetric around 0, with scale b. Its variance is $2b^2$; you can check this by integrating, since $\mathbb{E}[X^2] = 2\int_0^\infty x^2 \frac{1}{2b}e^{-x/b}\,\mathrm{d}x = 2b^2$ (Probability distributions). Chebyshev with $\sigma^2 = 2b^2$ gives $\Pr[|\text{error}| \geq t] \leq 2b^2/t^2$, and setting this to β gives the $1-\beta$ width $b\sqrt{2/\beta}$. With $b = 1$ and $\beta = 0.05$ that is $\sqrt{2/0.05} = \sqrt{40} \approx 6.3$.

Now use the shape of the noise. Integrating the density gives the exact tail $\Pr[|X| \geq t] = e^{-t/b}$, and setting $e^{-t/b} = \beta$ gives the width $b\ln(1/\beta) = \ln 20 \approx 3.0$. At $\beta = 10^{-6}$ the two widths are 1,414 (that is, $\sqrt{2\times 10^6}$) and 13.8 (that is, $\ln(10^6)$): ignoring the shape of the noise costs a factor of 100.

2.3.7. Check yourself

- Why can't you apply Markov directly to $X - \mu$? *(It can be negative, so step 1 of the Markov derivation fails.)*
- Which step of the sample-mean argument used independence, and is it more than you need? *(Only the vanishing of covariances. Pairwise uncorrelated samples suffice.)*

2.4. The Chernoff method

2.4.1. Context

Small failure probabilities like 10^{-5} are out of reach for polynomial bounds at sensible widths. The fix is to apply generalized Markov with $g(x) = e^{\lambda x}$. Its average is the MGF, which contains every moment of X at once, so the bound uses everything about the distribution, not just the mean or the variance. The resulting Chernoff bound is exponentially tight: Cramér's theorem says that for a sum of n independent copies of a variable, the probability of a large deviation decays exponentially in n with exactly the rate the optimized Chernoff bound gives, so no method

can improve its exponent for large sums. (Section F.2 in the appendices derives this matching lower bound.)

2.4.2. The recipe

The master bound. For any $\lambda > 0$, $e^{\lambda x}$ is positive and increasing, so generalized Markov applies with $g(x) = e^{\lambda x}$. Dividing $\mathbb{E}[e^{\lambda X}]$ by $e^{\lambda t}$ gives the first form below. Writing the MGF as $e^{\psi(\lambda)}$, where ψ is the logarithm of the MGF (the **log-MGF**), puts the whole bound into one exponent:

$$\Pr[X \geq t] \leq e^{-\lambda t}\,\mathbb{E}[e^{\lambda X}] = \exp\big(-(\lambda t - \psi(\lambda))\big), \qquad \psi(\lambda) = \ln \mathbb{E}[e^{\lambda X}]. \tag{2.9}$$

This holds for every $\lambda > 0$, so you are free to pick the λ that makes the bound smallest, which is the one that makes $\lambda t - \psi(\lambda)$ largest. The best exponent, $\sup_\lambda(\lambda t - \psi(\lambda))$, viewed as a function of t, has a name: the **Legendre transform** $\psi^*(t)$ of the log-MGF. It is the exponent Cramér's theorem says is exact (Section F.2).

In practice every Chernoff bound in this chapter is computed by the same five steps:

1. Write down the MGF of X.
2. If X is a sum of independent terms, factorize the MGF (Fact 4).
3. Bound each factor by something simple, usually with Fact 3.
4. Minimize the exponent over λ by setting its derivative to zero.
5. Simplify the result into a usable form.

Think of $e^{\lambda X}$ as a lens on the tail. A large λ magnifies the far tail but inflates $\mathbb{E}[e^{\lambda X}]$. A small λ keeps the expectation tame but magnifies little. Figure 2.2 shows the trade-off for a binomial: the bound as a function of λ has a clear minimum, and the relaxation of step 3 costs a little but moves the optimum to a closed form.

2.4.3. Warm-up: the Gaussian

Start with the case where every step is exact, a normal variable $X \sim \mathcal{N}(0, \sigma^2)$ with mean 0 and variance σ^2. Its MGF is $\mathbb{E}[e^{\lambda X}] = e^{\lambda^2\sigma^2/2}$ (Probability distributions). To see why, multiply the density, which is proportional to $e^{-x^2/(2\sigma^2)}$, by $e^{\lambda x}$ and complete the square in the exponent: $\lambda x - x^2/(2\sigma^2) = -(x - \lambda\sigma^2)^2/(2\sigma^2) + \lambda^2\sigma^2/2$. The first term is a normal density shifted to mean $\lambda\sigma^2$, which still integrates to 1, and the constant $e^{\lambda^2\sigma^2/2}$ is left over. So the log-MGF is the quadratic $\psi(\lambda) = \lambda^2\sigma^2/2$.

1. **Master bound.** Substitute the MGF: $\Pr[X \geq t] \leq \exp(-\lambda t + \lambda^2\sigma^2/2)$.
2. **Minimize.** The exponent is a parabola in λ. Its derivative $-t + \lambda\sigma^2$ vanishes at $\lambda = t/\sigma^2$. Substituting this λ gives the exponent $-t^2/\sigma^2 + t^2/(2\sigma^2) = -t^2/(2\sigma^2)$, so

$$\Pr[X \geq t] \leq e^{-t^2/(2\sigma^2)}. \tag{2.10}$$

Remember the shape of this calculation: a quadratic log-MGF gives a quadratic exponent. The sub-Gaussian section reuses it verbatim.

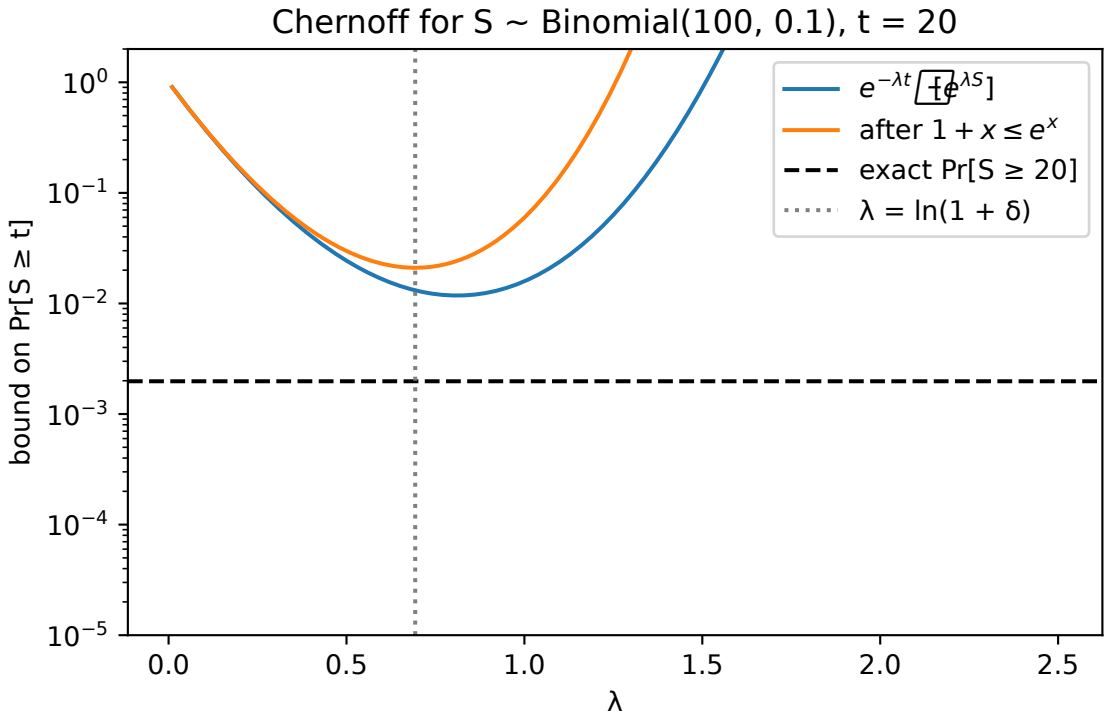

Figure 2.2.: The Chernoff bound $e^{-\lambda t}\mathbb{E}[e^{\lambda S}]$ for $S \sim \mathrm{Bin}(100, 0.1)$ and $t = 20$, as a function of λ, before and after the relaxation $1 + x \le e^x$. Both stay above the exact tail.

2.4.4. Main case: sums of Bernoullis

Now the case the method is most used for: counting how many of many independent yes/no events happen. Let $X_i \sim \mathrm{Bern}(p_i)$ be independent, each equal to 1 with probability p_i and 0 otherwise, let $S = \sum_i X_i$ be the count, and let $\mu = \mathbb{E}[S] = \sum_i p_i$ be its mean. The question is how likely S is to land a fraction r above or below μ.

Upper tail, $\Pr[S \geq (1+r)\mu]$ for $r > 0$. Follow the recipe.

1. **One factor.** X_i is 1 with probability p_i and 0 otherwise, so $\mathbb{E}[e^{\lambda X_i}] = p_i e^{\lambda} + (1-p_i) = 1 + p_i(e^{\lambda}-1)$. Fact 3 with $x = p_i(e^{\lambda}-1)$ bounds this by $\exp(p_i(e^{\lambda}-1))$. The right side is the MGF of a Poisson variable with mean p_i, since a Poisson(μ) variable has MGF $\exp(\mu(e^{\lambda}-1))$ (Probability distributions). In words: as far as the MGF can tell, a Bernoulli sum is dominated by a Poisson count with the same mean.
2. **Product.** By Fact 4 the MGF of the sum is the product of the factors, and the exponents add: $\mathbb{E}[e^{\lambda S}] \leq \exp\big(\sum_i p_i(e^{\lambda}-1)\big) = \exp(\mu(e^{\lambda}-1))$.
3. **Master bound** with $t = (1+r)\mu$: $\Pr[S \geq (1+r)\mu] \leq \exp(\mu(e^{\lambda}-1) - \lambda(1+r)\mu)$.
4. **Minimize.** The derivative of the exponent, $\mu e^{\lambda} - (1+r)\mu$, vanishes at $e^{\lambda} = 1+r$, so $\lambda = \ln(1+r)$, which is positive as required. Substituting, the exponent becomes $\mu r - (1+r)\mu \ln(1+r)$, so

$$\Pr[S \geq (1+r)\mu] \leq \left(\frac{e^r}{(1+r)^{1+r}}\right)^{\mu} = \exp\big(-\mu[(1+r)\ln(1+r) - r]\big). \tag{2.11}$$

5. **Simplify.** The bracket is awkward to invert, so replace the logarithm by a simpler lower bound, $\ln(1+r) \geq \frac{2r}{2+r}$ for $r \geq 0$. To see that this holds, let $f(r) = \ln(1+r) - \frac{2r}{2+r}$. It starts at $f(0) = 0$ and never decreases, because its derivative is $f'(r) = \frac{1}{1+r} - \frac{4}{(2+r)^2} = \frac{r^2}{(1+r)(2+r)^2} \geq 0$; so $f(r) \geq 0$. Putting the lower bound into the bracket gives $(1+r)\frac{2r}{2+r} - r = \frac{r^2}{2+r}$, so

$$\Pr[S \geq (1+r)\mu] \leq \exp\left(-\frac{r^2\mu}{2+r}\right). \tag{2.12}$$

Lower tail, $\Pr[S \leq (1-r)\mu]$ for $0 < r < 1$. The same recipe works if you look at $-S$ instead of S, because a small S is a large $-S$.

1. **Master bound for the lower tail.** For $\lambda > 0$, $S \leq s$ holds exactly when $e^{-\lambda S} \geq e^{-\lambda s}$, since $e^{-\lambda x}$ is decreasing. Markov applied to $e^{-\lambda S}$, and the same per-factor bound as before with $-\lambda$ in place of λ, give $\Pr[S \leq s] \leq e^{\lambda s}\,\mathbb{E}[e^{-\lambda S}] \leq \exp(\lambda s + \mu(e^{-\lambda}-1))$.
2. **Minimize.** With $s = (1-r)\mu$, the derivative $s - \mu e^{-\lambda}$ vanishes at $e^{-\lambda} = 1-r$, that is, $\lambda = -\ln(1-r) > 0$. Substituting gives $\exp\big(-\mu[r + (1-r)\ln(1-r)]\big)$.
3. **Simplify.** Expand the logarithm in its Taylor series, $\ln(1-r) = -\sum_{k\geq 1} r^k/k$, multiply by $1-r$ and collect powers of r: $(1-r)\ln(1-r) = -r + \sum_{k\geq 2} \frac{r^k}{k(k-1)}$. Every term of the sum is non-negative, so keeping only the first one ($k = 2$, which is $r^2/2$) gives the lower bound $-r + \frac{r^2}{2}$. The bracket is then at least $r^2/2$, so

$$\Pr[S \leq (1-r)\mu] \leq \exp\left(-\frac{r^2\mu}{2}\right). \tag{2.13}$$

2.4.5. Interpretation

The bounds depend on the expected count μ, not on the number of trials n. A million trials with $p = 10^{-6}$ expect a single event, and the count is far from concentrated. Rare events concentrate in relative terms only once you expect enough of them, because the exponent $r^2\mu$ grows with μ.

Chernoff also beats Hoeffding (the range-only bound of the next section) when p is small, and the reason is in step 1. That step keeps each p_i in the bound instead of replacing it by the worst case, so the bound implicitly knows the variance of the count, $\mu(1-p) \approx \mu$, which is small when p is small. A bound that only knows the range has to assume the largest variance the range allows. Figure 2.3 shows the gap.

Finally, the two tails differ. For large r, the upper-tail exponent $r^2\mu/(2+r)$ behaves like $r\mu$, so the tail decays like $\exp(-r\mu)$, not like $\exp(-r^2)$. Counts have Poisson-like right tails, not Gaussian ones: they can overshoot their mean by a lot more easily than they can undershoot it.

2.4.6. Example: sampled minibatch sizes

A training loop forms each minibatch by including each of $n = 60{,}000$ records independently with probability $q = 0.01$. The batch size B is a sum of Bern(q) variables, so the bounds above apply with $\mu = 60{,}000 \times 0.01 = 600$. How likely is the batch to be more than 20% off, that is, $r = 0.2$, so that $r^2 = 0.04$?

The upper-tail bound is $\exp(-0.04 \times 600/2.2) = e^{-10.9} \approx 1.8 \times 10^{-5}$, and the lower-tail bound is $\exp(-0.04 \times 600/2) = e^{-12} \approx 6.1 \times 10^{-6}$. The two events cannot happen together, so adding them gives the chance of either: B stays within $600 \pm 20\%$ except with probability about 2.4×10^{-5} per step. Over 1,000 steps, the union bound (Fact 2) adds the 1,000 per-step failure probabilities, $1{,}000 \times 2.4 \times 10^{-5}$, so every batch stays in that range except with probability about 0.024.

2.4.7. Check yourself

- Why must λ be positive for the upper tail? *(For $\lambda < 0$, $e^{\lambda x}$ is decreasing, so $X \geq t$ no longer implies $e^{\lambda X} \geq e^{\lambda t}$.)*
- Where exactly did independence enter? *(Only in factorizing the MGF in step 2.)*

2.5. Sub-Gaussian variables and Hoeffding

2.5.1. Context

Redoing the Chernoff calculation for every new distribution is tedious. The Gaussian warm-up showed that a quadratic log-MGF alone produces a Gaussian-shaped tail: nothing else about the normal distribution was used. So define a class by that one property, prove tail and sum bounds for the class once, and from then on only check membership. Hoeffding's inequality is the result for the most common member: bounded variables.

2.5.2. Definition

The idea is to call a variable sub-Gaussian when its MGF, centred at its mean μ, is never larger than the MGF of a normal variable, because then the Chernoff argument for the normal goes through with "$\leq$" in place of "=". Formally, X is **σ-sub-Gaussian** if its centred MGF is dominated by that of $\mathcal{N}(0, \sigma^2)$:

$$\mathbb{E}\big[e^{\lambda(X-\mu)}\big] \leq e^{\lambda^2\sigma^2/2} \quad \text{for all } \lambda \in \mathbb{R}. \tag{2.14}$$

The parameter σ, called the **variance proxy** when squared, is the effective standard deviation for tail purposes. It is at least the true standard deviation. To see why, expand both sides around $\lambda = 0$: the left side is $1 + \lambda^2 \operatorname{Var}(X)/2 + ...$ (the linear term vanishes because $X - \mu$ has mean 0) and the right side is $1 + \lambda^2\sigma^2/2 + ...$, so for small λ the inequality forces $\operatorname{Var}(X) \leq \sigma^2$. It can be much larger than the true standard deviation, and that slack is where these bounds lose accuracy.

2.5.3. Three properties, each one line

Tail. A sub-Gaussian variable has a tail no heavier than the normal's. The Gaussian warm-up used the MGF only through the inequality in the master bound, so repeating it with the sub-Gaussian inequality in place of the equality gives the same result:

$$\Pr[X - \mu \geq t] \leq e^{-t^2/(2\sigma^2)}. \tag{2.15}$$

The same holds for the lower tail, because $-X$ is also σ-sub-Gaussian (replace λ by $-\lambda$ in the definition). Adding the two one-sided bounds, the two-sided bound $\Pr[|X-\mu| \geq t]$ carries a factor of 2.

Sums. Variance proxies add under independence, like variances. The reason is Fact 4: the centred MGF of a sum of independent terms is the product of their centred MGFs, and each factor is bounded by a Gaussian MGF, whose exponents add. For independent X_i, each σ_i-sub-Gaussian with mean μ_i,

$$\mathbb{E}\big[e^{\lambda\sum_i(X_i-\mu_i)}\big] = \prod_i \mathbb{E}\big[e^{\lambda(X_i-\mu_i)}\big] \leq \prod_i e^{\lambda^2\sigma_i^2/2} = e^{\lambda^2(\sum_i \sigma_i^2)/2}, \tag{2.16}$$

so the sum is $\sqrt{\sum_i \sigma_i^2}$-sub-Gaussian.

Scaling and means. By Fact 4, $M_{cX}(\lambda) = M_X(c\lambda)$, so substituting $c\lambda$ for λ in the definition gives $e^{c^2\lambda^2\sigma^2/2}$: cX is $|c|\sigma$-sub-Gaussian. Now take the mean of n independent σ-sub-Gaussian variables. Their sum is $\sqrt{n\sigma^2} = \sigma\sqrt{n}$-sub-Gaussian by the sum rule, and dividing by n makes the mean $(\sigma\sqrt{n}/n) = (\sigma/\sqrt{n})$-sub-Gaussian. That is where the $1/\sqrt{n}$ rate comes from.

2.5.4. Hoeffding's lemma: bounded variables are sub-Gaussian

Statement. A variable trapped in an interval $[l, u]$ cannot have a heavy tail, since it cannot go beyond u at all. The lemma makes this quantitative: its MGF is bounded as if it were normal with standard deviation half the width of the interval. If $X \in [l, u]$, then X is $\frac{u-l}{2}$-sub-Gaussian:

$$\mathbb{E}[e^{\lambda(X-\mu)}] \leq \exp\left(\lambda^2(u-l)^2/8\right). \tag{2.17}$$

Derivation. Centre X so that $\mathbb{E}[X] = 0$ (shifting X and the interval by μ changes nothing on either side). A mean-zero variable must take values on both sides of 0, so $l \le 0 \le u$. The plan is to bound $e^{\lambda X}$ by something linear in X, whose average depends only on the mean, and then show that the resulting expression has a quadratic logarithm.

1. **Use convexity.** On $[l, u]$, the convex curve $e^{\lambda x}$ lies below the straight line (the chord) joining its values at the two endpoints. That line is the weighted average of the endpoint values, with weights that say how close x is to each end:
$$e^{\lambda x} \le \frac{u-x}{u-l} e^{\lambda l} + \frac{x-l}{u-l} e^{\lambda u}. \tag{2.18}$$
2. **Take expectations.** The right side is linear in x, so its average only needs $\mathbb{E}[X] = 0$: $\mathbb{E}[e^{\lambda X}] \le \frac{u}{u-l} e^{\lambda l} - \frac{l}{u-l} e^{\lambda u}$. This is exactly the MGF of the two-point variable that sits at l or u with mean 0.
3. **Reparametrize** to make the bound a function of one variable. Let $p = -l/(u-l) \in [0, 1]$, so that $\frac{u}{u-l} = 1 - p$ and $\lambda l = -hp$, where $h = \lambda(u-l)$; then $e^{\lambda u} = e^{\lambda l} e^h$. The right side becomes $e^{-hp}(1 - p + pe^h) = e^{\varphi(h)}$, where
$$\varphi(h) = -hp + \ln\left(1 - p + pe^h\right). \tag{2.19}$$
It remains to show $\varphi(h) \le h^2/8$, by a Taylor expansion around $h = 0$.
4. **Value and slope at 0.** $\varphi(0) = 0 + \ln 1 = 0$. The derivative is $\varphi'(h) = -p + \frac{pe^h}{1-p+pe^h}$, so $\varphi'(0) = -p + p = 0$.
5. **Bound the curvature.** Write $v = \frac{pe^h}{1-p+pe^h}$, a number in $[0, 1]$, so that $\varphi'(h) = -p + v$. Differentiating again gives $\varphi''(h) = v(1-v)$. A product of two non-negative numbers that add up to 1 is largest when both are $\frac{1}{2}$, so $\varphi''(h) \le 1/4$.
6. **Taylor with remainder.** Taylor's theorem says $\varphi(h) = \varphi(0) + h\varphi'(0) + \frac{h^2}{2}\varphi''(\xi)$ for some ξ between 0 and h. With the value and slope 0 and the curvature at most $\frac{1}{4}$, $\varphi(h) \le h^2/8 = \lambda^2(u-l)^2/8$.

The worst case is a fair coin on the two endpoints, whose variance is exactly $((u-l)/2)^2$: it puts all its mass as far from the mean as the interval allows.

2.5.5. Hoeffding's inequality

The average of n bounded independent variables is sub-Gaussian with a variance proxy that shrinks like $1/n$, so its tail is Gaussian-shaped with that proxy. Concretely, combine the lemma with the rule for means: the mean of n independent variables in $[l, u]$ is $\frac{u-l}{2\sqrt{n}}$-sub-Gaussian, so $\sigma^2 = (u-l)^2/(4n)$. Putting this into the tail bound $e^{-t^2/(2\sigma^2)}$ gives

$$\Pr\left[\bar{X}_n - \mu \ge t\right] \le \exp\left(-\frac{2nt^2}{(u-l)^2}\right). \tag{2.20}$$

As a two-sided confidence interval, add the matching lower tail to get $2\exp(-2nt^2/(u-l)^2)$, set it equal to β and solve for t (Fact 5): with probability at least $1 - \beta$, $|\bar{X}_n - \mu| < (u - l)\sqrt{\ln(2/\beta)/(2n)}$.

2.5.6. Interpretation

Hoeffding needs only the range, not the variance. That is its strength, since there is nothing to estimate, and its weakness, since it assumes the worst-case variance $(u-l)^2/4$, the variance of the fair coin on the endpoints.

When the true variance σ^2 is much smaller than that, use **Bernstein's inequality**, which keeps the variance in the bound. It is proved by the same Chernoff recipe, with a sharper bound on each factor's MGF that uses the variance and the size of the largest deviation (Boucheron, Lugosi & Massart, ch. 2, give the derivation, and Section F.1 in the appendices derives it step by step). For $|X_i - \mu| \le K$:

$$\Pr\left[\bar{X}_n - \mu \ge t\right] \le \exp\left(-\frac{nt^2}{2\sigma^2 + \frac{2}{3}Kt}\right). \tag{2.21}$$

The denominator shows the two regimes. For small t the $2\sigma^2$ term dominates and the bound looks Gaussian with the true variance; for large t the $\frac{2}{3}Kt$ term dominates and the bound decays only exponentially in t. Setting the bound equal to β and solving the quadratic in t shows that its width is at most $\sqrt{2\sigma^2 \ln(1/\beta)/n} + 2K\ln(1/\beta)/(3n)$: driven by the variance for moderate deviations, and by the range only at the far end.

Figure 2.3 puts all the bounds so far side by side for the mean of 200 Bernoulli(0.1) variables. Hoeffding even loses to Chebyshev at small deviations here, because the true variance $0.1 \times 0.9 = 0.09$ is far below Hoeffding's worst case of $1/4 = 0.25$ for variables in $[0, 1]$.

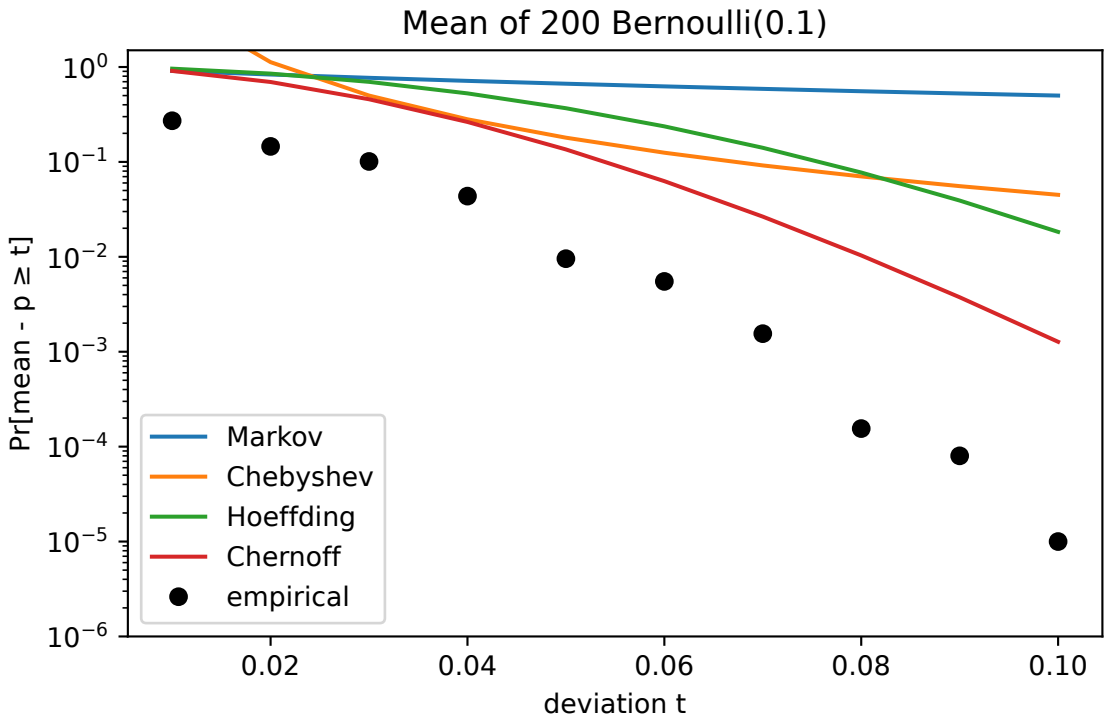

Figure 2.3.: Empirical tail of the mean of 200 Bernoulli(0.1) variables against the Markov, Chebyshev, Hoeffding and Chernoff bounds.

2.5.7. Example: generalization for a finite class

How far can a model's error on the training sample be from its error on the whole population? For one fixed model h with loss in $[0, 1]$, the **empirical risk** $\mathcal{L}(h; D)$, its average loss on a dataset D of n records drawn independently from the population $\mathcal{D}$, is a mean of n bounded terms whose expectation is the **true risk** $\mathcal{L}_{\mathcal{D}}(h)$, the average loss on the population. Two-sided Hoeffding with $u - l = 1$ gives $\Pr[|\mathcal{L}(h; D) - \mathcal{L}_{\mathcal{D}}(h)| \geq t] \leq 2e^{-2nt^2}$.

But a learner picks the model after seeing the data, so you need the bound for every model in the class at once. For a finite class H, apply the union bound (Fact 2) over its $|H|$ models: the chance that any one of them is off by t or more is at most $2|H|e^{-2nt^2}$. Setting this to β and solving for t gives $t = \sqrt{\ln(2|H|/\beta)/(2n)}$, so with probability at least $1 - \beta$,

$$|\mathcal{L}(h; D) - \mathcal{L}_{\mathcal{D}}(h)| \leq \sqrt{\frac{\ln(2|H|/\beta)}{2n}} \quad \text{for all } h \in H. \tag{2.22}$$

The size of the class enters only through $\ln |H|$, which is the $\ln k$ cost of Fact 2.

2.5.8. Example: estimating a small error rate

A classifier is tested on 1,000 negative records and makes 1 false positive. You want a 95% upper bound on its true false-positive rate, so the failure probability is $\beta = 0.05$ and $\ln(1/\beta) = \ln 20 \approx 3.0$. Three methods give very different answers.

Hoeffding, one-sided, adds the half-width $\sqrt{\ln(1/\beta)/(2n)} = \sqrt{\ln 20/2000} \approx 0.039$ to the measured rate of 1/1,000. That is about 40 times the rate you measured: the range $[0, 1]$ forces it to assume a variance of 0.25, when the true variance of a rate near 0.001 is about 0.001.

Bernstein uses that small variance. Plugging $\sigma^2 \approx 0.001$, $K = 1$ and $n = 1{,}000$ into its width gives $\sqrt{2 \times 0.001 \times 3.0/1000} + 2 \times 3.0/3000 \approx 0.0045$, almost ten times tighter. This is a heuristic: σ^2 was estimated from the same data, and a rigorous version (empirical Bernstein) is wider.

The exact answer comes from the binomial distribution itself. The **Clopper–Pearson** upper bound is the largest true rate p under which seeing 1 or fewer false positives in 1,000 trials still has probability at least 0.05; it is 0.0047.

Measuring rare rates is expensive: range-based bounds are useless near zero, and even exact intervals need many trials. This returns in later parts, wherever a small rate has to be certified empirically.

2.5.9. Check yourself

- Is a Laplace variable sub-Gaussian? *(No. Its MGF is infinite for $|\lambda| \geq 1/b$, so no quadratic bound holds for all λ. See the next section.)*
- Why is the fair coin on $\{l, u\}$ the worst case in Hoeffding's lemma? *(It maximizes the variance among variables on $[l, u]$, and step 5 is tight at $v = 1/2$.)*

2.6. Gaussian and Laplace tails

2.6.1. Context

The normal and Laplace distributions are the two standard models of additive noise, and their tails behave very differently: the normal tail decays like $e^{-t^2/2}$, the Laplace tail only like e^{-t}. This section gives sharp tail bounds for each, rules for the maximum of many draws, and the two-regime behaviour of sums of Laplace variables.

2.6.2. Gaussian tails

For the normal distribution you know the density exactly, so you can bound the tail integral directly instead of going through the MGF, and do better than Chernoff. Write $Z \sim \mathcal{N}(0,1)$ for a standard normal variable, with density $\varphi(z) = e^{-z^2/2}/\sqrt{2\pi}$. Two bounds hold for $t \geq 0$: the first is the Chernoff bound with an extra factor $\frac{1}{2}$, and the second, the **Mills ratio** bound, replaces the exponential by the density at t divided by t:

$$\Pr[Z \geq t] \leq \tfrac{1}{2} e^{-t^2/2}, \qquad \Pr[Z \geq t] \leq \frac{\varphi(t)}{t}. \tag{2.23}$$

Derivation of the first bound. The idea is to slide the tail back to start at 0 and compare it with the right half of the whole distribution, which has probability exactly $\frac{1}{2}$. Substitute $y = z - t$, so that the tail integral runs over $y \geq 0$. Expanding $(t+y)^2 = t^2 + 2ty + y^2$ splits the density into the factor $e^{-t^2/2}$, a factor e^{-ty}, and the standard normal density in y:

$$\Pr[Z \geq t] = \int_0^\infty \varphi(t+y)\,\mathrm{d}y = e^{-t^2/2} \int_0^\infty \frac{e^{-ty-y^2/2}}{\sqrt{2\pi}}\,\mathrm{d}y \leq e^{-t^2/2} \int_0^\infty \varphi(y)\,\mathrm{d}y = \tfrac{1}{2} e^{-t^2/2}. \tag{2.24}$$

The inequality drops the factor e^{-ty}, which is at most 1 for $t, y \geq 0$, and the last integral is $\frac{1}{2}$ because the normal density is symmetric around 0. This beats the Chernoff bound $e^{-t^2/2}$ of the warm-up by a factor of $\frac{1}{2}$.

Derivation of the second (Mills ratio). The idea is to multiply the density by a factor that is at least 1 on the tail and makes the integral easy. On $z \geq t$ the factor z/t is at least 1, and $z\varphi(z)$ has the simple antiderivative $-\varphi(z)$, because differentiating the density gives $\varphi'(z) = -z\varphi(z)$. So

$$\Pr[Z \geq t] = \int_t^\infty \varphi(z)\,\mathrm{d}z \leq \int_t^\infty \frac{z}{t}\varphi(z)\,\mathrm{d}z = \frac{1}{t}\big[-\varphi(z)\big]_t^\infty = \frac{\varphi(t)}{t}. \tag{2.25}$$

This bound is asymptotically exact as t grows, because the tail mass sits ever closer to t, where the factor z/t is close to 1. Figure 2.4 compares the bounds with the exact tail. At $t = 3$ the exact tail is 1.35×10^{-3}. Chebyshev gives $1/3^2 = 0.111$, Chernoff $e^{-9/2} = 0.0111$, the halved bound 0.0056, and Mills $\varphi(3)/3 = 0.00148$.

Working rules. These are the two widths you will use most for a normal variable $X \sim \mathcal{N}(0, \sigma^2)$; a normal with standard deviation σ is σZ, so every threshold scales by σ. For one draw, the first bound doubled covers both tails, $\Pr[|X| \geq t] \leq e^{-t^2/(2\sigma^2)}$, and setting this to β gives $\Pr[|X| \geq \sigma\sqrt{2\ln(1/\beta)}] \leq \beta$. For the maximum of k draws, ask each draw to fail with probability β/k and apply the union bound (Fact 2): every $|X_i| < \sigma\sqrt{2\ln(k/\beta)}$ with probability at least $1 - \beta$. Since $\ln(k/\beta) = \ln k + \ln(1/\beta)$, controlling k draws costs only a factor of about $\sqrt{\ln k}$ in the width.

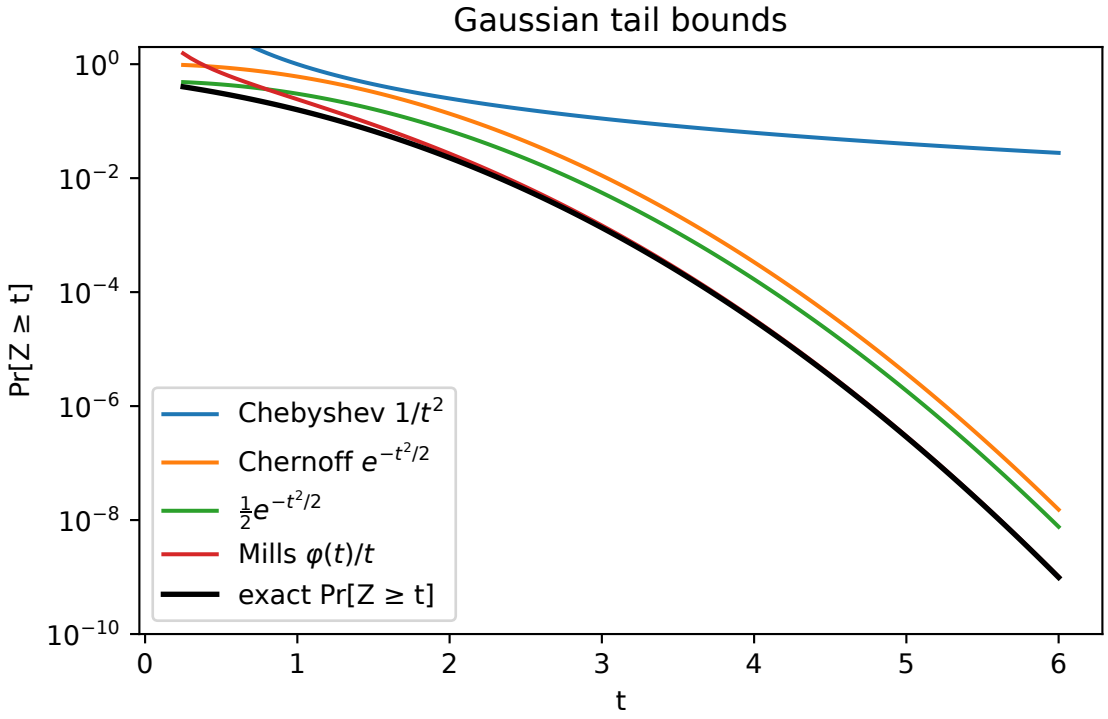

Figure 2.4.: The exact standard normal tail against the Chebyshev, Chernoff, halved Chernoff and Mills-ratio bounds.

2.6.3. Laplace tails

For the Laplace distribution the tail is exactly computable, so no bound is needed. Lap(b) has density $\frac{1}{2b}e^{-|x|/b}$, and integrating it from $t \geq 0$ to infinity gives

$$\Pr[X \geq t] = \tfrac{1}{2}e^{-t/b}, \qquad \Pr[|X| \geq t] = e^{-t/b}, \tag{2.26}$$

where the second form doubles the first because the density is symmetric.

Working rules. Setting $e^{-t/b} = \beta$ and solving gives the width for one draw: with probability at least $1-\beta$, $|X| \leq b\ln(1/\beta)$. For the maximum of k independent draws, ask each to fail with probability β/k and use the union bound: with probability at least $1-\beta$, every $|X_i| \leq b\ln(k/\beta)$.

The union bound is nearly exact here. All k independent draws stay below t with probability $(1-e^{-t/b})^k$, so $\Pr[\max_i |X_i| > t] = 1-(1-e^{-t/b})^k$, and when the per-draw tail $x = e^{-t/b}$ is small, $(1-x)^k \approx 1-kx$, so this is $\approx ke^{-t/b}$, exactly the union bound's sum. Figure 2.5 confirms it: the empirical failure rate sits at β for every k from 1 to 1,000.

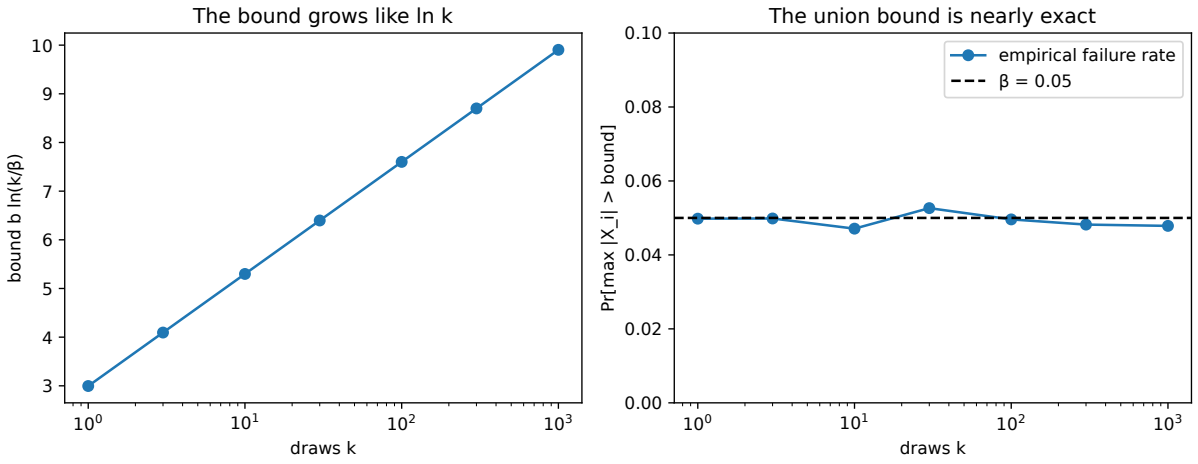

Figure 2.5.: Left: the bound $b\ln(k/\beta)$ grows like $\ln k$. Right: the empirical probability that the maximum of k Laplace draws exceeds it stays at $\beta = 0.05$.

2.6.4. Laplace is sub-exponential, not sub-Gaussian

MGF. The Laplace MGF is finite only for small λ, which rules out the sub-Gaussian definition (it must hold for every λ). Integrating $e^{\lambda x}$ against the density, the right half gives $\int_0^\infty \frac{1}{2b}e^{\lambda x - x/b}\,\mathrm{d}x = \frac{1}{2(1-\lambda b)}$, which is finite only for $\lambda < 1/b$, and the left half gives $\frac{1}{2(1+\lambda b)}$. Adding them, for $|\lambda| < 1/b$,

$$\mathbb{E}[e^{\lambda X}] = \frac{1}{1-\lambda^2 b^2} \tag{2.27}$$

(Probability distributions). It blows up as $|\lambda| \to 1/b$, so no bound of the form $e^{\lambda^2\sigma^2/2}$ can hold for all λ.

A quadratic bound near zero. For small λ, though, the log-MGF is still at most quadratic, which is all the Chernoff recipe needs as long as you only use those λ. The log-MGF is $-\ln(1-x)$

with $x = \lambda^2 b^2$, and $-\ln(1-x) = x + x^2/2 + x^3/3 + ... \le x + x^2 + \cdots = \frac{x}{1-x}$. For $0 \le x \le \frac{1}{2}$, $\frac{1}{1-x} \le 2$, so $-\ln(1-x) \le \frac{x}{1-x} \le 2x$. For $|\lambda| \le 1/(2b)$ you have $x \le \frac{1}{4}$, well inside that range, so

$$\mathbb{E}[e^{\lambda X}] \le e^{2\lambda^2 b^2}. \tag{2.28}$$

Sum of k independent Lap(b)**.** Let S be the sum of k independent Lap(b) variables. By Fact 4 the MGF of S is the product of k factors, each at most $e^{2\lambda^2 b^2}$, so $\mathbb{E}[e^{\lambda S}] \le e^{2k\lambda^2 b^2}$ for $|\lambda| \le 1/(2b)$. Run Chernoff with λ restricted to $(0, 1/(2b)]$. The result depends on whether the best λ is inside the allowed range.

1. **Find the unconstrained optimum.** The exponent to minimize is $-\lambda t + 2k\lambda^2 b^2$, a parabola whose derivative $-t + 4k\lambda b^2$ vanishes at $\lambda^* = t/(4kb^2)$.
2. **Small deviations.** $\lambda^* \le 1/(2b)$ exactly when $t \le 2kb$. Then λ^* is allowed, and substituting it gives the exponent $-t^2/(4kb^2) + t^2/(8kb^2) = -t^2/(8kb^2)$, so the bound is $\exp(-t^2/(8kb^2))$: Gaussian-like.
3. **Large deviations.** If $t > 2kb$, the best allowed λ is the boundary $\lambda = 1/(2b)$, which gives $\exp(-t/(2b) + k/2)$. In this regime $k/2 < t/(4b)$, so the exponent is at most $-t/(2b) + t/(4b) = -t/(4b)$, and the bound is at most $\exp(-t/(4b))$.

The two cases combine into one formula, because in each regime the smaller of the two expressions inside the minimum is the one that applies:

$$\Pr[S \ge t] \le \exp\left(-\min\left(\frac{t^2}{8kb^2},\ \frac{t}{4b}\right)\right). \tag{2.29}$$

Small deviations look Gaussian, with variance on the order of kb^2. Large deviations decay only exponentially. That two-regime shape is what *sub-exponential* means.

Figure 2.6 shows why the distinction matters. Take $k = 10$ and $b = 1$. The central limit theorem (CLT) says a sum of many independent terms is approximately normal with the same mean and variance, here mean 0 and variance $10 \times 2b^2 = 20$. That normal approximation matches the bulk: $\Pr[S \ge 10]$ is 1.42×10^{-2} empirically and 1.27×10^{-2} from the normal. But it badly underestimates the tail: $\Pr[S \ge 20]$ is 3.4×10^{-5} empirically and only 3.9×10^{-6} from the normal. Both deviations are in the Gaussian regime of the bound, since $t \le 2kb = 20$, so the bound gives $e^{-100/80} = 0.287$ at $t = 10$ and $e^{-400/80} = e^{-5} = 6.7 \times 10^{-3}$ at $t = 20$. The sub-exponential bound is loose, but it is valid everywhere.

2.6.5. Check yourself

- Why does the maximum of k normals grow like $\sqrt{\ln k}$ but the maximum of k Laplace draws like $\ln k$? *(Invert the tails: $e^{-t^2/2} = \beta/k$ gives $t = \sqrt{2\ln(k/\beta)}$, while $e^{-t/b} = \beta/k$ gives $t = b\ln(k/\beta)$.)*
- What does dropping the $\frac{1}{2}$ in the Gaussian tail bound cost in the width? *($\ln(1/(2\beta))$ becomes $\ln(1/\beta)$: $\ln 2 \approx 0.7$ more inside the square root.)*

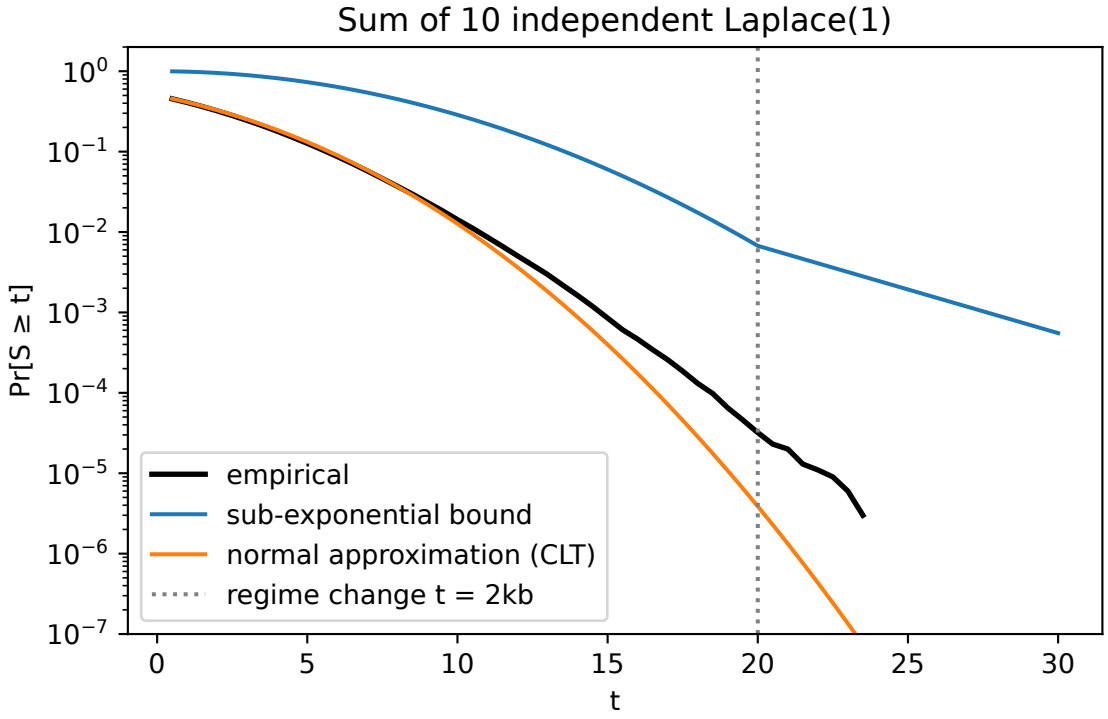

Figure 2.6.: Empirical tail of a sum of 10 Laplace(1) variables, against the sub-exponential bound and the normal approximation.

2.7. McDiarmid and Azuma

2.7.1. Context

So far, everything was a sum of independent terms. Two common situations break that. First, quantities such as a trained model's empirical risk are complicated functions of the data, not sums, so there is no MGF to factorize. Second, in sequential procedures each step can be chosen after seeing earlier outcomes, so the terms are dependent and Fact 4 no longer applies.

Azuma's inequality handles the second situation: dependent sums whose terms are "fresh" given the past, in the sense that each new term averages to zero whatever happened before. Such a running total is called a martingale. McDiarmid's inequality handles the first: it follows from Azuma by revealing the inputs of the function one at a time, and it applies to any function that no single input can move by much.

2.7.2. Azuma–Hoeffding

Setup. A **martingale** is a running total whose next step is zero on average given everything that has happened so far, like your fortune in a sequence of fair bets where you may choose each bet based on the previous ones. Formally, $W_0, W_1, \dots, W_n$ is a martingale if each increment $U_k = W_k - W_{k-1}$ has conditional mean zero given the past, $\mathbb{E}[U_k \mid \text{past}] = 0$. Assume each U_k lies in an interval $[A_k, A_k + d_k]$, where the position A_k may depend on the past but the length d_k is fixed in advance.

Statement. The total drift $W_n - W_0$ obeys the same tail bound as a sum of independent bounded terms, with the step lengths d_k playing the role of the ranges:

$$\Pr[W_n - W_0 \geq t] \leq \exp\left(-\frac{2t^2}{\sum_k d_k^2}\right). \tag{2.30}$$

Derivation. The Chernoff recipe needs the MGF of the total. Without independence it does not factorize, but you can still bound it one step at a time, starting from the last step and working back.

1. **Bound one step given the past.** Given the past, U_k is a mean-zero variable on an interval of length d_k, so Hoeffding's lemma (previous section) applies to it, with every expectation taken given the past: $\mathbb{E}[e^{\lambda U_k} \mid \text{past}] \leq e^{\lambda^2 d_k^2/8}$. The proof is the one in the previous section, run conditionally.
2. **Peel off the last increment.** The **tower property** says you can average in two stages: first average over the last step with the past held fixed, then average over the past; the result is the ordinary average. Split $W_n - W_0 = (W_{n-1} - W_0) + U_n$. With the past held fixed, $e^{\lambda(W_{n-1}-W_0)}$ is a constant and comes out of the inner average, which is then bounded by step 1:

$$\mathbb{E}\big[e^{\lambda(W_n - W_0)}\big] = \mathbb{E}\Big[e^{\lambda(W_{n-1}-W_0)}\,\mathbb{E}\big[e^{\lambda U_n} \mid \text{past}\big]\Big] \leq e^{\lambda^2 d_n^2/8}\,\mathbb{E}\big[e^{\lambda(W_{n-1}-W_0)}\big]. \tag{2.31}$$

3. **Repeat.** Apply the same step to $W_{n-1} - W_0$, then $W_{n-2} - W_0$, and so on, n times: $\mathbb{E}[e^{\lambda(W_n - W_0)}] \leq \exp(\lambda^2 \sum_k d_k^2/8)$. Peeling replaces Fact 4, which needed independence.

4. **Chernoff.** The exponent to minimize is $-\lambda t + \lambda^2 \sum_k d_k^2/8$. Its derivative vanishes at $\lambda = 4t/\sum_k d_k^2$, and substituting gives $\exp(-2t^2/\sum_k d_k^2)$.

Hoeffding is the special case of independent increments: there the past tells you nothing, and the conditional bound of step 1 is the ordinary lemma.

2.7.3. Example: an adaptive coin game

You have two coins, with heads probabilities 0.3 and 0.7. You flip 200 times; before each flip you pick the 0.7 coin if the previous flip was heads, and the 0.3 coin otherwise. The flips are dependent, and the number of heads is not binomial, so Hoeffding does not apply.

What you can control is how far the heads count drifts from what your own choices predicted. Let X_k be 1 if flip k is heads, let p_k be the bias of the coin chosen at step k, and let $W_n = \sum_{k \le n}(X_k - p_k)$: heads minus the heads you "expected" given your choices. Given the past, the coin is fixed, so $X_k - p_k$ has mean $p_k - p_k = 0$ and lies in $[-p_k, 1 - p_k]$, an interval of length 1. So W_n is a martingale with $d_k = 1$, $\sum_k d_k^2 = 200$, and Azuma gives $\Pr[W_{200} \ge t] \le e^{-2t^2/200}$. At $t = 20$ the exponent is $2 \times 400/200 = 4$ and the bound is $e^{-4} = 1.83 \times 10^{-2}$, while simulation gives 1.12×10^{-3} (Figure 2.7). The bound pays for assuming the worst-case variance, exactly as Hoeffding does: each step's true variance is $p_k(1 - p_k) = 0.21$, not the 0.25 the interval allows.

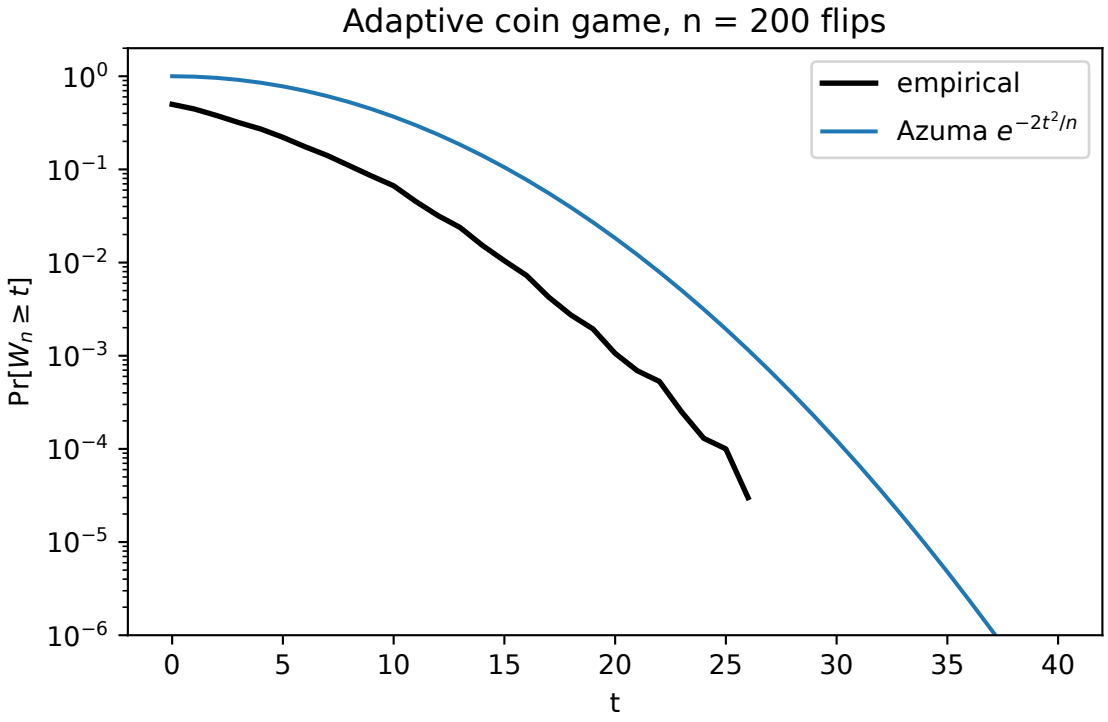

Figure 2.7.: Empirical tail of the martingale in the adaptive coin game against the Azuma bound.

2.7.4. McDiarmid (bounded differences)

Statement. If a function of many independent inputs cannot be moved much by any single input, it concentrates around its mean as tightly as a sum of bounded terms would. Let $X_1, \dots, X_n$ be independent, and suppose that changing only the i-th input, with all others held fixed, changes f by at most c_i. Then

$$\Pr\left[f(X) - \mathbb{E}f(X) \geq t\right] \leq \exp\left(-\frac{2t^2}{\sum_i c_i^2}\right). \tag{2.32}$$

Derivation via the Doob martingale. The idea is to turn f into a martingale by revealing the inputs one at a time and tracking your best guess of f as you go. Each revealed input moves the guess by a bounded amount, and Azuma does the rest.

1. **Build the martingale.** After seeing $X_1, \dots, X_k$, your best guess of $f(X)$ is its conditional average, $W_k = \mathbb{E}[f(X) \mid X_1, \dots, X_k]$. Before seeing anything, the guess is $W_0 = \mathbb{E}f$; after seeing everything, it is $W_n = f(X)$. So $W_n - W_0$ is exactly the deviation you want to bound. (W_k) is a martingale by the tower property: averaging the next guess W_k over the not-yet-seen X_k gives back the current guess W_{k-1}, so each increment has mean zero given the past.
2. **Bound the range of each increment.** By independence, the unseen inputs do not depend on the seen ones, so W_k is the average of f over fresh copies of $X_{k+1}, \dots, X_n$, with $X_1, \dots, X_k$ fixed at their observed values. Hold $X_1, \dots, X_{k-1}$ fixed. Then W_k depends only on X_k, and changing X_k changes every term of that average by at most c_k, so it changes the average by at most c_k. As X_k varies, W_k therefore stays in an interval of length at most c_k, and so does $U_k = W_k - W_{k-1}$, whose position depends on the past through W_{k-1}.
3. **Apply Azuma** with $d_k = c_k$.

Interpretation. The bounded-difference constant c_i measures how much one input can move the output: a per-record influence. Small per-record influence forces the output to concentrate. The same quantity returns in later parts under the name *sensitivity*.

Example: stability. The empirical risk of a fixed model with loss in $[0, 1]$ is an average of n losses, so changing one record changes it by at most $1/n$: $c_i = 1/n$, $\sum_i c_i^2 = n/n^2 = 1/n$, and McDiarmid gives concentration $\exp(-2nt^2)$. That is Hoeffding again, now as a special case. The real power is for functions that are not sums. Bousquet & Elisseeff apply McDiarmid to the risk of a model *trained* on the data: if retraining after changing one record moves the loss by at most γ, a stability constant, each input has bounded influence on the trained model's risk, and the generalization gap concentrates (Algorithmic stability and generalization).

2.7.5. Check yourself

- Why can't you use Hoeffding in the adaptive coin game? *(The coin chosen at each step depends on earlier flips, so the flips are not independent. Only their conditional structure is controlled.)*
- In the McDiarmid derivation, where is the independence of the X_i used? *(In step 2: the average over the unrevealed inputs must not change when X_k changes.)*

2.8. Code: check every bound by simulation

The script code/concentration.py draws every figure in this chapter and computes the numbers quoted in it. Each bound and each simulated quantity is a small typed function; the script calls them once for the table and loops them over parameters for the figures. From the repository root:

```
uv run python code/part01-prerequisites/concentration.py
```

Table 2.5 shows the output with seed 0.

Table 2.5.: Results of the chapter's script with seed 0.

Experiment	Result
Bernoulli mean, $n = 200$, $p = 0.1$, $t = 0.05$	Empirical 9.6×10^{-3}; Markov 0.67; Chebyshev 0.18; Hoeffding 0.37; Chernoff 0.135
Maximum of $k = 100$ draws of Lap(1), $\beta = 0.05$	Bound 7.60; empirical failure rate 0.0486
Standard normal tail at $t = 3$	Exact 1.35×10^{-3}; Chebyshev 0.111; Chernoff 0.0111; halved 0.0056; Mills 0.00148
Sum of $k = 10$ draws of Lap(1)	$t = 10$: empirical 1.42×10^{-2}, bound 0.287, normal 1.27×10^{-2}. $t = 20$: empirical 3.4×10^{-5}, bound 6.7×10^{-3}, normal 3.9×10^{-6}
Adaptive coin game, $n = 200$, $t = 20$	Empirical 1.12×10^{-3}; Azuma 1.83×10^{-2}

tests/test_concentration.py checks that the output still matches this table.

What to take from it

The first row shows that variance matters. The mean of 200 Bernoulli(0.1) variables has mean 0.1 and variance 0.09/200, and the question is how likely it is to reach 0.15. Markov gives $0.1/0.15 = 0.67$, Chebyshev $0.09/(200 \times 0.05^2) = 0.18$, Hoeffding $e^{-2\times 200\times 0.05^2} = e^{-1} = 0.37$, and Chernoff, with $\mu = 20$ and $r = 0.5$, $e^{-0.25\times 20/2.5} = e^{-2} = 0.135$. Hoeffding loses to Chebyshev because $p(1-p) = 0.09$ is far below the worst case 0.25: range-based bounds pay for ignoring the variance.

The second row shows that a union bound can be nearly exact. The bound $\ln(100/0.05) = 7.60$ fails at the empirical rate 0.0486, close to the target 0.05, because for independent draws with small individual tails the chance that any one fails is almost the sum of the individual chances.

The third row shows that the Mills ratio is the bound to use far out. At $t = 3$ it is within 10% of the exact tail, while the Chernoff bound is 8 times too large.

The fourth row shows that the CLT is not a tail bound. For the Laplace sum it underestimates $\Pr[S \geq 20]$ by a factor of 9, since 3.4×10^{-5} is about nine times 3.9×10^{-6}. When the answer must be a guarantee, use a bound.

The last row shows that Azuma handles adaptivity, at the price of the worst-case variance.

2.10. Cheat sheet

Table 2.6 collects the bounds. Tails are one-sided unless noted, and β is the failure probability.

Table 2.6.: Summary of the bounds in this chapter.

Bound	Assumption	Tail $\Pr[X-\mu \geq t] \leq$	Width at failure probability β
Markov	$X \geq 0$	μ/t (for $\Pr[X \geq t]$)	μ/β
Chebyshev	Variance σ^2	σ^2/t^2 (two-sided)	$\sigma/\sqrt{\beta}$
Sub-Gaussian	MGF $\leq e^{\lambda^2\sigma^2/2}$	$e^{-t^2/(2\sigma^2)}$	$\sigma\sqrt{2\ln(1/\beta)}$
Hoeffding	Mean of n independent variables in $[l,u]$	$e^{-2nt^2/(u-l)^2}$	$(u-l)\sqrt{\ln(1/\beta)/(2n)}$
Chernoff (multiplicative)	Sum of independent Bernoullis, mean μ	$e^{-r^2\mu/(2+r)}$ at $t=r\mu$	$\approx \sqrt{2\mu\ln(1/\beta)}$ for small r
Gaussian $\mathcal{N}(0,\sigma^2)$	—	$\frac{1}{2}e^{-t^2/(2\sigma^2)}$	$\sigma\sqrt{2\ln(1/\beta)}$, two-sided
Laplace Lap(b)	—	$\frac{1}{2}e^{-t/b}$; two-sided exactly $e^{-t/b}$	$b\ln(1/\beta)$, two-sided
McDiarmid	Independent inputs, bounded differences c_i	$e^{-2t^2/\sum_i c_i^2}$	$\sqrt{\sum_i c_i^2 \ln(1/\beta)/2}$
Azuma–Hoeffding	Martingale, increments in intervals of length d_i	$e^{-2t^2/\sum_i d_i^2}$	$\sqrt{\sum_i d_i^2 \ln(1/\beta)/2}$
Sum of k Laplace	Independent Lap(b)	$e^{-\min(t^2/(8kb^2),\ t/(4b))}$	$b\sqrt{8k\ln(1/\beta)}$ while that is $\leq 2kb$; else $4b\ln(1/\beta)$

Rules of thumb

- Variance-only bounds cost $1/\sqrt{\beta}$; exponential bounds cost $\sqrt{\ln(1/\beta)}$; heavy (sub-exponential) tails cost $\ln(1/\beta)$.
- k estimates add $\ln k$ inside the logarithm, via the union bound.
- If the variance is much smaller than the range allows, use Chernoff or Bernstein, not Hoeffding.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

3. Divergences

3.1. Why this matters

Someone hands you a die. It is either fair, or loaded so that a six comes up half the time. You may roll it as often as you like. Three questions come up at once:

- **On average,** how much does one roll tell you about which die you hold?
- **In the worst case,** how strongly can a single roll point the wrong way?
- **With one roll,** how often can the best possible guess be right?

Each question has its own answer, and each answer is a **divergence**: a number that is zero when two distributions P and Q are equal and grows as they become easier to tell apart. The same questions come up all over machine learning. When you fit a model q_θ to data from p, you need to know how far the fit is from the truth. When you run an A/B test or watch a feature drift in production, you need to know how many samples it takes to see the change. When you perturb the data a little, you need to know how much any downstream statistic can move. Later parts ask the same questions about the outputs of an algorithm run on two different inputs.

A divergence is not a distance in general. Asking "how fast do rolls of the loaded die expose it?" is a different question from "how fast do rolls of the fair die clear it?", so a divergence can be asymmetric, giving P against Q a different value from Q against P, and it can fail the triangle inequality.

3.1.1. The one idea: the likelihood ratio

You see an outcome x and want to know which distribution it came from. The natural thing to compare is how likely x is under each one. Their quotient, the **likelihood ratio**

$$r(x) = \frac{p(x)}{q(x)}, \tag{3.1}$$

says how many times more likely x is under P than under Q. Its logarithm, $\ln r(x)$, is the **evidence** that x gives for P: positive when x favours P, negative when it favours Q, zero when x says nothing. The logarithm is used because evidence from independent observations should add up, and logarithms turn the product of their ratios into a sum. Natural logarithms measure evidence in units called **nats**. Table 3.1 shows the ratio and the evidence for the die, with P the loaded die and Q the fair one.

Table 3.1.: The loaded die P against the fair die Q, outcome by outcome. This is the running example of the chapter.

Roll x	1	2	3	4	5	6
$p(x)$ (loaded)	0.1	0.1	0.1	0.1	0.1	0.5
$q(x)$ (fair)	1/6	1/6	1/6	1/6	1/6	1/6
$r(x) = p(x)/q(x)$	0.6	0.6	0.6	0.6	0.6	3
$\ln r(x)$	-0.511	-0.511	-0.511	-0.511	-0.511	1.099

A six is three times more likely under the loaded die ($0.5/\frac{1}{6} = 3$). It is fairly strong evidence for "loaded", $\ln 3 = 1.10$ nats. Any other roll is $0.1/\frac{1}{6} = 0.6$ times as likely under the loaded die, weak evidence for "fair", $\ln 0.6 = -0.51$ nats. For continuous pairs, $r(x)$ is a curve. Figure 1.7 in Probability distributions draws $\ln r$, written $L(x)$ there, for a normal density and for a Laplace density, each against a copy of itself shifted sideways. The normal's log-ratio is a straight line that grows without bound. The Laplace's is flat beyond a point, so it never exceeds a fixed value. That difference comes back in every section of this chapter.

Every divergence in this chapter is a summary of the likelihood ratio. The divergences differ only in which summary they take, and each summary answers one question (Table 3.2). In the table, $\mathbb{E}_P$ means an average over outcomes drawn from P, $\mathbb{E}_Q$ an average over outcomes drawn from Q, and $(y)_+ = \max(y, 0)$ keeps only the positive part of a number.

Table 3.2.: Each divergence answers one question, by summarizing the likelihood ratio $r = p/q$ in its own way.

Question	Divergence	Summary of r
How much evidence does one observation give, on average?	Kullback–Leibler (KL)	$\mathbb{E}_P[\ln r]$, the average evidence
The same, but counting rare large ratios more	Rényi of order α	the log of a power mean of r, from typical ($\alpha \to 1$) to largest ($\alpha \to \infty$)
How strong is the strongest evidence any outcome can give?	Max-divergence	$\ln \max r$
How often is the best single guess right?	Total variation (TV)	$\mathbb{E}_Q[(r-1)_+]$, the mass where P beats Q
The same, when one answer must be γ times more convincing	Hockey-stick E_γ	$\mathbb{E}_Q[(r-\gamma)_+]$, the mass where P beats γQ
All of the above at once	f-divergences	$\mathbb{E}_Q[f(r)]$ for a convex f

Because every divergence is a function of r, there is one rule they all obey. Processing the data, by binning it, computing a feature or adding noise, can only average likelihood ratios together. It can never sharpen them, so no divergence can grow. That is the **data-processing inequality**.

Table 3.3 lists the results of the chapter and where each is used.

Table 3.3.: The results of this chapter and where each is used.

Result	Where it is used
KL, Gibbs' inequality	Maximum likelihood, variational inference, the cost of a wrong model
Additivity over independent samples	Sample sizes for telling two distributions apart
Rényi divergence, its limits and monotonicity	Tail bounds on the evidence; a single family from average case to worst case
Max-divergence	The worst-case ratio of probabilities of any event
Total variation	Best single-shot test; how much any bounded statistic can change
Hockey-stick E_γ	Tests with unequal priors or costs; rejection sampling with a low envelope
f-divergences	One definition and one proof for every divergence above
Data-processing inequality	Coarse-graining, features and summaries never increase a divergence
Pinsker, Bretagnolle–Huber	Turning an easy KL calculation into a bound on TV

How to read this chapter. On a first pass, read the KL, Rényi, total variation, data-processing and Pinsker sections, and in each one read the context, statement, interpretation and example before the derivation. The Gaussian and Laplace sections are worked examples; do the Gaussian one by hand. Two derivations are there for completeness and can wait for a second pass: the Laplace Rényi integral and the hockey-stick representation of f-divergences (Equation 3.27).

The distributions used here (normal, Laplace) and the comparison of a density with its shifted copy are in Probability distributions. The Chernoff method and the log of the moment generating function (MGF) are in Concentration inequalities. Where this chapter uses a fact from those pages, it restates it.

Conventions. P and Q have probability mass functions or densities p and q. We write sums $\sum_x$; for densities, read them as integrals. Logarithms are natural, so divergences are in nats. We use $0 \ln 0 = 0$. When P puts mass where Q puts none, $r = \infty$ there and most divergences below are infinite.

3.2. Toolkit: three facts every derivation uses

Each section below follows the same arc: the question the divergence answers, its definition and properties, derivations, an interpretation, an example, and a self-check. The derivations reuse three facts. Skim them now and come back when a derivation cites one.

3.2.1. Fact 1 — Change of measure: $\mathbb{E}_P[g] = \mathbb{E}_Q[r\,g]$

Some divergences are averages over outcomes drawn from P, others over outcomes drawn from Q. This fact lets you switch between the two. The idea: an outcome that is three times as likely under P as under Q should count three times as much when you average under Q but want the answer that P would give. Multiplying each term by $r(x) = p(x)/q(x)$ does exactly that reweighting. For any function g, as long as Q gives positive probability to every outcome that P does,

$$\mathbb{E}_P[g(X)] = \sum_x p(x)g(x) = \sum_x q(x)\frac{p(x)}{q(x)}g(x) = \mathbb{E}_Q[r(X)\,g(X)]. \tag{3.2}$$

The middle step only multiplies and divides by $q(x)$.

Two special cases come up again and again. With $g = 1$ the left side is 1, so $\mathbb{E}_Q[r] = 1$: the likelihood ratio always averages to 1 under Q. On the die, $\frac{1}{6}(5 \times 0.6 + 3) = 1$. In words, if the data really come from Q, the outcomes that favour P are rare enough to balance how strongly they favour it. With $g = \mathbf{1}[A]$, the indicator that is 1 on an event A and 0 elsewhere, the fact reads $\Pr_P[A] = \mathbb{E}_Q[r\,\mathbf{1}[A]]$. For the event "roll is 6" this gives $\frac{1}{6} \times 3 = 0.5$, the loaded die's probability of a six.

3.2.2. Fact 2 — Jensen's inequality

A function φ is **convex** when its graph bends upward, like a bowl, so that every chord lies above the graph. For such a function, averaging first and then applying φ gives less than applying φ first and then averaging:

$$\varphi(\mathbb{E}X) \le \mathbb{E}\varphi(X). \tag{3.3}$$

If φ is strictly convex (no straight pieces), equality holds only when X is constant.

The reason is that a convex function lies above each of its tangent lines. Let $m = \mathbb{E}X$ and take the tangent at m: $\varphi(x) \ge \varphi(m) + c(x - m)$ for every x, where c is the slope there. Average both sides over X. The term $c(X - m)$ averages to 0, because X averages to m, which leaves $\mathbb{E}\varphi(X) \ge \varphi(m)$. If φ is strictly convex, the tangent touches the graph only at m, so equality forces $X = m$ with probability 1.

A small case shows the gap. Let X be 0.6 or 3 with probability $\frac{1}{2}$ each, the die's two likelihood ratios, and $\varphi(x) = x^2$. Then $\varphi(\mathbb{E}X) = 1.8^2 = 3.24$, while $\mathbb{E}\varphi(X) = \frac{1}{2}(0.36 + 9) = 4.68$. Jensen is what makes every divergence non-negative, what orders the Rényi divergences by their order, and what drives the data-processing inequality.

3.2.3. Fact 3 — The best event is $\{r > \gamma\}$

Several divergences ask for the event A that makes $\Pr_P[A] - \gamma \Pr_Q[A]$ as large as possible, for some weight $\gamma \ge 0$. The answer is to collect every outcome where p beats γq and nothing else. Writing $(y)_+ = \max(y, 0)$,

$$\max_A \big[\Pr_P[A] - \gamma \Pr_Q[A]\big] = \sum_x \big(p(x) - \gamma q(x)\big)_+, \tag{3.4}$$

attained at $A^* = \{x : p(x) > \gamma q(x)\} = \{r > \gamma\}$.

The reason is that the quantity is a sum over the outcomes in A: $\Pr_P[A] - \gamma \Pr_Q[A] = \sum_{x \in A} (p(x) - \gamma q(x))$. An outcome adds a positive term exactly when $p(x) > \gamma q(x)$, and a negative or zero term otherwise. So the sum is largest when A contains all the outcomes with positive terms and none of the others, and its value is then the sum of the positive parts.

Randomized choices do no better. Instead of a set, you could include each outcome with some probability $\phi(x) \in [0, 1]$, and get $\sum_x \phi(x)(p(x) - \gamma q(x))$. Each term is a number between 0 and the bracket, so the sum is largest when $\phi(x) = 1$ where the bracket is positive and $\phi(x) = 0$ elsewhere: that is the indicator of A^* again.

On the die with $\gamma = 1$, only the six has $p > q$, so $A^* = \{6\}$ and the maximum is $0.5 - \frac{1}{6} = \frac{1}{3}$. This fact gives the total variation, the hockey-stick divergence and Pinsker's inequality.

3.3. KL divergence

3.3.1. Context

Roll the die n times and add up the evidence from each roll: $\sum_{i=1}^{n} \ln r(x_i)$. If the die is loaded, sixes come up often and the sum climbs. If it is fair, the many small negative terms win and the sum falls. Figure 3.1 shows eight runs of each. The runs are noisy, but each family drifts along a straight line. The slope of that line, the average evidence per roll, is the **KL divergence**. It is the speed at which data from P convince you that they are not from Q.

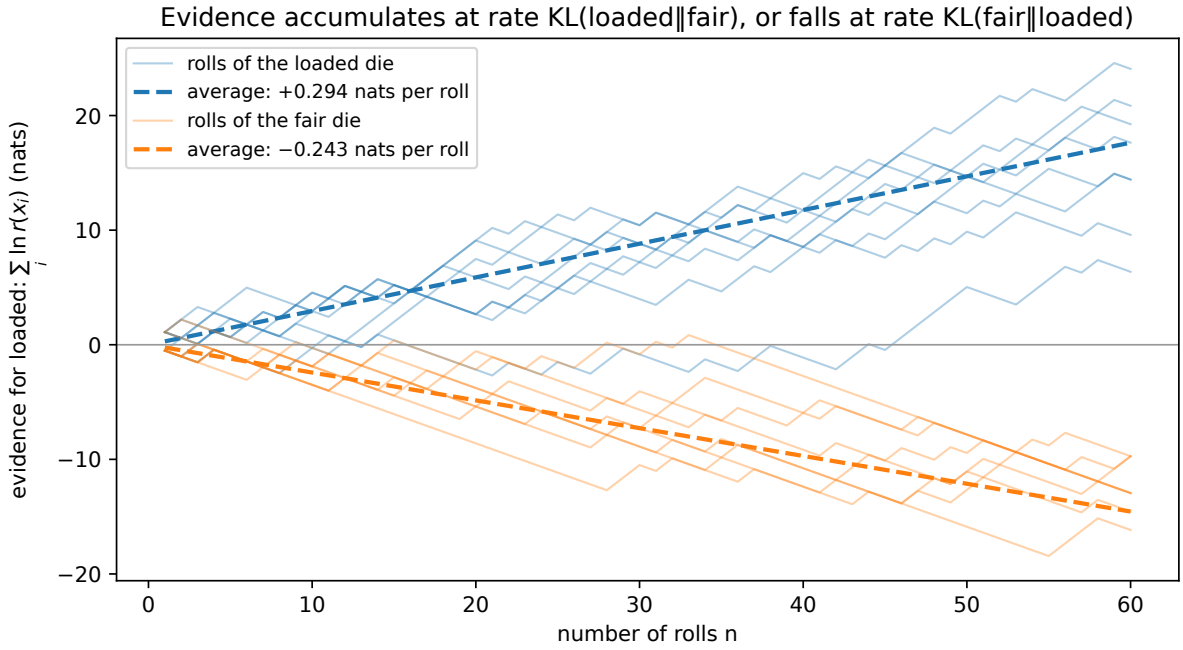

Figure 3.1.: Cumulative evidence for "loaded", $\sum_i \ln r(x_i)$, over 60 rolls. Blue: eight runs with the loaded die, drifting up at $D_{\mathrm{KL}}(P\|Q) = 0.294$ nats per roll. Orange: eight runs with the fair die, drifting down at $D_{\mathrm{KL}}(Q\|P) = 0.243$ nats per roll. Dashed lines are the averages.

The same number measures a model's fit. If the data come from p and you model them with q_θ, then $\ln \frac{p(x)}{q_\theta(x)}$ is the evidence that x gives for the truth over the model. KL is its average: how much worse the model explains the data than the truth does. Minimizing it over θ is maximum likelihood.

3.3.2. Statement

The KL divergence is the average evidence for P that one observation gives, when the observation really comes from P:

$$D_{\mathrm{KL}}(P\|Q) = \mathbb{E}_P\left[\ln \frac{p(X)}{q(X)}\right] = \sum_x p(x) \ln \frac{p(x)}{q(x)}. \tag{3.5}$$

Write $L(x) = \ln r(x)$ for the **log-likelihood ratio**, the evidence of a single outcome. Then $D_{\mathrm{KL}}(P\|Q) = \mathbb{E}_P[L]$. It has three properties, each proved in the derivation.

1. **Gibbs' inequality:** $D_{\mathrm{KL}}(P\|Q) \geq 0$, with equality only if $P = Q$. Data from P never favour Q on average.
2. **Not symmetric:** in general $D_{\mathrm{KL}}(P\|Q) \neq D_{\mathrm{KL}}(Q\|P)$, because the two directions average different evidence over different data.
3. **Additive over independent coordinates:** evidence from independent observations adds up, so their divergences add too,

$$D_{\mathrm{KL}}(P_1 \times P_2 \,\|\, Q_1 \times Q_2) = D_{\mathrm{KL}}(P_1\|Q_1) + D_{\mathrm{KL}}(P_2\|Q_2). \tag{3.6}$$

   Here $P_1 \times P_2$ is the distribution of a pair drawn independently from P_1 and P_2. In particular, n i.i.d. samples carry n times the KL divergence of one. That is the straight line in Figure 3.1.

3.3.3. Derivation

Gibbs' inequality. The claim is that data from P cannot, on average, favour Q. The proof turns KL into an average of a convex function and applies Jensen.

1. **Flip the ratio.** $\ln \frac{p}{q} = -\ln \frac{q}{p}$, so $D_{\mathrm{KL}}(P\|Q) = \mathbb{E}_P[-\ln \frac{q(X)}{p(X)}]$. The function $-\ln$ is strictly convex: its graph bends upward.
2. **Apply Jensen (Fact 2)**, which says that for a convex function the average of the function is at least the function of the average: $\mathbb{E}_P[-\ln \frac{q}{p}] \geq -\ln \mathbb{E}_P[\frac{q}{p}]$.
3. **Compute the inner average.** $\mathbb{E}_P[q/p] = \sum_{x:p(x)>0} p(x)\frac{q(x)}{p(x)} = \sum_{x:p(x)>0} q(x)$. This is Q's mass on the outcomes P can produce, which is at most 1. The logarithm of a number at most 1 is at most 0, so $-\ln$ of it is ≥ 0.
4. **When is it zero?** Equality needs equality in step 2, which for a strictly convex function means q/p is constant on the outcomes P can produce. It also needs equality in step 3, so Q has no mass outside those outcomes. A constant ratio between two distributions that both sum to 1 on the same outcomes must be 1, so $p = q$.

Additivity. Evidence from independent observations adds up, so its average does too.

1. **Densities multiply.** Under a product distribution the probability of a pair is the product of the probabilities, $p_1(x_1)p_2(x_2)$ under P and $q_1(x_1)q_2(x_2)$ under Q.
2. **So the log-likelihood ratio is a sum.** The ratio of products is the product of ratios, and the logarithm of a product is a sum: $L(x_1, x_2) = L_1(x_1) + L_2(x_2)$.
3. **Average.** Expectations are linear, and the P-average of $L_i(X_i)$ depends only on the distribution P_i of that coordinate, so it equals $D_{\mathrm{KL}}(P_i \| Q_i)$. Adding the two gives Equation 3.6.

Maximum likelihood minimizes KL. Split the logarithm of the ratio into the log of the truth minus the log of the model. Only the second part depends on the model's parameter θ:

$$D_{\mathrm{KL}}(P\|Q_\theta) = \underbrace{\mathbb{E}_P[\ln p(X)]}_{\text{does not depend on } \theta} - \mathbb{E}_P[\ln q_\theta(X)]. \tag{3.7}$$

So minimizing KL over θ is the same as maximizing the expected log-likelihood $\mathbb{E}_P[\ln q_\theta(X)]$. You cannot compute that expectation, because you do not know p, but its sample version $\frac{1}{n}\sum_i \ln q_\theta(x_i)$ is the average log-likelihood that maximum likelihood maximizes.

3.3.4. Interpretation

Signal against noise. After n rolls of the loaded die, the total evidence is a sum of n independent per-roll terms, so its mean is n times the per-roll mean and its variance is n times the per-roll variance. That gives a mean of $0.2939\,n$ (the drift) and a standard deviation of $0.8047\sqrt{n}$ (the spread of $\ln r$ is 0.8047 per roll, from the script). The drift grows like n and the noise like $\sqrt{n}$, so the drift overtakes the noise once $0.2939\,n > 0.8047\sqrt{n}$, that is once $n > (0.8047/0.2939)^2 = 7.50$ rolls. The same argument with any pair says that the number of observations you need scales like $1/D_{\mathrm{KL}}(P\|Q)$. The total variation and Pinsker sections make this precise.

Which direction you minimize matters. KL is an average under its *first* argument, so the two directions punish different mistakes. There are two options when you fit a model q_θ to a target p:

- $D_{\mathrm{KL}}(P\|Q_\theta)$ **(forward, maximum likelihood)** averages over the data. Where $p > 0$ but $q_\theta \approx 0$, the term $\ln(p/q_\theta)$ explodes. The model is forced to cover every region the data visits. It is **mass-covering**.
- $D_{\mathrm{KL}}(Q_\theta\|P)$ **(reverse)** averages over the model. Regions the model ignores cost nothing, but putting model mass where $p \approx 0$ is heavily punished. It is **mode-seeking**. Variational inference minimizes this direction, because it only needs samples and densities from the model q_θ, and p only up to a constant.

Figure 3.2 shows both fits of a single Gaussian $\mathcal{N}(\mu, \sigma^2)$ to data from two bumps, $p = \frac{1}{2}\mathcal{N}(-2, 0.5^2) + \frac{1}{2}\mathcal{N}(2, 0.5^2)$.

The forward fit has a closed form. For a Gaussian q, the negative log-density is $\ln\sigma + \frac{1}{2}\ln(2\pi) + \frac{(x-\mu)^2}{2\sigma^2}$, so its average under p is $-\mathbb{E}_p[\ln q(X)] = \ln\sigma + \frac{1}{2}\ln(2\pi) + \frac{\mathbb{E}_p(X-\mu)^2}{2\sigma^2}$. Setting its derivative in μ to zero makes μ the mean of p, $\mathbb{E}_p X = 0$, since the bumps sit symmetrically at ± 2. Setting its derivative in σ to zero makes σ^2 the variance of p. That variance has two parts: the bump centres are 2 away from the mean, which contributes 2^2, and each bump has its own spread 0.5^2. So $\sigma^2 = \mathrm{Var}_p\, X = 2^2 + 0.5^2$, and $\sigma = 2.06$. This is **moment matching**: the forward fit copies

the mean and variance of the data. The result is a wide bump that puts most of its mass in the valley between the modes, where there is no data.

The reverse fit has no closed form, and a grid search finds $\mu = 2.00$, $\sigma = 0.50$: the fit sits exactly on one bump and ignores the other. Its reverse KL is $0.693 = \ln 2$. The reason is that on that bump, p is the bump's own density times its weight $\frac{1}{2}$, while the model is that density with weight 1. So $q/p \approx 2$ everywhere the model puts mass, and the average of $\ln(q/p)$ under q is about $\ln 2$.

Each fit is bad in the other's direction. The forward fit has forward KL 0.724 but reverse KL 2.097. The reverse fit has reverse KL 0.693 but forward KL 15.307, because it gives almost no probability to the left bump, where half the data lie.

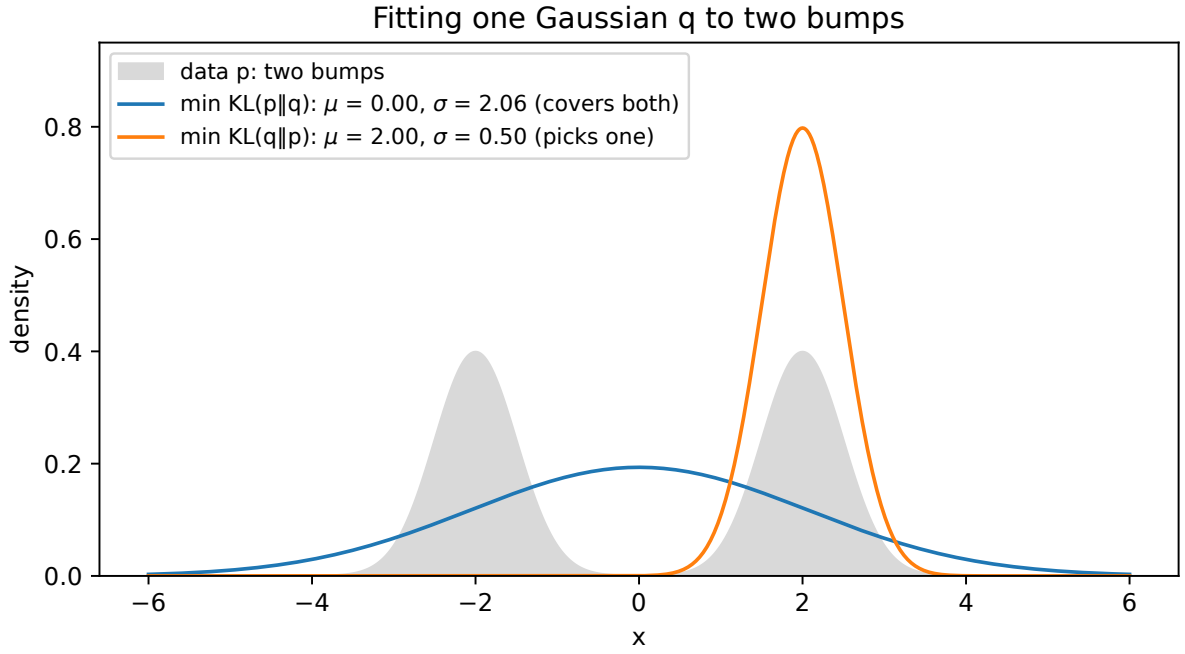

Figure 3.2.: Fitting one Gaussian to a two-bump density p. Minimizing $D_{\mathrm{KL}}(p\|q)$ matches the mean and variance and covers both bumps; minimizing $D_{\mathrm{KL}}(q\|p)$ locks onto one bump.

3.3.5. Example: the loaded die

Use Table 3.1. Under P, each of the five non-sixes has probability 0.1 and evidence $\ln 0.6$, and the six has probability 0.5 and evidence $\ln 3$. The five non-sixes together have probability $5 \times 0.1 = 0.5$, the same as the six, so both terms carry weight 0.5 and the logarithms combine:

$$D_{\mathrm{KL}}(P\|Q) = 5 \times 0.1 \ln 0.6 + 0.5 \ln 3 = 0.5 \ln(0.6 \times 3) = 0.5 \ln 1.8 = 0.2939. \tag{3.8}$$

In the other direction the average is under the fair die, which gives the non-sixes total weight $\frac{5}{6}$ and the six weight $\frac{1}{6}$, and the evidence is now for "fair", $\ln(q/p)$:

$$D_{\mathrm{KL}}(Q\|P) = \tfrac{5}{6} \ln \tfrac{1}{0.6} + \tfrac{1}{6} \ln \tfrac{1}{3} = 0.4257 - 0.1831 = 0.2426. \tag{3.9}$$

The two directions differ. Rolls of the loaded die produce sixes, where the evidence for "loaded" is strong ($\ln 3 = 1.10$ nats). Rolls of the fair die produce mostly non-sixes, where the evidence for "fair" is weaker ($\ln(1/0.6) = 0.51$ nats). So a loaded die gives itself away faster than a fair one proves its innocence. By additivity, 20 rolls of the loaded die give an expected $20 \times 0.2939 = 5.88$ nats of evidence for "loaded". Turning nats back into a likelihood ratio means exponentiating, which gives $e^{20 \times 0.5 \ln 1.8} = 1.8^{10} = 357$.

3.3.6. Check yourself

- If $q(x) = 0$ at a point where $p(x) > 0$, what is $D_{\mathrm{KL}}(P\|Q)$, and what does that mean for maximum likelihood? *(It is infinite. A model that gives zero probability to an observed outcome has log-likelihood $-\infty$, which is why practical models keep every probability positive.)*
- Why is the forward-KL fit to the two bumps centred at 0, where p is almost zero? *(The forward KL only rewards matching the mean and variance of p. Having mass where $p \approx 0$ costs nothing in that direction.)*

3.4. Rényi divergence

3.4.1. Context

KL is the average of $\ln r$ under P. Exponentiating an average of logarithms gives a **geometric mean**, so $e^{D_{\mathrm{KL}}}$ is the geometric mean of the likelihood ratio. Nothing forces you to use the geometric mean. Other means of the same numbers weight large values more, or less. All the usual ones belong to one family, the **power mean** with exponent s, $m_s = \left(\mathbb{E}_P[r^s]\right)^{1/s}$: raise each value to the power s, average, and undo the power. The harmonic mean is $s = -1$, the arithmetic mean is $s = 1$, the geometric mean is the limit $s \to 0$, and $s \to \infty$ picks out the largest value. On the die, under P the ratio is 0.6 or 3, each with probability $\frac{1}{2}$ (Table 3.1). Its means are in Table 3.4.

Table 3.4.: Different means of the die's likelihood ratio under P. Their logarithms are the Rényi divergences of orders 0, 1, 2 and ∞.

Mean of r under P	Value	Its logarithm	Divergence
Harmonic, $1/\mathbb{E}_P[1/r]$	1.0000	0	D_0
Geometric, $e^{\mathbb{E}_P[\ln r]}$	1.3416	0.2939	$D_1 = D_{\mathrm{KL}}$
Arithmetic, $\mathbb{E}_P[r]$	1.8000	0.5878	D_2
Largest value, $\max r$	3.0000	1.0986	D_∞

The **Rényi divergence of order** α is the logarithm of one of these means, the power mean with exponent $s = \alpha - 1$. The order is a dial. Near $\alpha = 1$ you get the typical evidence (KL). As α grows, the mean is pulled toward the largest ratio, and you get the worst case. The family keeps KL's best property, additivity over independent samples. It also controls how often the evidence can be large, which KL alone cannot tell you.

3.4.2. Statement

Written out, the log of the power mean with exponent $\alpha - 1$ is the log of $\mathbb{E}_P[r^{\alpha-1}]$ divided by $\alpha - 1$. Because averaging under P is averaging under Q with an extra factor r (Fact 1), the same number can be written as an average under Q or as a plain sum. For $\alpha \in (0,1) \cup (1,\infty)$,

$$D_\alpha(P\|Q) = \frac{1}{\alpha-1} \ln \sum_x p(x)^\alpha q(x)^{1-\alpha} = \frac{1}{\alpha-1} \ln \mathbb{E}_Q\big[r^\alpha\big] = \frac{1}{\alpha-1} \ln \mathbb{E}_P\big[r^{\alpha-1}\big]. \tag{3.10}$$

Two equivalent forms do most of the work. The first is the power-mean form of the context. With $m_s = \left(\mathbb{E}_P[r^s]\right)^{1/s}$ and, for $s = 0$, the geometric mean $m_0 = e^{\mathbb{E}_P[\ln r]}$,

$$D_\alpha(P\|Q) = \ln m_{\alpha-1}. \tag{3.11}$$

The second connects Rényi divergence to the Chernoff method of Concentration inequalities. The **moment generating function** of a random variable Y is $\lambda \mapsto \mathbb{E}[e^{\lambda Y}]$, and its logarithm is the quantity the Chernoff method optimizes to bound tails. Apply it to the evidence $L = \ln r$ under P, and call the result $\psi(\lambda) = \ln \mathbb{E}_P[e^{\lambda L}]$. Since $e^{\lambda L} = r^\lambda$, $\psi(\alpha - 1)$ is exactly the logarithm inside the definition, so

$$D_\alpha(P\|Q) = \frac{\psi(\alpha-1)}{\alpha-1}. \tag{3.12}$$

The family has five properties, each derived below.

1. **Limit $\alpha \to 1$:** $D_\alpha \to D_{\mathrm{KL}}$, because the power mean tends to the geometric mean. So we set $D_1 = D_{\mathrm{KL}}$.
2. **Limit $\alpha \to \infty$:** a power mean with a huge exponent is dominated by the largest value, so $D_\alpha \to D_\infty(P\|Q) = \ln \max_x r(x)$, the **max-divergence**. (For densities, the maximum is an essential supremum: the largest value that r exceeds with positive probability.) The same number is the largest ratio of probabilities that P and Q give to any event:

$$D_\infty(P\|Q) = \ln \max_{A:\, \Pr_Q[A]>0} \frac{P(A)}{Q(A)}. \tag{3.13}$$

3. **Monotone:** D_α is non-decreasing in α, because power means grow with their exponent.
4. **Additive over independent coordinates:** $D_\alpha(P_1 \times P_2 \| Q_1 \times Q_2) = D_\alpha(P_1\|Q_1) + D_\alpha(P_2\|Q_2)$ for every α, as for KL.
5. **Skew symmetry:** for $0 < \alpha < 1$, $D_\alpha(P\|Q) = \frac{\alpha}{1-\alpha} D_{1-\alpha}(Q\|P)$. In particular $D_{1/2}$ is symmetric, since then $\frac{\alpha}{1-\alpha} = 1$.

Table 3.5 lists the orders that have names of their own.

Table 3.5.: Rényi divergences of special orders.

Order	$D_\alpha(P\|Q)$	What it measures
$\alpha \to 0$	$-\ln \Pr_Q[p(X) > 0]$	Only whether Q puts mass outside the support of P
$\alpha = \frac{1}{2}$	$-2 \ln \sum_x \sqrt{p(x)q(x)}$	Symmetric; the sum is the Bhattacharyya coefficient, the overlap of $\sqrt{p}$ and $\sqrt{q}$

Order	$D_\alpha(P\|Q)$	What it measures
$\alpha = 1$	$\mathbb{E}_P[\ln r]$	KL: the average evidence
$\alpha = 2$	$\ln \mathbb{E}_Q[r^2] = \ln\left(1 + \chi^2(P\|Q)\right)$	The second moment of r, with $\chi^2 = \mathbb{E}_Q[(r-1)^2]$
$\alpha \to \infty$	$\ln \max r$	The worst case

3.4.3. Derivation

The forms agree. Fact 1 says an average under Q of r times something equals the average under P of that something. With "something" $= r^{\alpha-1}$, $\mathbb{E}_Q[r^\alpha] = \mathbb{E}_Q[r \cdot r^{\alpha-1}] = \mathbb{E}_P[r^{\alpha-1}]$, and writing either average as a sum gives $\sum_x p^\alpha q^{1-\alpha}$. Dividing $\ln \mathbb{E}_P[r^{\alpha-1}]$ by $\alpha - 1$ is the same as taking the logarithm of $\left(\mathbb{E}_P[r^{\alpha-1}]\right)^{1/(\alpha-1)} = m_{\alpha-1}$, which gives Equation 3.11. And $r^{\alpha-1} = e^{(\alpha-1)L}$, so $\ln \mathbb{E}_P[r^{\alpha-1}] = \psi(\alpha-1)$, which gives Equation 3.12.

Monotonicity is the power-mean inequality. A larger exponent leans harder on the large values, so power means grow with their exponent: $m_{s_1} \le m_{s_2}$ for $s_1 < s_2$. Each case is one use of Jensen (Fact 2): a convex function of an average is at most the average of the function, and for a concave function (one that bends downward) the inequality is reversed.

1. *Both exponents positive.* The function $\varphi(y) = y^{s_2/s_1}$ is convex for $y \ge 0$, because its exponent s_2/s_1 is above 1. Jensen applied to $Y = r^{s_1}$ gives $\left(\mathbb{E}_P[r^{s_1}]\right)^{s_2/s_1} \le \mathbb{E}_P\left[(r^{s_1})^{s_2/s_1}\right] = \mathbb{E}_P[r^{s_2}]$. Raising both sides to the positive power $1/s_2$ keeps the order and gives $m_{s_1} \le m_{s_2}$.
2. *Against the geometric mean.* ln is concave, so Jensen runs the other way: for $s > 0$, $\ln \mathbb{E}_P[r^s] \ge \mathbb{E}_P[\ln r^s] = s\,\mathbb{E}_P[\ln r]$. Dividing by $s > 0$ gives $\ln m_s \ge \ln m_0$. For $s < 0$ the same inequality holds before dividing, and dividing by a negative s flips it: $\ln m_s \le \ln m_0$.
3. *Both exponents negative.* Now $s_2/s_1 \in (0,1)$, so φ is concave and step 1's inequality reverses. Raising to the negative power $1/s_2$ reverses it again, so the conclusion $m_{s_1} \le m_{s_2}$ is the same.

With $s = \alpha - 1$, this says D_α is non-decreasing in α. On the die, the rows of Table 3.4 increase from top to bottom.

ψ is convex, with $\psi(0) = 0$ and $\psi'(0) = D_{\mathrm{KL}}$. This is what ties Rényi divergence to the Chernoff method, and what gives the limit $\alpha \to 1$ below.

1. **Value at 0.** $\psi(0) = \ln \mathbb{E}_P[e^0] = \ln 1 = 0$.
2. **First derivative.** Differentiate the logarithm of the average, passing the derivative inside the average: $\psi'(\lambda) = \mathbb{E}_P[Le^{\lambda L}]/\mathbb{E}_P[e^{\lambda L}]$. This is an average of L in which each outcome x gets weight proportional to $p(x)e^{\lambda L(x)} = p(x)r(x)^\lambda$. Those weights define the **tilted** distribution: P reweighted toward outcomes with large r when $\lambda > 0$. At $\lambda = 0$ there is no tilt, and $\psi'(0) = \mathbb{E}_P[L] = D_{\mathrm{KL}}(P\|Q)$.
3. **Second derivative.** Differentiating the quotient once more gives $\psi''(\lambda) = \frac{\mathbb{E}_P[L^2 e^{\lambda L}]}{\mathbb{E}_P[e^{\lambda L}]} - \left(\frac{\mathbb{E}_P[Le^{\lambda L}]}{\mathbb{E}_P[e^{\lambda L}]}\right)^2$, the mean square of L minus its squared mean under the tilted distribution. That is the variance of L under the tilted distribution. A variance is never negative, so ψ is convex. In terms of the divergence, $(\alpha-1)D_\alpha = \psi(\alpha-1)$ is convex in α.

Limit $\alpha \to 1$. Since $\psi(0) = 0$, Equation 3.12 can be written $D_\alpha = \frac{\psi(\alpha-1)-\psi(0)}{(\alpha-1)-0}$, the slope of ψ between 0 and $\alpha - 1$. As $\alpha \to 1$ that slope tends to the derivative $\psi'(0)$, which is D_{KL} by step 2. (This needs ψ to be finite near 0. Section F.4 in the appendices proves the limit from below in general, and from above whenever some D_α with $\alpha > 1$ is finite; van Erven & Harremoës treat every case.)

Limit $\alpha \to \infty$. Let $r_{\max} = \max_x r(x)$, the largest likelihood ratio on the support of P. A high power of r is dominated by its largest value, so squeeze D_α between two bounds that both tend to $\ln r_{\max}$.

1. *Upper bound.* Every $r(x) \le r_{\max}$, so $\mathbb{E}_P[r^{\alpha-1}] \le r_{\max}^{\alpha-1}$, and taking logs and dividing by $\alpha - 1 > 0$ gives $D_\alpha \le \ln r_{\max}$ for every $\alpha > 1$.
2. *Lower bound.* Let x^* be a point where $r(x^*) = r_{\max}$. Dropping every other term of the average can only make it smaller: $\mathbb{E}_P[r^{\alpha-1}] \ge p(x^*) r_{\max}^{\alpha-1}$, so $D_\alpha \ge \ln r_{\max} + \frac{\ln p(x^*)}{\alpha-1}$.
3. *Squeeze.* The last term is a fixed number divided by $\alpha - 1$, so it tends to 0 as $\alpha \to \infty$, and $D_\alpha \to \ln r_{\max}$. (For densities, replace x^* by a set of positive probability on which $r > r_{\max} - \xi$, and let $\xi \to 0$.)

Limit $\alpha \to 0$. As $\alpha \to 0$, $p^\alpha \to 1$ wherever $p > 0$, and the terms with $p = 0$ are 0 for every $\alpha > 0$. So $\sum_x p^\alpha q^{1-\alpha} \to \sum_{x:\, p(x)>0} q(x) = \Pr_Q[p(X) > 0]$, the mass Q puts where P can land. Divide its logarithm by $\alpha - 1 \to -1$ to get $-\ln \Pr_Q[p(X) > 0]$.

Max-divergence over events. The largest ratio for a single outcome is also the largest ratio for any event, because an event's probability is a sum of outcomes' probabilities, each at most $r_{\max}$ times its Q-probability. Formally, Fact 1 with the indicator of A gives $\Pr_P[A] = \mathbb{E}_Q[r\mathbf{1}[A]] \le r_{\max}\, \mathbb{E}_Q[\mathbf{1}[A]] = r_{\max}\, \Pr_Q[A]$, so $\Pr_P[A]/\Pr_Q[A] \le r_{\max}$. The event $A = \{x^*\}$ attains it.

Additivity. As for KL, the log-likelihood ratio of a pair is a sum, $L_1(X_1) + L_2(X_2)$, and under $P_1 \times P_2$ the two terms are independent. For independent variables the moment generating function of a sum is the product of their moment generating functions: $e^{\lambda(L_1+L_2)} = e^{\lambda L_1} e^{\lambda L_2}$, and the average of a product of independent factors is the product of their averages (Fact 4 of Concentration inequalities). Taking logarithms, $\psi = \psi_1 + \psi_2$. Divide by $\alpha - 1$.

Skew symmetry. The defining sum is symmetric under swapping the roles of p and q together with α and $1 - \alpha$. Indeed $\sum_x p^\alpha q^{1-\alpha} = \sum_x q^{1-\alpha} p^{1-(1-\alpha)}$, and the right side is the sum that defines $D_{1-\alpha}(Q\|P)$. Its logarithm is $(\alpha-1)D_\alpha(P\|Q)$ on one hand and $((1-\alpha)-1)D_{1-\alpha}(Q\|P) = -\alpha D_{1-\alpha}(Q\|P)$ on the other. Divide by $\alpha - 1$.

The same facts as a picture. Equation 3.12 says D_α is the slope of the chord of ψ from $(0, 0)$ to $(\lambda, \psi(\lambda))$, with $\lambda = \alpha - 1$. For a convex function through the origin, chords get steeper as λ grows (monotonicity), and they approach the tangent at 0 as $\lambda \to 0$ (the KL limit). Figure 3.3 draws this for the die.

3.4.4. Interpretation

Where each order looks. D_α is built from the sum $\sum_x p(x)^\alpha q(x)^{1-\alpha}$. Divide each term by the total and you get a distribution. It is the tilted distribution of the derivation with $\lambda = \alpha - 1$, since $p^\alpha q^{1-\alpha} = p\, r^{\alpha-1}$, and the slope $\psi'(\alpha - 1)$ is the average evidence L under it. So the tilted

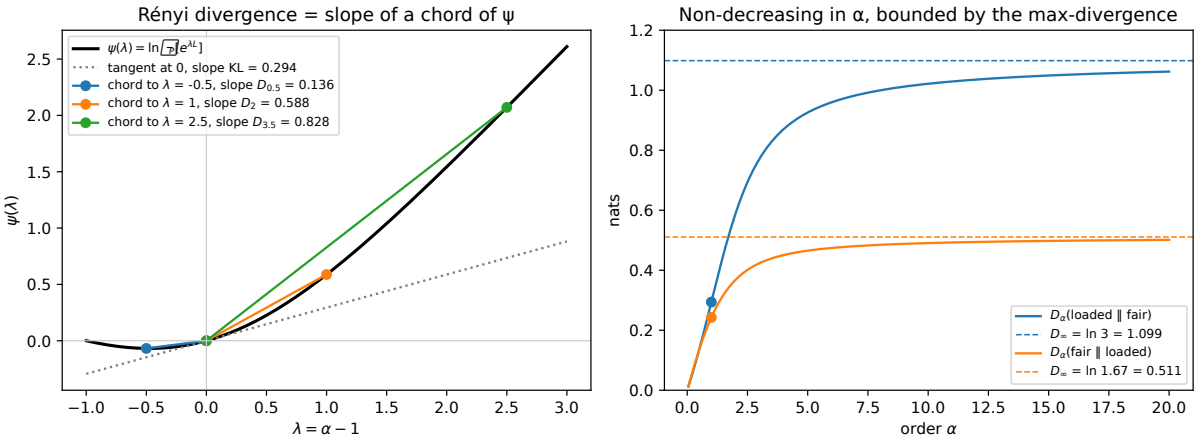

Figure 3.3.: Left: the log-MGF ψ of the log-likelihood ratio for the loaded die against the fair die. The Rényi divergence D_α is the slope of the chord from the origin to $\lambda = \alpha - 1$, and the tangent at 0 has slope KL. Right: D_α as a function of α, in both directions, rising to the max-divergence $\ln \max r$.

distribution shows which outcomes the order α pays attention to. At $\alpha = 1$ it is P itself. As α grows, it moves toward the outcomes with the largest r.

Figure 3.4 draws it for two pairs with the same shift and variance, a Gaussian pair and a Laplace pair, and the difference between them is the difference between a log-ratio that keeps growing and one that stops. For the Gaussian pair, the log-ratio is a straight line in x, so the tilt keeps finding larger ratios further out. The tilted distribution is again normal, centred at $(1-\alpha)s$ for a shift s (derived in the next section). It slides into the tail at a constant speed and never stops, so D_α grows without bound and $D_\infty = \infty$. For the Laplace pair with shift t (measured in units of the Laplace scale), the log-ratio already equals its maximum t on all of $x \le 0$, and no outcome has a larger one. The tilted distribution piles up on that region and stops moving, so D_α levels off at $D_\infty = t$.

Rényi divergence controls the tail of the evidence. How often does a sample from Q look like strong evidence for P, at least c nats? The Chernoff method answers this kind of question. Markov's inequality says that a non-negative variable exceeds a level k with probability at most its mean divided by k. Applying it to $e^{\alpha L}$, which is non-negative and exceeds $e^{\alpha c}$ exactly when $L \ge c$, gives a bound in terms of the average of $e^{\alpha L} = r^\alpha$ under Q. That average is exactly what the Rényi divergence of order α measures: by the definition, $\mathbb{E}_Q[r^\alpha] = e^{(\alpha-1)D_\alpha(P\|Q)}$. So for any $\alpha > 0$,

$$\Pr_Q[L \ge c] \le e^{-\alpha c}\,\mathbb{E}_Q[e^{\alpha L}] = e^{-\alpha c}\,\mathbb{E}_Q[r^\alpha] = \exp\big(-\alpha c + (\alpha-1)D_\alpha(P\|Q)\big). \tag{3.14}$$

At $\alpha = 1$ the divergence term drops out and this is $\Pr_Q[r \ge e^c] \le e^{-c}$: Markov's inequality applied to r itself, whose Q-mean is 1 (Fact 1). It holds for *any* pair of distributions. Larger α uses more about the pair and can do much better. KL alone cannot give a bound like this, because an average says nothing about how often a variable is far from it.

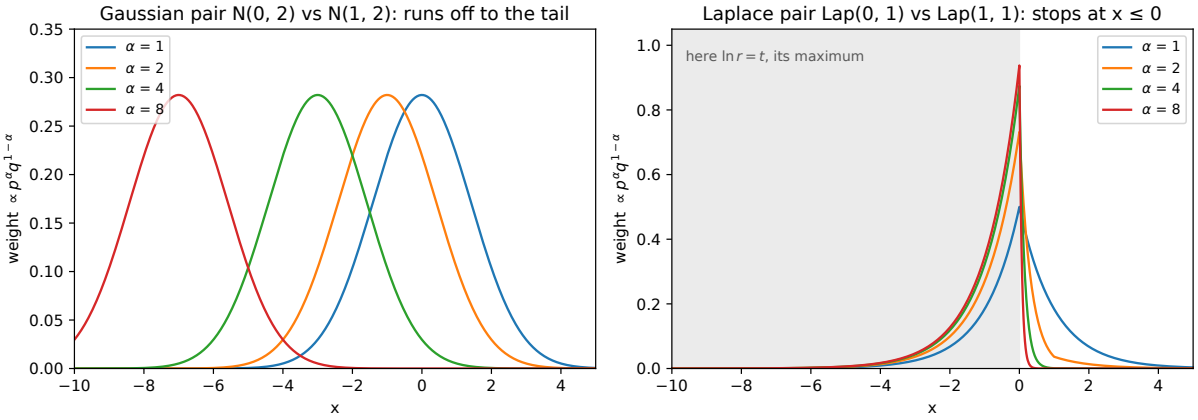

Figure 3.4.: Where the Rényi divergence of order α looks: the normalized weights $p^\alpha q^{1-\alpha}$ for $\alpha = 1, 2, 4, 8$. Left: $\mathcal{N}(0, 2)$ against $\mathcal{N}(1, 2)$; the weight is $\mathcal{N}(1-\alpha, 2)$ and runs off into the left tail. Right: $\mathrm{Lap}(0, 1)$ against $\mathrm{Lap}(1, 1)$; the weight collects on $x \le 0$ (shaded), where the log-likelihood ratio is already at its maximum, and stops.

3.4.5. Example: the die across orders

The script computes D_α for the die in both directions:

Table 3.6.: Rényi divergences between the loaded and the fair die.

α	0.5	1 (KL)	2	5	10	∞
$D_\alpha(P\|Q)$, loaded ‖ fair	0.1362	0.2939	0.5878	0.9257	1.0216	1.0986
$D_\alpha(Q\|P)$, fair ‖ loaded	0.1362	0.2426	0.3677	0.4653	0.4906	0.5108

Check two entries by hand. At order 2 the definition is $\ln \mathbb{E}_Q[r^2]$, and under the fair die r is 0.6 with probability $\frac{5}{6}$ and 3 with probability $\frac{1}{6}$, so $D_2(P\|Q) = \ln\left(\frac{5}{6} \times 0.36 + \frac{1}{6} \times 9\right) = \ln 1.8 = 0.5878$, the log of the arithmetic mean in Table 3.4. The max-divergences are the logs of the largest ratios in each direction, $\ln 3 = 1.0986$ and $\ln(1/0.6) = \ln \frac{5}{3} = 0.5108$. Every row increases, as monotonicity requires. The $\alpha = 0.5$ entries agree, as skew symmetry requires. The order-10 value is already within 7% of the worst case ($1.0216/1.0986 = 0.93$), because the die has only two values of r and the larger one has probability $\frac{1}{2}$ under P, so the power mean reaches the maximum quickly.

3.4.6. Check yourself

- Using Equation 3.12, why does a quadratic ψ give a Rényi divergence that is linear in α? *(If $\psi(\lambda) = a\lambda + b\lambda^2$, then $\psi(\alpha-1)/(\alpha-1) = a + b(\alpha-1)$. The Gaussian pair below is exactly this case.)*

- Can $D_2(P\|Q)$ be finite while $D_\infty(P\|Q)$ is infinite? *(Yes. D_∞ is infinite whenever r is unbounded, even if large ratios are rare enough that $\mathbb{E}_Q[r^2]$ is finite. The Gaussian pair below is an example.)*

3.5. Two Gaussians with equal variance, by hand

3.5.1. Context

The most common pair in practice is a distribution and a shifted copy of it: the same noise around two different centres, the same feature distribution before and after a drift, two classes with the same spread. For two normals with equal variance, every divergence has a closed form. The computation is the standard exercise for this chapter, so try it yourself before reading the derivation.

3.5.2. Statement

Let $P = \mathcal{N}(0, \sigma^2)$ and $Q = \mathcal{N}(s, \sigma^2)$: the same bell curve with standard deviation σ, centred at 0 and at s. What matters is how far apart the centres are compared with the width of the curves, so write $\mu = s/\sigma$ for the shift in standard deviations. KL is half the square of that shift, each Rényi divergence is α times the KL, and the max-divergence is infinite because the likelihood ratio is unbounded:

$$D_{\mathrm{KL}}(P\|Q) = \frac{s^2}{2\sigma^2} = \frac{\mu^2}{2}, \qquad D_\alpha(P\|Q) = \frac{\alpha s^2}{2\sigma^2} = \frac{\alpha\mu^2}{2}, \qquad D_\infty(P\|Q) = \infty. \tag{3.15}$$

Shifting both distributions by the same amount changes nothing, so the same holds for $\mathcal{N}(m_0, \sigma^2)$ against $\mathcal{N}(m_1, \sigma^2)$, with means m_0 and m_1 and $s = m_1 - m_0$.

3.5.3. Derivation

The log-likelihood ratio (also in Probability distributions). Everything follows from the evidence $L(x)$, so compute it first. The normal density with mean m is $\frac{1}{\sigma\sqrt{2\pi}} e^{-(x-m)^2/(2\sigma^2)}$. In the ratio p/q the constants in front cancel, and the log of the ratio of exponentials is the difference of the exponents:

$$L(x) = \ln \frac{p(x)}{q(x)} = \frac{(x-s)^2 - x^2}{2\sigma^2} = \frac{s^2 - 2sx}{2\sigma^2}. \tag{3.16}$$

The last step expands $(x-s)^2 = x^2 - 2sx + s^2$, and the x^2 cancels. So L is a straight line in x. For $s > 0$ it is positive left of the midpoint $s/2$, where x is closer to P's centre than to Q's.

KL. KL is the average of this line when x comes from P.

1. **Set up.** $D_{\mathrm{KL}} = \mathbb{E}_P[L(X)]$ with $X \sim \mathcal{N}(0, \sigma^2)$.
2. **Average a line.** L is linear in x, so its average is L at the average of X. Under P that average is $\mathbb{E}_P X = 0$, and $L(0) = \frac{s^2}{2\sigma^2}$.

Rényi, route 1: complete the square. The plan is to write $p^\alpha q^{1-\alpha}$ as a constant times a normal density, because a normal density integrates to 1 and only the constant survives.

1. **Pull out the constants.** We need $\int p^\alpha q^{1-\alpha}\,\mathrm{d}x$. Both densities share the factor $\frac{1}{\sigma\sqrt{2\pi}}$, and $(\frac{1}{\sigma\sqrt{2\pi}})^\alpha(\frac{1}{\sigma\sqrt{2\pi}})^{1-\alpha} = \frac{1}{\sigma\sqrt{2\pi}}$. What remains is $\exp\big(-\frac{1}{2\sigma^2}[\alpha x^2 + (1-\alpha)(x-s)^2]\big)$.
2. **Expand the bracket.** $\alpha x^2 + (1-\alpha)(x^2 - 2sx + s^2) = x^2 - 2(1-\alpha)sx + (1-\alpha)s^2$.
3. **Complete the square** with $m = (1-\alpha)s$. Since $(x-m)^2 = x^2 - 2mx + m^2$, the bracket is $(x-m)^2 + (1-\alpha)s^2 - (1-\alpha)^2 s^2 = (x-m)^2 + \alpha(1-\alpha)s^2$, using $(1-\alpha) - (1-\alpha)^2 = (1-\alpha)\alpha$.
4. **Integrate.** The factor with $(x-m)^2$, together with $\frac{1}{\sigma\sqrt{2\pi}}$, is a normal density with mean m and integrates to 1. (That normal, $\mathcal{N}((1-\alpha)s, \sigma^2)$, is the tilted distribution of Figure 3.4.) Only the constant part of the bracket is left:

$$\int p^\alpha q^{1-\alpha}\,\mathrm{d}x = \exp\left(-\frac{\alpha(1-\alpha)s^2}{2\sigma^2}\right). \tag{3.17}$$

5. **Take the logarithm and divide by** $\alpha - 1$**.** Since $\frac{-\alpha(1-\alpha)}{\alpha-1} = \alpha$, this gives $D_\alpha = \frac{\alpha s^2}{2\sigma^2}$.

Rényi, route 2: the log-likelihood ratio is normal. The plan is to use Equation 3.12, which needs the log of the moment generating function of L under P, and for a normal variable that is known in closed form.

1. **The distribution of** L**.** Under P, $L(X) = \frac{s^2}{2\sigma^2} - \frac{s}{\sigma^2}X$ is a linear function of a normal variable, so it is normal. Its mean is $\frac{s^2}{2\sigma^2}$ (because $\mathbb{E}X = 0$) and its variance is $\frac{s^2}{\sigma^4}\sigma^2 = \frac{s^2}{\sigma^2}$ (a constant factor a multiplies a variance by a^2).
2. **Its log moment generating function.** For a normal variable Y with mean m and variance v, $\ln \mathbb{E}[e^{\lambda Y}] = \lambda m + \frac{\lambda^2}{2}v$ (Probability distributions). With the mean and variance of step 1, $\psi(\lambda) = \lambda\frac{s^2}{2\sigma^2} + \frac{\lambda^2}{2}\frac{s^2}{\sigma^2}$.
3. **Divide.** By Equation 3.12, $D_\alpha = \frac{\psi(\alpha-1)}{\alpha-1} = \frac{s^2}{2\sigma^2} + (\alpha-1)\frac{s^2}{2\sigma^2} = \frac{\alpha s^2}{2\sigma^2}$.

Max-divergence. $L(x)$ is a line with non-zero slope, so it is unbounded above (as $x \to -\infty$ when $s > 0$). The largest evidence is infinite, so $D_\infty = \infty$.

Checks. At $\alpha = 1$ the Rényi formula gives $s^2/(2\sigma^2)$, the KL value. It is increasing in α, as monotonicity requires. And it is additive: for n independent coordinates with shifts s_i, the divergences add to $\alpha\sum_i s_i^2/(2\sigma^2) = \alpha\|s\|^2/(2\sigma^2)$. It depends on the shift vector only through its length. That is what it must do, because the standard normal in many dimensions looks the same in every direction: rotating the space turns any shift into any other shift of the same length, without changing the pair (Section E.1 in the appendices proves this rotation invariance).

3.5.4. Interpretation

Only the signal-to-noise ratio matters. Every divergence depends on s and σ only through $\mu = s/\sigma$, so doubling the noise has the same effect as halving the shift.

The dependence is quadratic in the shift, so a small shift costs very little: $\mu = 0.1$ gives KL $= 0.1^2/2 = 0.005$. This is why a small drift is hard to see in one sample and needs many.

The average case is finite but the worst case is infinite. Every D_α with finite α is finite, but the likelihood ratio is unbounded in the tails (Probability distributions, the shifted-copy section). Large ratios exist but are rare, and Equation 3.14 makes "rare" precise, as the example shows.

3.5.5. Example: how often does a sample from Q favour P strongly?

Take $\mu = 1$. Then Equation 3.15 gives $D_{\mathrm{KL}} = \frac{1}{2} = 0.5$, $D_2 = 1$ and $D_{10} = 5$. The script also estimates KL as the average of L over a million draws from P and gets 0.4990.

Now ask how often an observation from Q gives at least $c = 2$ nats of evidence for P. That is a likelihood ratio of $e^2 \approx 7.4$ in the wrong direction. The exact answer comes from solving $L \geq c$ for x. Since $L(x) = \frac{s^2 - 2sx}{2\sigma^2}$ decreases in x, $L \geq c$ when $x \leq \frac{s}{2} - \frac{c\sigma^2}{s}$. Under Q, $x = s + \sigma Z$ with Z standard normal, so the condition is $Z \leq -\frac{\mu}{2} - \frac{c}{\mu}$. Write Φ for the standard normal cumulative distribution function, so that $\Phi(z)$ is the probability that $Z \leq z$. Then $\Pr_Q[L \geq c] = \Phi(-\frac{\mu}{2} - \frac{c}{\mu}) = \Phi(-0.5 - 2) = \Phi(-2.5) = 0.0062$.

How close do the bounds of Equation 3.14 come? With $\alpha = 1$ the bound is Markov's, which holds for any pair and gives $e^{-2} = 0.1353$. The Gaussian pair lets you do better by choosing α. With $D_\alpha = \alpha\mu^2/2$, the exponent of the bound is $-\alpha c + \alpha(\alpha - 1)\mu^2/2$. It is a parabola in α, and setting its derivative $-c + (2\alpha - 1)\mu^2/2$ to zero gives the best order, $\alpha = c/\mu^2 + \frac{1}{2} = 2.5$. There the exponent is $-2.5 \times 2 + 2.5 \times 1.5/2 = -3.125$, so the bound is $e^{-3.125} = 0.0439$.

The Rényi bound is 7 times the exact value (0.0439/0.0062), against 22 times for Markov (0.1353/0.0062). The remaining gap is the usual price of the Chernoff method (Concentration inequalities): Markov's inequality is loose for any variable that is not concentrated on two values.

3.5.6. Check yourself

- What are D_{KL} and D_2 between $\mathcal{N}(0, I_d)$ and $\mathcal{N}(v, I_d)$ for $v = (0.1, \ldots, 0.1) \in \mathbb{R}^{100}$? *($\|v\|^2 = 100 \times 0.01 = 1$, so $KL = 0.5$ and $D_2 = 1$: a hundred tiny shifts add up to one unit shift.)*
- Why is $D_{\mathrm{KL}}(P\|Q) = D_{\mathrm{KL}}(Q\|P)$ for this pair, although KL is not symmetric in general? *(Reflecting $x \mapsto s - x$ swaps P and Q, and divergences do not change under a bijection of the outcome space: by the data-processing inequality, applying the bijection cannot increase a divergence, and neither can undoing it.)*

3.6. Two Laplace distributions with shifted location

3.6.1. Context

The Laplace distribution is the other standard noise model. Its density with centre m and scale b is $\frac{1}{2b}e^{-|x-m|/b}$: a sharp peak with tails that fall off exponentially, more slowly than the normal's. Probability distributions showed that its log-likelihood ratio against a shifted copy is bounded, unlike the normal's. This section computes the full Rényi family for that pair and compares it with a Gaussian pair of the same variance. The comparison turns "bounded against unbounded likelihood ratio" into a difference you can see in the divergences.

3.6.2. Statement

Let $P = \mathrm{Lap}(0, b)$ and $Q = \mathrm{Lap}(s, b)$ with $s \geq 0$, and write $t = s/b$ for the shift in units of the scale. The max-divergence is just the shift t, KL is slightly less, and every Rényi divergence has a closed form:

$$D_{\mathrm{KL}}(P\|Q) = t + e^{-t} - 1, \qquad D_\infty(P\|Q) = t, \tag{3.18}$$

$$D_\alpha(P\|Q) = \frac{1}{\alpha - 1} \ln\left(\frac{\alpha}{2\alpha - 1} e^{(\alpha-1)t} + \frac{\alpha - 1}{2\alpha - 1} e^{-\alpha t}\right) \qquad (\alpha \neq \tfrac{1}{2}, 1). \tag{3.19}$$

At $\alpha = \frac{1}{2}$ both coefficients divide by zero, and the bracket is replaced by its limit $(1 + \frac{t}{2})e^{-t/2}$.

3.6.3. Derivation

Rescaling $x \mapsto x/b$ is a bijection: it can be undone, so it loses nothing and does not change any divergence. Take $b = 1$ and $s = t$.

Max-divergence. With $b = 1$ the densities are $\frac{1}{2}e^{-|x|}$ and $\frac{1}{2}e^{-|x-t|}$, so the evidence is the difference of the exponents, $L(x) = |x - t| - |x|$. Two numbers whose distance is t cannot have absolute values that differ by more than t (the triangle inequality), so $|L(x)| \leq t$. For every $x \leq 0$, both x and $x - t$ are negative, so $|x - t| = t - x$ and $|x| = -x$, and $L(x) = t$ exactly. So $\max L = t$ (Probability distributions).

KL. KL is the average of L under P, and the work is to average $|X - t|$.

1. **Set up.** $D_{\mathrm{KL}} = \mathbb{E}_P[L] = \mathbb{E}|X - t| - \mathbb{E}|X|$ with $X \sim \mathrm{Lap}(0, 1)$. The second term is $\mathbb{E}|X| = 1$, because $|X|$ has the exponential density e^{-y} on $y \geq 0$, whose mean is 1.
2. **Split off the negative part.** For any number y, $|y| = y + 2(-y)_+$: if $y \geq 0$ both sides are y, and if $y < 0$ the right side is $y - 2y = -y$. With $y = X - t$, and $\mathbb{E}X = 0$, this gives $\mathbb{E}|X - t| = -t + 2\,\mathbb{E}(t - X)_+$.
3. **Write the positive part as an integral.** $(t - X)_+$ is the length of the interval from X up to t, which is $\int_{-\infty}^{t} \mathbf{1}[X \leq x]\,\mathrm{d}x$. Averaging inside the integral gives $\mathbb{E}(t - X)_+ = \int_{-\infty}^{t} \Pr[X \leq x]\,\mathrm{d}x$. The Laplace cumulative distribution function is $\Pr[X \leq x] = \frac{1}{2}e^{x}$ for $x < 0$ and $1 - \frac{1}{2}e^{-x}$ for $x \geq 0$, so this is $\int_{-\infty}^{0} \frac{1}{2}e^{x}\,\mathrm{d}x + \int_{0}^{t} (1 - \frac{1}{2}e^{-x})\mathrm{d}x = \frac{1}{2} + t - \frac{1}{2}(1 - e^{-t}) = t + \frac{1}{2}e^{-t}$.
4. **Combine.** $\mathbb{E}|X - t| = -t + 2(t + \frac{1}{2}e^{-t}) = t + e^{-t}$, and $D_{\mathrm{KL}} = t + e^{-t} - 1$.

Rényi (can wait for a second reading; only the result is used later). We need $I(\alpha) = \int p^\alpha q^{1-\alpha} = \frac{1}{2}\int \exp(-\alpha|x| - (1 - \alpha)|x - t|)\mathrm{d}x$. The absolute values change sign at 0 and t, and between those points each one is a plain linear function, so split the line into the three pieces of Table 3.7. On each piece the exponent is linear in x, and the integral of an exponential of a linear function is elementary.

Table 3.7.: The three pieces of the Laplace Rényi integral.

Piece	Exponent $-\alpha\lvert x\rvert - (1-\alpha)\lvert x - t\rvert$	Integral of e^{exponent}
$x < 0$	$x - (1 - \alpha)t$	$e^{-(1-\alpha)t}$
$0 \leq x \leq t$	$(1 - 2\alpha)x - (1 - \alpha)t$	$\dfrac{e^{-\alpha t} - e^{-(1-\alpha)t}}{1 - 2\alpha}$

Piece	Exponent $-\alpha\lvert x\rvert - (1-\alpha)\lvert x-t\rvert$	Integral of e^{exponent}
$x > t$	$-x + (1-\alpha)t$	$e^{-\alpha t}$

1. **Collect the $e^{-\alpha t}$ terms.** Add the three integrals and halve. The coefficient of $e^{-\alpha t}$ is $\frac{1}{2}(1 + \frac{1}{1-2\alpha}) = \frac{1-\alpha}{1-2\alpha} = \frac{\alpha-1}{2\alpha-1}$.
2. **Collect the other terms.** The coefficient of $e^{-(1-\alpha)t} = e^{(\alpha-1)t}$ is $\frac{1}{2}(1 - \frac{1}{1-2\alpha}) = \frac{-\alpha}{1-2\alpha} = \frac{\alpha}{2\alpha-1}$.
3. **Take the logarithm.** $\frac{1}{\alpha-1} \ln I(\alpha)$ is Equation 3.19.
4. **Check against KL.** The Rényi divergence must tend to KL as $\alpha \to 1$. $I(1) = \int p = 1$, so $D_\alpha = \frac{\ln I(\alpha) - \ln I(1)}{\alpha-1}$ is a difference quotient of $\ln I$ and tends to its derivative at 1, $I'(1)/I(1)$. Differentiating the closed form of I at $\alpha = 1$ gives $I'(1) = -1 + t + e^{-t}$, so the limit is $t + e^{-t} - 1$, as above.

3.6.4. Interpretation: Laplace against Gaussian at the same variance

To compare the two noise models fairly, give them the same variance. $\text{Lap}(0, b)$ has variance $2b^2$, so compare it with the Gaussian pair $\mathcal{N}(0, 2b^2)$ against $\mathcal{N}(s, 2b^2)$. Its standardized shift is $\mu = s/(\sqrt{2}\,b) = t/\sqrt{2}$, so $D_\alpha = \alpha\mu^2/2 = \alpha t^2/4$ by Equation 3.15.

For small shifts, the Laplace pair is further apart. Expanding $e^{-t} = 1 - t + \frac{t^2}{2} - \ldots$, the Laplace KL $t + e^{-t} - 1$ is $\approx t^2/2$: twice the Gaussian's $t^2/4$. The Laplace density's sharp peak makes small shifts easier to detect, because the peak moves visibly.

For large orders the comparison reverses. The Gaussian D_α grows linearly in α forever. The Laplace D_α rises and saturates at t, because the likelihood ratio can never exceed e^t (Figure 3.5, and Figure 3.4 for where each order looks). At $t = 1$ the script solves for the order where the two curves cross: for orders above 2.98, the Gaussian pair is the *more* distinguishable one in the Rényi sense.

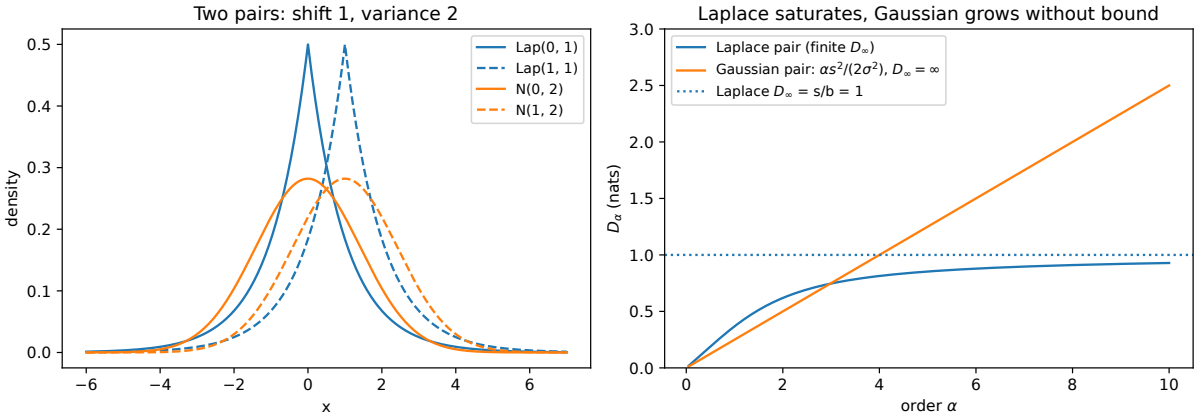

Figure 3.5.: Left: a Laplace pair and a Gaussian pair, both with shift 1 and variance 2. Right: their Rényi divergences as a function of the order α. The Gaussian's grows linearly without bound; the Laplace's levels off at its max-divergence $s/b = 1$.

3.6.5. Example: shift of one scale unit

Table 3.8 compares $t = 1$ ($b = 1$, $s = 1$) with the Gaussian pair of variance 2, for which $D_\alpha = \alpha/4$.

Table 3.8.: Rényi divergences of a Laplace pair and a Gaussian pair with the same shift and variance.

	KL	$D_{0.5}$	D_2	D_{10}	D_∞
Laplace, $t = 1$	0.3679	0.1891	0.6191	0.9287	1.0000
Gaussian, same variance	0.2500	0.1250	0.5000	2.5000	∞

By hand: at $t = 1$ the Laplace KL is $1 + e^{-1} - 1 = e^{-1} = 0.3679$, and the Monte Carlo average of L over a million draws gives 0.3684. At $\alpha = 2$ the coefficients in Equation 3.19 are $\frac{2}{3}$ and $\frac{1}{3}$ and the prefactor is 1, so $D_2 = \ln\left(\frac{2}{3}e + \frac{1}{3}e^{-2}\right) = \ln 1.8573 = 0.6191$. In the bulk (small α) the Laplace pair is further apart. In the worst case the Gaussian pair is.

3.6.6. Check yourself

- Why does D_α for the Laplace pair stay below t for every α? *(Monotonicity in α and the limit $D_\infty = t$: a non-decreasing function that tends to t never exceeds it.)*
- For which x is the Laplace log-likelihood ratio at its maximum t, and how likely is that region under P? *(For every $x \le 0$, which has probability $\frac{1}{2}$ under P. The worst case is not rare at all, unlike for the Gaussian.)*

3.7. Total variation

3.7.1. Context

KL and Rényi divergences are convenient to compute, but they do not directly answer operational questions. **Total variation** does. Draw p and q on the same axes. Where the curves overlap, an observation cannot tell you which distribution it came from. Where they don't, it can. Total variation is the part that does not overlap: the mass of P that sits above Q. It answers three questions at once. It is the largest difference in the probability that P and Q give to any event. It is the largest amount by which any bounded statistic can change when you replace Q by P. And it is how well the best possible test can tell P from Q with one observation.

3.7.2. Statement

The total variation has four equal forms, and each says the same thing from a different side: the largest gap between the probabilities of one event, the mass where p sits above q, half the total absolute difference between the two probability tables, and the average under Q of how far r exceeds 1:

$$\mathrm{TV}(P,Q) = \max_A |\Pr_P[A] - \Pr_Q[A]| = \sum_x (p(x)-q(x))_+ = \frac{1}{2}\sum_x |p(x)-q(x)| = \mathbb{E}_Q[(r-1)_+]. \tag{3.20}$$

Equivalently, the overlap of the two curves is $\sum_x \min(p(x),q(x)) = 1 - \mathrm{TV}(P,Q)$. It has three uses and one structural property.

1. **Bounded statistics.** For every g with values in $[l,u]$, $|\mathbb{E}_P g - \mathbb{E}_Q g| \le (u-l)\,\mathrm{TV}(P,Q)$.
2. **Best single-shot test.** Nature picks P or Q with probability $\frac{1}{2}$ each and shows you one draw. Guessing blind is right half the time, and seeing the draw adds half the TV. The best possible guess is correct with probability
$$\Pr[\text{correct}] = \frac{1}{2} + \frac{1}{2}\mathrm{TV}(P,Q). \tag{3.21}$$
3. **TV is a metric:** symmetric, zero only if $P = Q$, and it satisfies the triangle inequality (it is half an ℓ_1 distance, the sum of absolute differences). It is always between 0 and 1.

3.7.3. Derivation

The forms of Equation 3.20. Each form follows from the previous one.

1. **The best event.** Fact 3 with $\gamma = 1$ says the event that maximizes $\Pr_P[A] - \Pr_Q[A]$ collects every outcome where $p > q$, so $\max_A[\Pr_P[A] - \Pr_Q[A]] = \sum_x (p-q)_+$.
2. **Absolute values come for free.** The differences $p - q$ sum to $1 - 1 = 0$, so the positive and negative parts have equal mass: $\sum(p-q)_+ = \sum(q-p)_+$. So $\max_A[\Pr_Q[A] - \Pr_P[A]]$ has the same value, which lets you put absolute values on $\Pr_P[A] - \Pr_Q[A]$.
3. **Half the absolute difference.** $|y| = y_+ + (-y)_+$, so $\sum|p-q| = \sum(p-q)_+ + \sum(q-p)_+ = 2\sum(p-q)_+$.
4. **An average under Q.** $p - q = q(r-1)$, so $\sum_x (p-q)_+ = \sum_x q\,(r-1)_+ = \mathbb{E}_Q[(r-1)_+]$.
5. **Overlap.** At each x, $\min(p,q)$ is p minus whatever of p sticks out above q: $\min(p,q) = p - (p-q)_+$. Sum over x: $\sum\min(p,q) = 1 - \mathrm{TV}$.

Bounded statistics. The idea is that a statistic with values in an interval is a "soft event", and Fact 3 bounds soft events as well as sharp ones. Shift g by a constant, which does not change $\mathbb{E}_P g - \mathbb{E}_Q g$, so that it takes values in $[0, u-l]$. Then $\mathbb{E}_P g - \mathbb{E}_Q g = \sum_x g(x)(p(x)-q(x))$. The function $\phi = g/(b-a)$ has values in $[0,1]$, and the randomized version of Fact 3 says $\sum_x \phi(x)(p(x)-q(x)) \le \sum(p-q)_+$. Multiplying by $u-l$ gives the bound $(u-l)\sum(p-q)_+$, and the same argument with g replaced by $-g$ bounds the other sign.

Best single-shot test.

1. **Score a test.** A test says "P" when $x \in A$ and "Q" otherwise. It is right when the draw came from P and lands in A, or came from Q and lands outside A, so it is correct with probability $\frac{1}{2}\Pr_P[A] + \frac{1}{2}(1 - \Pr_Q[A]) = \frac{1}{2} + \frac{1}{2}(\Pr_P[A] - \Pr_Q[A])$.

2. **Choose the best event.** Maximize over A with Fact 3: the best test is $A^* = \{p > q\}$, "say P when the observation is more likely under P", and it achieves Equation 3.21.
3. **Randomizing does not help.** A randomized test says "P" with probability $\phi(x) \in [0, 1]$, and by the second part of Fact 3 it does no better.

Concretely, on the die. Table 3.9 evaluates Equation 3.20 outcome by outcome.

Table 3.9.: Total variation between the loaded and the fair die, outcome by outcome.

Roll	1–5 (each)	6	Sum
$p - q$	$0.1 - \frac{1}{6} = -\frac{1}{15}$	$0.5 - \frac{1}{6} = \frac{1}{3}$	0
$(p - q)_+$	0	$\frac{1}{3}$	$\frac{1}{3}$
$\lvert p - q \rvert$	$\frac{1}{15}$	$\frac{1}{3}$	$\frac{2}{3}$

So TV $= \frac{1}{3}$, and half the absolute sum, $\frac{1}{2} \times \frac{2}{3}$, agrees. The best test says "loaded" exactly when it sees a six, and it is right with probability $\frac{1}{2} + \frac{1}{2} \times \frac{1}{3} = \frac{1}{2} + \frac{1}{6} = \frac{2}{3}$.

3.7.4. Interpretation

TV is the bottom line for one observation. No classifier, however clever, can beat $\frac{1}{2} + \frac{1}{2}$TV accuracy from a single draw with equal priors, because the best test of the derivation already reaches it.

It also bounds how much any fixed procedure can change when the data distribution changes. If the test distribution moves from Q to P with TV ≤ 0.01, then the accuracy of *any* fixed classifier moves by at most 0.01. Its accuracy is the average of a statistic with values in $[0, 1]$ (1 for a correct prediction, 0 for a wrong one), so the bounded-statistics property applies with $u - l = 1$.

TV is not additive. For n i.i.d. samples, $\mathrm{TV}(P^n, Q^n)$ is not $n\,\mathrm{TV}(P, Q)$. It is capped at 1 and has no simple formula. That is why you usually compute KL or a Rényi divergence for n samples, where additivity makes it trivial, and convert to TV with Pinsker's inequality (Section 3.11).

3.7.5. Example: telling two Gaussians apart from n samples

For $P = \mathcal{N}(0, \sigma^2)$ and $Q = \mathcal{N}(s, \sigma^2)$ with $s > 0$, the best event collects the outcomes more likely under P. The two bell curves cross at the midpoint $s/2$, so $A^* = \{p > q\} = \{x < s/2\}$. Write Φ for the standard normal cumulative distribution function, $\Phi(z) = \Pr[Z \leq z]$ for a standard normal Z. In standard units the midpoint is $\mu/2$ above P's centre and $\mu/2$ below Q's, with $\mu = s/\sigma$, so $\Pr_P[A^*] = \Phi(\frac{\mu}{2})$ and $\Pr_Q[A^*] = \Phi(-\frac{\mu}{2})$. The normal curve is symmetric, so $\Phi(-z) = 1 - \Phi(z)$, and

$$\mathrm{TV} = \Pr_P[A^*] - \Pr_Q[A^*] = \Phi\Big(\frac{\mu}{2}\Big) - \Phi\Big(-\frac{\mu}{2}\Big) = 2\Phi\Big(\frac{\mu}{2}\Big) - 1, \qquad \mu = s/\sigma. \tag{3.22}$$

At $\mu = 1$, TV $= 0.3829$, and by Equation 3.21 the best test is right with probability $\frac{1}{2} + \frac{1}{2}(2\Phi(0.5) - 1) = \Phi(0.5) = 0.6915$ (Figure 3.6, left).

Now suppose each observation is shifted by only $\mu = 0.1$ standard deviations, and you see n i.i.d. samples. The evidence of the whole sample is the sum of the evidence of each sample,

$\sum_i L(x_i) = \sum_i \frac{s^2 - 2sx_i}{2\sigma^2} = \frac{n(s^2 - 2s\bar{x})}{2\sigma^2}$, which depends on the data only through the sample mean $\bar{x}$. So nothing is lost by looking only at $\bar{x}$. The sample mean has the same centre as one observation and a variance n times smaller: it is $\mathcal{N}(0, \sigma^2/n)$ under P and $\mathcal{N}(s, \sigma^2/n)$ under Q. That is a Gaussian pair with standardized shift $s/(\sigma/\sqrt{n}) = \mu\sqrt{n}$. So the best test thresholds the sample mean at $s/2$. Table 3.10 gives its accuracy, exactly and by simulation.

Table 3.10.: Telling $\mathcal{N}(0, 1)$ from $\mathcal{N}(0.1, 1)$ with n samples.

n	$\mu\sqrt{n}$	TV	Best accuracy	Simulated (20,000 trials)
100	1	0.3829	0.6915	0.6916
400	2	0.6827	0.8413	0.8424

A shift of a tenth of a standard deviation is invisible in one sample ($\mathrm{TV} = 2\Phi(0.05) - 1 = 0.0399$) but clear with a few hundred. The accuracy depends on n only through $\mu\sqrt{n}$, so reaching a given accuracy needs n proportional to $1/\mu^2$, that is to $1/D_{\mathrm{KL}}(P\|Q)$, since $D_{\mathrm{KL}}(P\|Q) = \mu^2/2$.

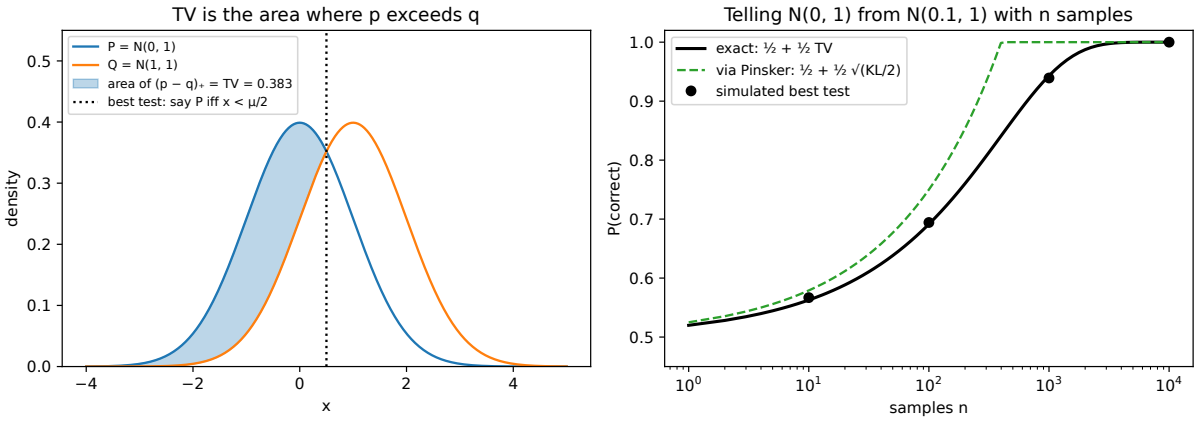

Figure 3.6.: Left: two unit-variance Gaussians one standard deviation apart. The shaded area, where p exceeds q, is the total variation, and the best test thresholds at the midpoint. Right: the best accuracy for telling $\mathcal{N}(0, 1)$ from $\mathcal{N}(0.1, 1)$ as the number of samples grows, exactly, by simulation, and as bounded through Pinsker's inequality.

3.7.6. Check yourself

- Two distributions have disjoint supports. What is their TV, and what does the best test do? *($\mathrm{TV} = 1$: the event "x is in the support of P" has probability 1 under P and 0 under Q. The test looks at which support x falls in and is always right.)*
- Why is $\mathrm{TV}(P, Q) \le 1 - e^{-D_\infty(P\|Q)}$? *(Hint: $p/q \le e^{D_\infty}$ everywhere, so $q \ge pe^{-D_\infty}$, and $\sum(p - q)_+ \le \sum p(1 - e^{-D_\infty})$.)*

3.8. Hockey-stick divergence

3.8.1. Context

TV measures the mass of p that sticks out above q. Now scale q up by a factor $\gamma \geq 1$ and measure the mass of p that *still* sticks out above γq (Figure 3.7). Only outcomes where p is more than γ times q count, so the **hockey-stick divergence** E_γ measures how much of the difference between P and Q comes from likelihood ratios above γ. It shows up whenever one kind of error must be avoided more than the other: tests with unequal priors or unequal costs. It also shows up in **rejection sampling**, a way to draw samples from a target p using draws from an easier q: propose from q and keep each proposal with a probability that corrects for the difference. This needs an envelope $\gamma q \geq p$. If your γ is too small, the part of p above γq is exactly what you lose.

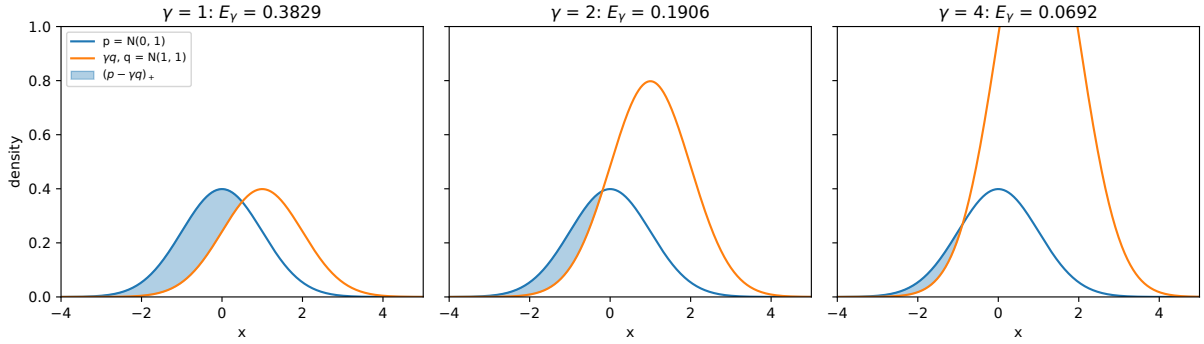

Figure 3.7.: The hockey-stick divergence as an area, for $p = \mathcal{N}(0,1)$ and $q = \mathcal{N}(1,1)$. Raising γ lifts the curve γq, and E_γ is the shaded mass of p still above it: 0.3829 (the total variation) at $\gamma = 1$, then 0.1906 and 0.0692. It shrinks but never reaches zero, because r is unbounded in the left tail.

3.8.2. Statement

The hockey-stick divergence is the TV with q replaced by γq. Like the TV, it is the largest gap $\Pr_P[A] - \gamma \Pr_Q[A]$ over events, the mass of p above γq, and an average under Q of how far r exceeds the threshold. For $\gamma \geq 1$,

$$E_\gamma(P\|Q) = \max_A \left[\Pr_P[A] - \gamma \Pr_Q[A]\right] = \sum_x \left(p(x) - \gamma q(x)\right)_+ = \mathbb{E}_Q[(r-\gamma)_+]. \tag{3.23}$$

The name comes from the shape of $t \mapsto (t-\gamma)_+$: flat, then a straight line. It has four properties.

1. $E_1(P\|Q) = \mathrm{TV}(P,Q)$: with no scaling it is the TV.
2. E_γ is non-increasing and convex in γ, and $E_\gamma = 0$ exactly when $\gamma \geq \max r = e^{D_\infty(P\|Q)}$: once γq covers p everywhere, nothing sticks out.
3. In terms of the log-likelihood ratio, it is a difference of two tail probabilities: $E_\gamma(P\|Q) = \Pr_P[L > \ln\gamma] - \gamma \Pr_Q[L > \ln\gamma]$.

4. **Unequal priors.** If P has prior probability $\pi \le \frac{1}{2}$ and Q has $1-\pi$, the smallest possible probability of a wrong guess from one observation is $\pi(1 - E_\gamma(P\|Q))$ with $\gamma = (1-\pi)/\pi$, the prior odds against P. Always guessing Q errs with probability π, and the observation removes a fraction E_γ of that.

3.8.3. Derivation

1. **The forms.** Fact 3 with weight γ gives the maximum and the sum, and $p - \gamma q = q(r-\gamma)$ turns the sum into $\sum q(r-\gamma)_+ = \mathbb{E}_Q[(r-\gamma)_+]$.
2. **Property 1:** set $\gamma = 1$ in Equation 3.20.
3. **Property 2:** for each outcome, $(r(x)-\gamma)_+$ as a function of γ is a hockey stick turned around, a straight descending line that flattens at 0, so it is non-increasing and convex. An average of non-increasing convex functions is non-increasing and convex. Every term vanishes exactly when $\gamma \ge r(x)$ for all x, that is when $\gamma \ge \max r$.
4. **Property 3:** the terms of $\sum(p-\gamma q)_+$ are non-zero only on $\{r > \gamma\} = \{L > \ln\gamma\}$. On that set the sum of p is $\Pr_P[L > \ln\gamma]$ and the sum of γq is $\gamma \Pr_Q[L > \ln\gamma]$.
5. **Property 4:** guessing "P" on A errs when the draw came from P and fell outside A, or came from Q and fell inside A, so it errs with probability $\pi \Pr_P[A^c] + (1-\pi)\Pr_Q[A]$. Factoring out π and writing $\gamma = (1-\pi)/\pi$, this is $\pi - \pi[\Pr_P[A] - \gamma \Pr_Q[A]]$. Minimizing the error means maximizing the bracket, which by Fact 3 is E_γ.

Closed forms for the shifted pairs. Property 3 turns E_γ into two tail probabilities, and for the Gaussian and Laplace pairs both are known. Write $c = \ln\gamma$.

For the Gaussian pair ($\mu = s/\sigma$), the evidence is the line $L(x) = \frac{s^2 - 2sx}{2\sigma^2}$, and $L > c$ when $x < \frac{s}{2} - \frac{c\sigma^2}{s}$, that is when $x/\sigma < \frac{\mu}{2} - \frac{c}{\mu}$. Under P, x/σ is standard normal, so $\Pr_P[L > c] = \Phi(\frac{\mu}{2} - \frac{c}{\mu})$. Under Q, x/σ is a standard normal plus μ, so $\Pr_Q[L > c] = \Phi(-\frac{\mu}{2} - \frac{c}{\mu})$. Therefore

$$E_\gamma = \Phi\Big(\frac{\mu}{2} - \frac{c}{\mu}\Big) - \gamma\,\Phi\Big(-\frac{\mu}{2} - \frac{c}{\mu}\Big). \tag{3.24}$$

It is positive for every γ, because $D_\infty = \infty$: no finite γ covers p.

For the Laplace pair ($t = s/b$, $b = 1$), the evidence $L(x) = |x-t| - |x|$ is t on $x \le 0$, $-t$ on $x \ge t$, and $t - 2x$ in between. For $0 \le c < t$, $L > c$ happens on that middle piece when $x < \frac{t-c}{2}$. Under $P = \mathrm{Lap}(0,1)$ the probability of $X < \frac{t-c}{2}$, a positive point, is $\Pr_P[\cdot] = 1 - \frac{1}{2}e^{-(t-c)/2}$. Under Q, $X - t$ is a $\mathrm{Lap}(0,1)$ variable that must be below $\frac{t-c}{2} - t = -\frac{t+c}{2}$, so $\Pr_Q[\cdot] = \frac{1}{2}e^{-(t+c)/2}$. Since $\gamma e^{-(t+c)/2} = e^c e^{-(t+c)/2} = e^{-(t-c)/2}$, the two halves combine:

$$E_\gamma = 1 - e^{-(t - \ln\gamma)/2} \quad \text{for } 1 \le \gamma \le e^t, \qquad E_\gamma = 0 \text{ beyond.} \tag{3.25}$$

At $\gamma = 1$ this gives $\mathrm{TV} = 1 - e^{-t/2}$.

3.8.4. Interpretation

The curve $\gamma \mapsto E_\gamma$ shows how much of the difference between P and Q comes from large likelihood ratios. TV is its value at $\gamma = 1$, and the max-divergence is where it hits zero (Figure 3.8). For the die, the only outcome with $r > \gamma$, for $1 \le \gamma < 3$, is the six, which contributes $p - \gamma q = 0.5 - \gamma/6$.

So $E_\gamma = 0.5 - \gamma/6$ falls linearly to zero at $\gamma = 3$. For the Laplace pair it reaches zero at $\ln\gamma = t$. The Gaussian curve never reaches zero, but it gets very small. In this sense E_γ separates a likelihood ratio that is *never* large (Laplace) from one that is large only *with small probability* (Gaussian).

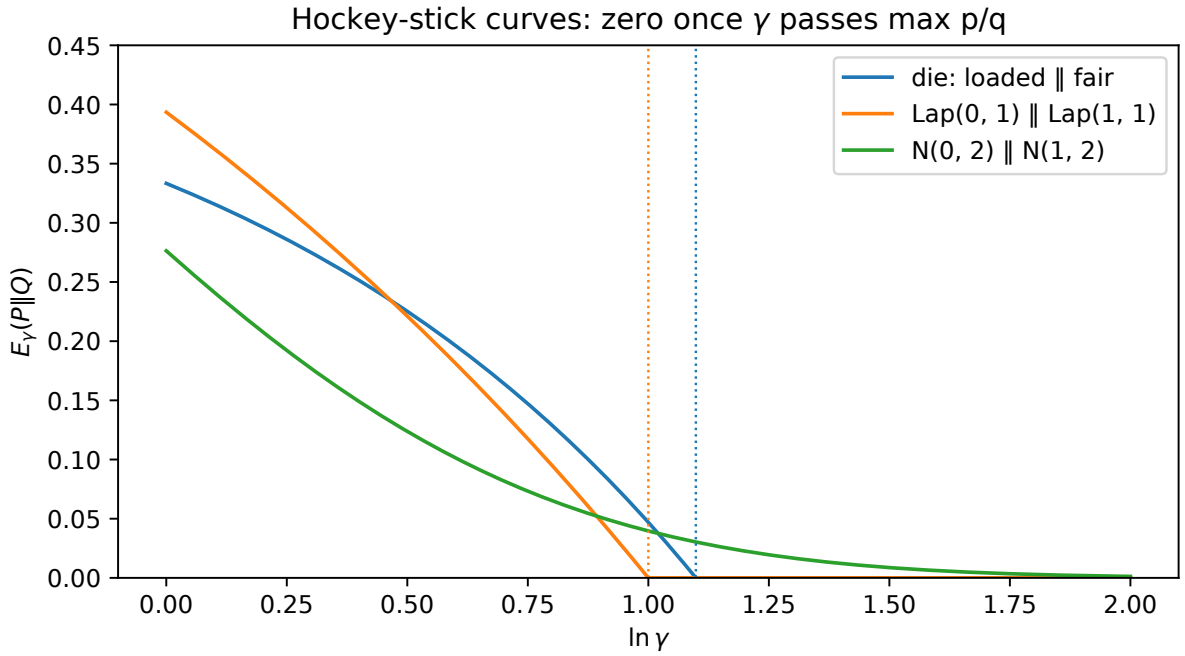

Figure 3.8.: The hockey-stick divergence $E_\gamma(P\|Q)$ as a function of $\ln\gamma$ for the loaded die, a Laplace pair and a Gaussian pair with the same variance. The die and Laplace curves reach zero at their max-divergences ($\ln 3$ and 1, dotted lines); the Gaussian curve stays positive.

3.8.5. Example: rejection sampling with an envelope that is too low

You want samples from the loaded die p, using rolls of the fair die q as proposals, with envelope γq. Propose $x \sim q$ and accept it with probability $\min\left(1, \frac{p(x)}{\gamma q(x)}\right)$. The chance of proposing x and accepting it is $q(x)\min(1, p/(\gamma q)) = \min(p, \gamma q)/\gamma$, so the accepted rolls have distribution $\tilde{p} \propto \min(p, \gamma q)$. Where the envelope covers p this is p; where it does not, the excess of p is cut off.

With $\gamma = 3 = \max r$, the envelope covers p, so $\tilde{p} = p$ exactly. Each proposal is accepted with total probability $\sum \min(p, 3q)/3 = 1/\gamma = \frac{1}{3}$.

With $\gamma = 2$, the envelope $2q = \frac{1}{3}$ is below $p(6) = 0.5$. The uncovered mass is $E_2(P\|Q) = 0.5 - \frac{1}{3} = \frac{1}{6}$ (the script gives 0.1667). The acceptance rate rises to $\sum \min(q, p/\gamma) = (1 - E_2)/\gamma = \frac{5}{12}$, since $\sum \min(p, \gamma q)$ is all of p except the part above γq, which is $1 - E_\gamma$. But the output is wrong: $\min(p, 2q) = (0.1, \ldots, 0.1, \frac{1}{3})$ sums to $\frac{5}{6}$, and dividing by $\frac{5}{6}$ gives $\tilde{p} = (0.12, \ldots, 0.12, 0.4)$. A six now comes up 40% of the time instead of 50%: $\mathrm{TV}(P, \tilde{P}) = 0.5 - 0.4 = 0.1$.

In general $\mathrm{TV}(P, \tilde{P}) \le E_\gamma(P\|Q)$ (Exercise 4 in the exercise book). The hockey-stick divergence is exactly the price of a cheap envelope.

3.8.6. Check yourself

- Why must $\gamma \ge 1$ in the definition? *(For $\gamma < 1$, $\max_A[\Pr_P[A] - \gamma \Pr_Q[A]] \ge 1 - \gamma > 0$ even when $P = Q$, by taking A to be everything. The quantity no longer vanishes at $P = Q$.)*
- For the Gaussian pair with $\mu = 1$, the script gives $E_2 = 0.1906$, and a Monte Carlo average of $(r-2)_+$ over a million draws from Q gives 0.1892. Which form of E_γ does the simulation use, and why does it need samples from Q, not P? *(The form $\mathbb{E}_Q[(r-\gamma)_+]$, which is an average under Q, so a sample average estimates it only when the samples come from Q.)*

3.9. f-divergences

3.9.1. Context

KL, TV and E_γ were defined separately, but each is an average under Q of some function of the likelihood ratio. The function says how much a given ratio counts as "difference". Naming it gives one family, the **f-divergences**, with one proof of non-negativity and one proof of the data-processing inequality for all its members. Rényi divergence is not a member, but it is an increasing function of one, so it inherits everything.

3.9.2. Statement

Pick a convex function f that is zero at $t = 1$, so that a ratio of 1 (no evidence either way) counts as no difference. The f-divergence averages f of the likelihood ratio under Q. For a convex $f : (0, \infty) \to \mathbb{R}$ with $f(1) = 0$,

$$D_f(P\|Q) = \mathbb{E}_Q\big[f(r(X))\big] = \sum_x q(x)\, f\Big(\frac{p(x)}{q(x)}\Big). \tag{3.26}$$

Table 3.11 lists the common choices of f, called **generators**.

Table 3.11.: Common f-divergences, their generators, and their values for the loaded die against the fair die.

Divergence	$f(t)$	Die, loaded ‖ fair
KL, $D_{\mathrm{KL}}(P\|Q)$	$t \ln t$	0.2939
Reverse KL, $D_{\mathrm{KL}}(Q\|P)$	$-\ln t$	0.2426
Total variation	$\frac{1}{2}\lvert t-1\rvert$	0.3333
Hockey-stick E_γ ($\gamma = 2$)	$(t-\gamma)_+$	0.1667
χ^2	$(t-1)^2$	0.8000
Squared Hellinger H^2	$(\sqrt{t}-1)^2$	0.1317

Rényi as a transform. The Rényi divergence is a logarithm of $\mathbb{E}_Q[r^\alpha]$, and $\mathbb{E}_Q[r^\alpha]$ minus 1 is an f-divergence. For $\alpha > 1$, $f(t) = t^\alpha - 1$ is convex with $f(1) = 0$, so $D_f = \mathbb{E}_Q[r^\alpha] - 1$ and $D_\alpha = \frac{1}{\alpha-1}\ln(1 + D_f)$, an increasing function of D_f. For $0 < \alpha < 1$, t^α is concave, so use the convex $f(t) = 1 - t^\alpha$. Then $D_f = 1 - \mathbb{E}_Q[r^\alpha]$ and $D_\alpha = \frac{1}{\alpha-1}\ln(1 - D_f)$, again increasing in D_f (the logarithm decreases in D_f, and $\frac{1}{\alpha-1}$ is negative).

Non-negativity. $D_f(P\|Q) \geq 0$, with equality when $P = Q$.

The hockey-stick curves determine every f-divergence (can wait for a second reading). The idea is that any convex f can be built from hockey-stick shapes $(t-\gamma)_+$ and $(\gamma-t)_+$, one bend at each γ, weighted by how sharply f bends there, its second derivative $f''(\gamma)$. Averaging each hockey stick under Q gives a hockey-stick divergence, so the f-divergence is a weighted sum of them. If f is twice differentiable,

$$D_f(P\|Q) = \int_1^\infty f''(\gamma)\, E_\gamma(P\|Q)\,\mathrm{d}\gamma + \int_0^1 \gamma f''(\gamma)\, E_{1/\gamma}(Q\|P)\,\mathrm{d}\gamma. \tag{3.27}$$

3.9.3. Derivation

Non-negativity. Jensen (Fact 2) says the average of a convex function is at least the function of the average, and Fact 1 says r averages to 1 under Q. So $\mathbb{E}_Q[f(r)] \geq f(\mathbb{E}_Q[r]) = f(1) = 0$.

Equation 3.27. The plan is to write $f(t)$ as hockey sticks for each fixed t, then put in $t = r(X)$ and average.

1. **Taylor's theorem around $t = 1$.** With the remainder written as an integral, $f(t) = f(1) + f'(1)(t-1) + \int_1^t f''(\gamma)(t-\gamma)\,\mathrm{d}\gamma$: the value at 1, the tangent line, and the curvature accumulated between 1 and t.
2. **Rewrite the remainder with hockey sticks,** so that one formula holds for all t at once: it equals $\int_1^\infty f''(\gamma)(t-\gamma)_+\,\mathrm{d}\gamma + \int_0^1 f''(\gamma)(\gamma-t)_+\,\mathrm{d}\gamma$. For $t \geq 1$, $(t-\gamma)_+$ is zero past $\gamma = t$, so the first integral is the remainder and the second is zero. For $t < 1$, swapping the limits of $\int_1^t$ flips the sign of $(t-\gamma)$ into $(\gamma-t)$ on $[t, 1]$, which is the second integral, and the first is zero.
3. **Average under Q.** Put $t = r(X)$ and average. $f(1) = 0$, and $\mathbb{E}_Q[r-1] = 0$ by Fact 1, so the first two terms vanish.
4. **The first integral.** $\mathbb{E}_Q[(r-\gamma)_+] = E_\gamma(P\|Q)$ by definition.
5. **The second integral.** $\mathbb{E}_Q[(\gamma-r)_+] = \sum(\gamma q - p)_+ = \gamma\sum(q - p/\gamma)_+ = \gamma E_{1/\gamma}(Q\|P)$, the hockey-stick divergence in the other direction.

Concretely, KL on the die. For $f(t) = t\ln t$, $f'(t) = \ln t + 1$ and $f''(\gamma) = 1/\gamma$. From Section 3.8, $E_\gamma(P\|Q) = \frac{1}{2} - \frac{\gamma}{6}$ for $1 \leq \gamma \leq 3$ and 0 beyond. In the other direction, $q/p = \frac{5}{3}$ on rolls 1–5 and $\frac{1}{3}$ on the six. For $\gamma \leq 1$, the term $(q - p/\gamma)_+$ is positive on a non-six when $\frac{1}{6} > \frac{0.1}{\gamma}$, that is when $\gamma > 0.6$, and never on the six. So $E_{1/\gamma}(Q\|P) = 5(\frac{1}{6} - \frac{0.1}{\gamma})_+ = \frac{5}{6} - \frac{1}{2\gamma}$ for $\gamma > 0.6$. The weight $\gamma f''(\gamma)$ is 1. Then

$$\int_1^3 \frac{1}{\gamma}\Big(\frac{1}{2} - \frac{\gamma}{6}\Big)\mathrm{d}\gamma + \int_{0.6}^1 \Big(\frac{5}{6} - \frac{1}{2\gamma}\Big)\mathrm{d}\gamma = \Big(\tfrac{1}{2}\ln 3 - \tfrac{1}{3}\Big) + \Big(\tfrac{1}{3} - \tfrac{1}{2}\ln\tfrac{5}{3}\Big) = \tfrac{1}{2}\ln 1.8 = 0.2939, \tag{3.28}$$

the KL computed directly. The first integral is $\frac{1}{2}\ln 3 - \frac{2}{6}$; the second is $\frac{5}{6} \times 0.4 - \frac{1}{2}\ln\frac{1}{0.6}$; and $\ln 3 - \ln\frac{5}{3} = \ln 1.8$. The script repeats the integral numerically and also gets 0.2939.

3.9.4. Interpretation

Each f weights the likelihood ratio differently (Figure 3.9). χ^2 grows quadratically in t, so it is dominated by outcomes with large ratios; on the die it is 0.80, the largest entry in Table 3.11. TV and E_γ grow linearly and ignore everything below a threshold. Reverse KL blows up as $t \to 0$, so it punishes outcomes that P almost never produces.

The E_γ curves are complete information. By Equation 3.27, if you know E_γ in both directions for all $\gamma \geq 1$, you know every f-divergence, and so every Rényi divergence. Later parts use this to move between different ways of saying two distributions are close.

f-divergences are also used to train models. They have a variational form, $D_f(P\|Q) = \sup_T \left(\mathbb{E}_P[T] - \mathbb{E}_Q[f^*(T)]\right)$, where $f^*(u) = \sup_t \left(ut - f(t)\right)$ is the convex conjugate of f and the supremum runs over functions T of the outcome. Both expectations can be estimated from samples, so a divergence can be estimated without knowing either density. Estimating the supremum with a neural network T from samples is how a variant of the generative adversarial network (GAN), the f-GAN, trains generative models (Nowozin, Cseke & Tomioka, 2016).

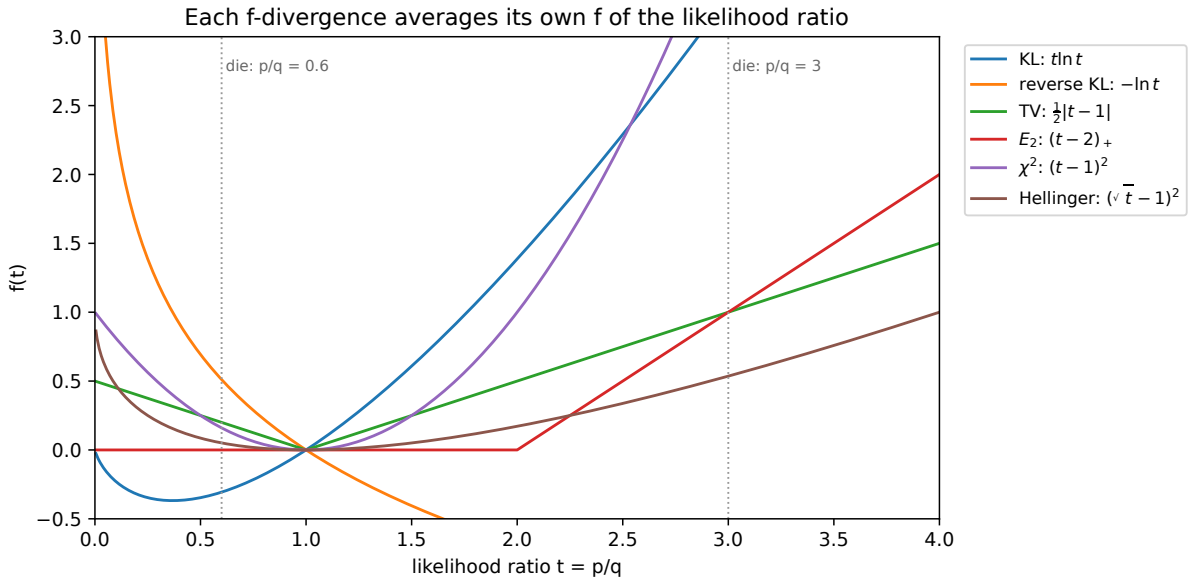

Figure 3.9.: The generator functions f of six f-divergences, as functions of the likelihood ratio $t = p/q$. All are convex and vanish at $t = 1$. The dotted lines mark the two likelihood ratios of the loaded die.

3.9.5. Check yourself

- Why does $f(t) = t \ln t$ give $D_{\mathrm{KL}}(P\|Q)$ when the definition averages under Q? *($\mathbb{E}_Q[r \ln r] = \mathbb{E}_P[\ln r]$ by Fact 1.)*
- Adding $c(t-1)$ to f gives a different function. Does it change D_f? *(No: $\mathbb{E}_Q[c(r-1)] = 0$. So TV can equally use $f(t) = (t-1)_+$.)*

3.10. The data-processing inequality

3.10.1. Context

You rarely look at raw data. You bin it, compute features, threshold a score, or pass it through a randomized algorithm. The **data processing inequality** (DPI) says that none of this can make two distributions easier to tell apart. The reason is simple. When processing maps several inputs to the same output, the output's likelihood ratio is an *average* of the inputs' likelihood ratios. Averaging pulls strong evidence toward weak evidence: a six (ratio 3) reported together with a two and a four (ratio 0.6 each) becomes a moderate ratio of $(3 + 0.6 + 0.6)/3 = 1.4$. Every divergence is a convex summary of the ratios, and by Jensen, averaging first can only make a convex summary smaller. This is the most used property of divergences. It turns "any processing" into "no gain", without knowing what the processing is.

3.10.2. Statement

Processing may be random, so describe it by its output probabilities. A **channel** (or Markov kernel) K maps each input x to a distribution $K(\cdot \mid x)$ over outputs y. A deterministic function is the special case $K(y \mid x) = \mathbf{1}[y = g(x)]$. Feeding $X \sim P$ through K gives the output distribution $PK(y) = \sum_x p(x)K(y \mid x)$, and likewise QK. The inequality says the outputs are never further apart than the inputs. For every f-divergence and every channel,

$$D_f(PK \| QK) \le D_f(P \| Q). \tag{3.29}$$

The same holds for every Rényi divergence D_α, including D_∞. Equality holds when the processing keeps the likelihood ratio: when $r(x)$ can be computed from y. Such a y is a **sufficient statistic**.

A useful special case. The coarsest processing reports only whether an event A happened. That turns P and Q into two coins, with probabilities of heads $\Pr_P[A]$ and $\Pr_Q[A]$, and the KL between two coins with heads probabilities a and b is the **binary KL** $\mathrm{kl}(a\|b)$. So for every event A,

$$D_{\mathrm{KL}}(P\|Q) \ge \mathrm{kl}(\Pr_P[A] \,\|\, \Pr_Q[A]), \qquad \mathrm{kl}(a\|b) = a \ln \frac{a}{b} + (1-a) \ln \frac{1-a}{1-b}. \tag{3.30}$$

3.10.3. Derivation

1. **The output's likelihood ratio is an average of the input's.** For each output y, write $p(x) = q(x)r(x)$ inside $PK(y)$ and divide by $QK(y)$:

$$r_Y(y) = \frac{PK(y)}{QK(y)} = \sum_x \frac{q(x)K(y \mid x)}{QK(y)}\, r(x) = \mathbb{E}\big[r(X) \mid Y = y\big], \tag{3.31}$$

   where (X, Y) is drawn as $X \sim Q$, then $Y \sim K(\cdot \mid X)$. The weights $q(x)K(y \mid x)/QK(y)$ are exactly the conditional probabilities of X given $Y = y$ (Bayes' rule), so the sum is a conditional average.
2. **Jensen, conditionally.** Fact 2 holds for any distribution, in particular for the conditional distribution of X given $Y = y$. For convex f, the function of an average is at most the average of the function: $f(r_Y(y)) = f(\mathbb{E}[r(X) \mid Y = y]) \le \mathbb{E}[f(r(X)) \mid Y = y]$.

3. **Average over $Y \sim QK$.** The left side becomes $\mathbb{E}_{QK}[f(r_Y)] = D_f(PK\|QK)$. On the right, averaging the conditional averages over Y gives the overall average (the tower property), $\mathbb{E}_Q[f(r(X))] = D_f(P\|Q)$.
4. **Rényi.** D_α is an increasing function of an f-divergence (Section 3.9), so the inequality carries over. For D_∞, take $\alpha \to \infty$.
5. **Equality.** If $r(x)$ is a function of y, then $r(X)$ is constant given $Y = y$, and Jensen in step 2 holds with equality.

Concretely, on the die. Report only whether the roll is odd or even (Table 3.12).

Table 3.12.: Processing the die roll into its parity averages the likelihood ratio within each output.

y	Rolls	$PK(y)$	$QK(y)$	$r_Y = PK(y)/QK(y)$	Average of r over the rolls, Q-weighted
even	2, 4, 6	0.7	0.5	1.4	$(0.6 + 0.6 + 3)/3 = 1.4$
odd	1, 3, 5	0.3	0.5	0.6	$(0.6 + 0.6 + 0.6)/3 = 0.6$

The ratios 0.6 and 3 on the even rolls are averaged into 1.4: the strong evidence of a six is diluted by the twos and fours. The KL of the parity is computed like any KL, as the P-weighted average of $\ln r_Y$, and drops from 0.2939 to $0.7 \ln 1.4 + 0.3 \ln 0.6 = 0.0823$. If instead you report only whether the roll is a six, nothing is lost: r depends only on that bit, so the bit is sufficient, and the KL stays at $\mathrm{kl}(0.5\|\frac{1}{6}) = 0.5 \ln 3 + 0.5 \ln 0.6 = 0.2939$.

3.10.4. Interpretation

There is no free lunch from processing. A feature extractor, a summary statistic or a quantizer can only lose information about which of two distributions produced the data. Any accuracy you get from a processed output, you could have got from the raw input, by applying the same processing yourself.

Randomized processing is included. The channel can use its own randomness, as long as that randomness does not depend on whether the input came from P or Q: the channel K is the same in both worlds.

The special case gives lower bounds from a single event. $D_{\mathrm{KL}} \geq \mathrm{kl}(\Pr_P[A]\|\Pr_Q[A])$ says: if the divergence is small, then no event can have very different probabilities under P and Q. Hypothesis testing uses this form to bound the errors of any test.

3.10.5. Example: binning a Gaussian

$P = \mathcal{N}(0, 1)$ and $Q = \mathcal{N}(1, 1)$ have KL $1^2/2 = 0.5$. Suppose a sensor reports x only to a resolution w: it rounds x into bins of width w, with an edge at the midpoint $\frac{1}{2}$. Within each bin, the log-likelihood ratio, a straight line for the raw data, is replaced by a single level (Figure 3.10).

The wider the bins, the more evidence is averaged away. Table 3.13 gives the KL between the binned distributions, from the script.

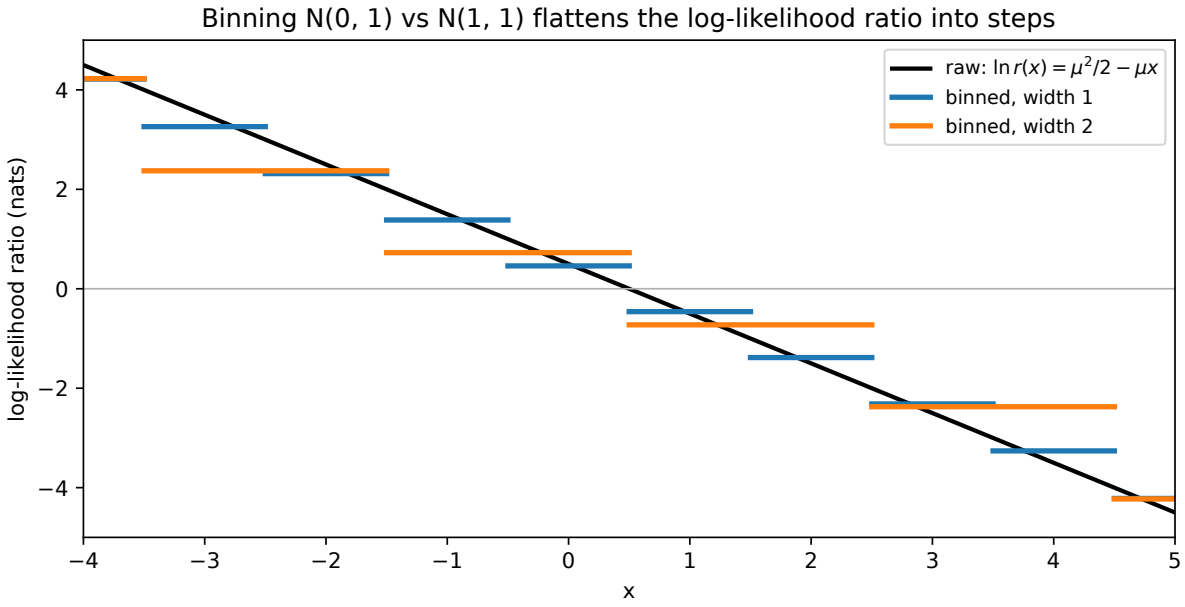

Figure 3.10.: The log-likelihood ratio of $\mathcal{N}(0,1)$ against $\mathcal{N}(1,1)$, raw (black line) and after rounding x into bins of width 1 and 2. Each bin reports one value, the log of the Q-weighted average of r over the bin, so the line becomes a staircase. Wider bins give flatter steps and less evidence.

Table 3.13.: KL between $\mathcal{N}(0,1)$ and $\mathcal{N}(1,1)$ after rounding x into bins.

Bin width w	0.5	1	2	one bit: $x < \frac{1}{2}$?	raw
KL after binning	0.4898	0.4618	0.3781	0.3090	0.5

Coarser bins lose more, but slowly: a single bit, the threshold at the midpoint, keeps 62% of the KL ($0.3090/0.5 = 0.618$, Figure 3.11). That bit is the best single-shot test from the total variation section, and it keeps all of the TV, since TV is attained by that very event. So the same processing can keep one divergence whole while losing 38% of another: different divergences lose different amounts.

3.10.6. Check yourself

- Is the DPI violated if a processing step increases the *accuracy* of some particular classifier? *(No. The DPI bounds the best accuracy over all tests. A processing step can help a bad classifier, but it cannot beat the best test on the raw data.)*
- Why is the sample mean of n Gaussian observations lossless for telling $\mathcal{N}(0,1)$ from $\mathcal{N}(\mu,1)$? *(The log-likelihood ratio of the sample is a function of the sample mean, so it is sufficient and the DPI holds with equality.)*

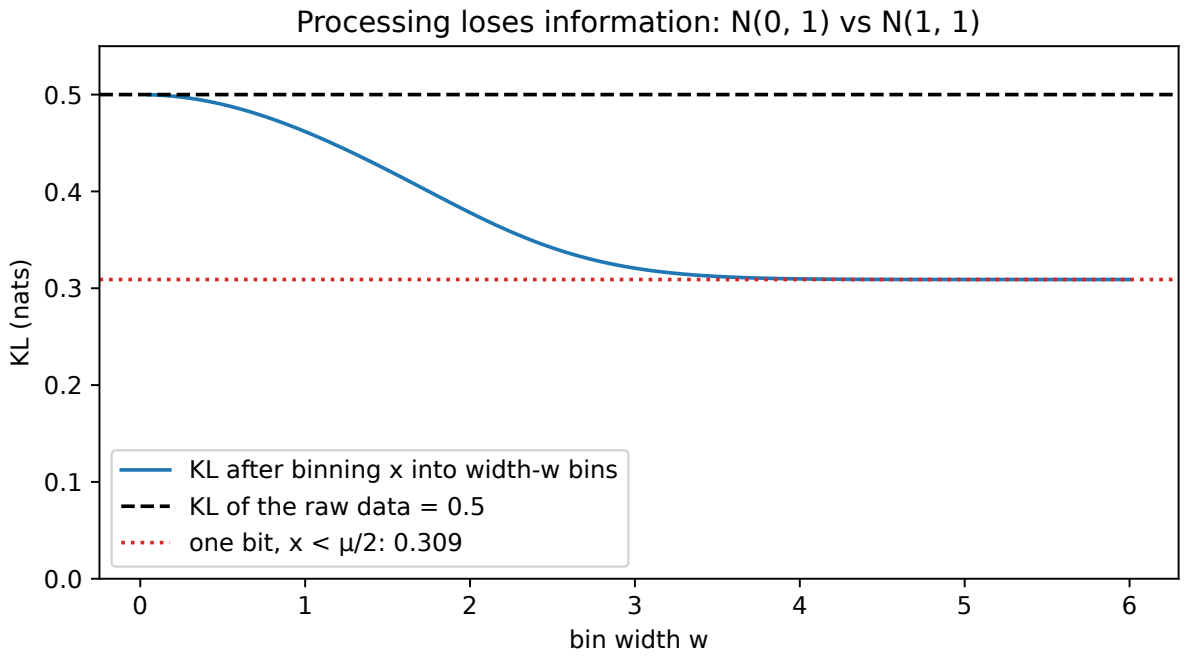

Figure 3.11.: KL between $\mathcal{N}(0,1)$ and $\mathcal{N}(1,1)$ after rounding the observation into bins of width w. It never exceeds the raw-data value 0.5, and it falls to the one-bit value 0.309 as the bins grow.

3.11. Pinsker's inequality

3.11.1. Context

KL is easy to compute and adds up over samples. TV is what you want: it is the accuracy of the best test and the largest change in any bounded statistic. **Pinsker's inequality** converts the first into a bound on the second.

3.11.2. Statement

Pinsker's inequality says that TV is at most the square root of half the KL. The square root is there because, for nearby distributions, TV grows linearly in the difference while KL grows quadratically, as the derivation shows:

$$\mathrm{TV}(P,Q) \le \sqrt{\tfrac{1}{2} D_{\mathrm{KL}}(P\|Q)}. \tag{3.32}$$

For large KL, where Equation 3.32 exceeds 1 and says nothing (TV is never above 1), use the **Bretagnolle–Huber** inequality, which stays below 1 for every KL:

$$\mathrm{TV}(P,Q) \le \sqrt{1 - e^{-D_{\mathrm{KL}}(P\|Q)}}. \tag{3.33}$$

3.11.3. Derivation

Why a square root. Before the proof, here is where the shape comes from. Let P be close to Q, and write $r = 1 + h$ with h small: $h(x)$ is the relative difference between p and q at x. Then $\mathbb{E}_Q[h] = \mathbb{E}_Q[r] - 1 = 0$ by Fact 1.

1. *TV is linear in h:* $\mathrm{TV} = \frac{1}{2}\mathbb{E}_Q|r-1| = \frac{1}{2}\mathbb{E}_Q|h|$, by the form $\frac{1}{2}\sum|p-q| = \frac{1}{2}\sum q|r-1|$.
2. *KL is quadratic in h:* $D_{\mathrm{KL}} = \mathbb{E}_P[\ln r] = \mathbb{E}_Q[r \ln r]$ by Fact 1. For small h, $\ln(1+h) = h - \frac{h^2}{2} + O(h^3)$, so $(1+h)\ln(1+h) = h + \frac{h^2}{2} + O(h^3)$. The first term averages to 0, so $D_{\mathrm{KL}} \approx \frac{1}{2}\mathbb{E}_Q[h^2]$.
3. *Compare:* the average of $|h|$ is at most the root of the average of h^2 (Cauchy–Schwarz, or Jensen with the convex function y^2): $\mathbb{E}_Q|h| \le \sqrt{\mathbb{E}_Q[h^2]}$. So $\mathrm{TV} \lesssim \frac{1}{2}\sqrt{2D_{\mathrm{KL}}} = \sqrt{D_{\mathrm{KL}}/2}$.

That is Pinsker's inequality for nearby distributions, constant included. The proof below makes it exact for all P and Q.

Pinsker. The plan is to reduce any pair to a pair of coins, where the inequality is a one-variable calculus fact.

1. **Reduce to two outcomes.** Let $A^* = \{p > q\}$, $a = \Pr_P[A^*]$ and $b = \Pr_Q[A^*]$. By Fact 3, this event attains the TV, so $\mathrm{TV} = a - b$. Reporting only whether $x \in A^*$ turns P and Q into coins with heads probabilities a and b, and by the special case of the data-processing inequality (Section 3.10) this can only lower KL: $D_{\mathrm{KL}}(P\|Q) \ge \mathrm{kl}(a\|b)$. So it is enough to show $\mathrm{kl}(a\|b) \ge 2(a-b)^2$ for all $a, b \in (0,1)$.
2. **Fix a and vary b.** Let $g(b) = \mathrm{kl}(a\|b) - 2(a-b)^2$, the gap we want to show is non-negative. Then $g(a) = 0$, because two equal coins have zero KL.
3. **Differentiate:** $\frac{\mathrm{d}}{\mathrm{d}b}\mathrm{kl}(a\|b) = -\frac{a}{b} + \frac{1-a}{1-b} = \frac{b-a}{b(1-b)}$, and $\frac{\mathrm{d}}{\mathrm{d}b}(-2(a-b)^2) = 4(a-b)$, so
$$g'(b) = (b-a)\left(\frac{1}{b(1-b)} - 4\right). \tag{3.34}$$
4. **Sign:** $b(1-b) \le \frac{1}{4}$ (a product of two numbers that add to 1 is largest when both are $\frac{1}{2}$), so the bracket is ≥ 0. Then $g' \le 0$ for $b < a$ and $g' \ge 0$ for $b > a$: g decreases to its minimum at $b = a$, where it is 0, and increases after. So $g \ge 0$.
5. **Combine:** $D_{\mathrm{KL}} \ge \mathrm{kl}(a\|b) \ge 2(a-b)^2 = 2\,\mathrm{TV}^2$, which rearranges to Equation 3.32.

Bretagnolle–Huber. The plan is to bound the overlap $\sum\sqrt{pq}$ from both sides: above by TV, below by KL.

1. **Split into min and max.** At each x, $\min(p,q)\cdot\max(p,q) = pq$, so $\sqrt{pq} = \sqrt{\min(p,q)}\sqrt{\max(p,q)}$. The Cauchy–Schwarz inequality, $\left(\sum_x u_x v_x\right)^2 \le \sum_x u_x^2 \sum_x v_x^2$, then gives $\left(\sum_x \sqrt{pq}\right)^2 \le \sum_x \min(p,q) \cdot \sum_x \max(p,q)$.
2. **Express in TV.** $\sum\min(p,q) = 1 - \mathrm{TV}$ and $\sum\max(p,q) = 1 + \mathrm{TV}$, since $\min + \max = p + q$ sums to 2 and $\max - \min = |p-q|$ sums to $2\,\mathrm{TV}$. So $\left(\sum\sqrt{pq}\right)^2 \le (1-\mathrm{TV})(1+\mathrm{TV}) = 1 - \mathrm{TV}^2$.
3. **Express in KL.** $\sum_x \sqrt{pq} = \sum_x p\sqrt{q/p} = \mathbb{E}_P[e^{-L/2}]$. The function $e^{-y/2}$ is convex, so by Jensen $\mathbb{E}_P[e^{-L/2}] \ge e^{-\mathbb{E}_P[L]/2} = e^{-D_{\mathrm{KL}}/2}$.
4. **Combine:** squaring step 3 and using step 2, $e^{-D_{\mathrm{KL}}} \le 1 - \mathrm{TV}^2$, which rearranges to Equation 3.33.

3.11.4. Interpretation: how tight are these?

Near zero, Pinsker has the right shape. Take two coins with heads probabilities $\frac{1}{2} \pm \frac{\xi}{2}$. They differ by ξ on each side, so TV $= \xi$. For coins near $\frac{1}{2}$, the binary KL is about the squared difference divided by $2 \times \frac{1}{2} \times \frac{1}{2}$, so KL $\approx 2\xi^2$, and Equation 3.32 gives $\sqrt{\xi^2} = \xi$: it is tight as $\xi \to 0$, and the constant $\frac{1}{2}$ cannot be improved. In the square-root argument above, this is the case where $|h|$ is the same on every outcome, so Cauchy–Schwarz is an equality. For the Laplace pair, KL $\approx t^2/2$ and TV $= 1 - e^{-t/2} \approx t/2$ for small t, and Pinsker gives $\sqrt{t^2/4} = t/2$, so it is also nearly tight there.

For large KL, Pinsker is useless. It passes 1 at KL $= 2$ ($\sqrt{2/2} = 1$), while TV can never exceed 1. Bretagnolle–Huber is always at most 1, and solving for where the two bounds cross shows it is better than Pinsker once KL is above 1.59 (Figure 3.12).

For Gaussians, Pinsker loses a constant factor. KL $= \mu^2/2$ gives the bound $\sqrt{\mu^2/4} = \mu/2$, while the exact TV is $2\Phi(\mu/2) - 1$. For small μ the normal density near 0 is about its peak height $1/\sqrt{2\pi}$, so $2\Phi(\mu/2) - 1 \approx \mu/\sqrt{2\pi} \approx 0.40\mu$. Here $|h|$ varies across outcomes, so Cauchy–Schwarz has slack.

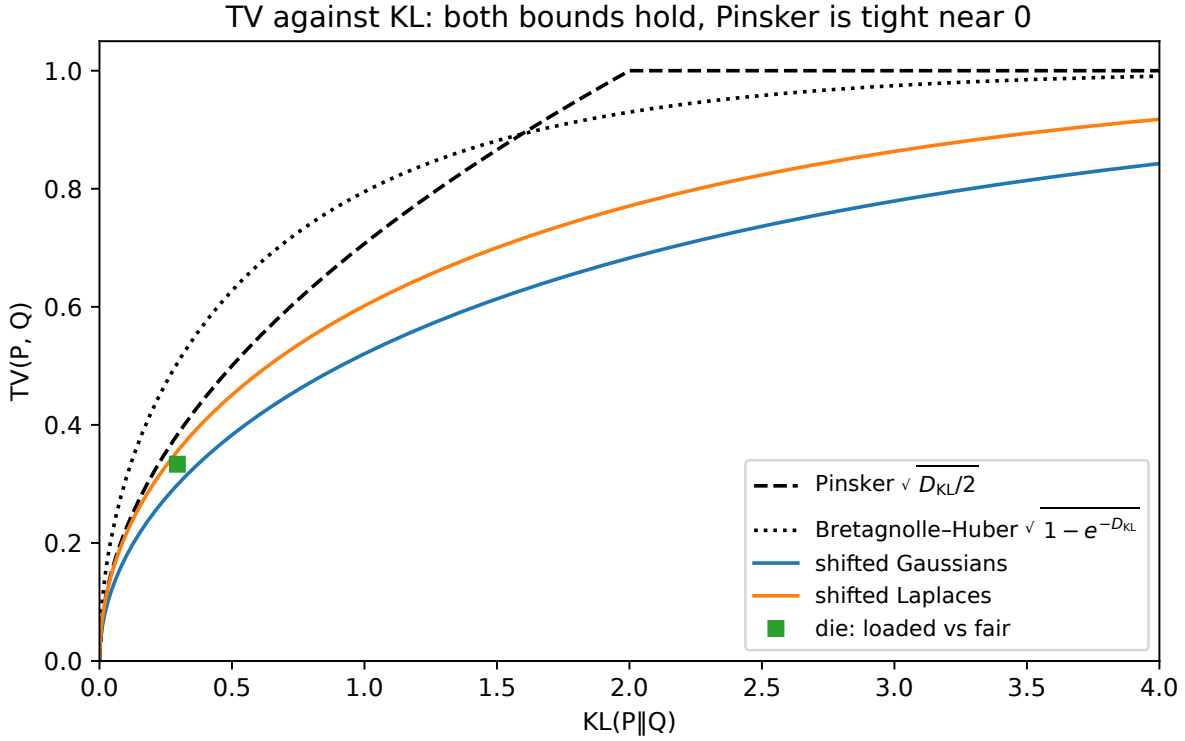

Figure 3.12.: Total variation against KL for shifted Gaussian pairs, shifted Laplace pairs and the die, with the Pinsker and Bretagnolle–Huber bounds. Every pair lies below both bounds; Pinsker is close near KL $= 0$ and vacuous beyond KL $= 2$.

3.11.5. Example: how many samples to tell two distributions apart?

KL is additive, so n i.i.d. samples have $D_{\mathrm{KL}}(P^n\|Q^n) = n\,D_{\mathrm{KL}}(P\|Q)$, and Pinsker gives $\mathrm{TV}(P^n,Q^n) \le \sqrt{n\,D_{\mathrm{KL}}(P\|Q)/2}$. By Equation 3.21, the best accuracy is at most $\frac{1}{2}+\frac{1}{2}\sqrt{n\,D_{\mathrm{KL}}(P\|Q)/2}$. For that bound to get close to 1, $n\,D_{\mathrm{KL}}(P\|Q)$ must be of order 1, so getting accuracy close to 1 needs n on the order of $1/D_{\mathrm{KL}}(P\|Q)$, whatever test you use.

For $\mathcal{N}(0,1)$ against $\mathcal{N}(0.1,1)$, $D_{\mathrm{KL}}(P\|Q) = 0.1^2/2 = 0.005$, and Table 3.14 compares the bounds with the exact TV. For example, at $n = 100$ Pinsker gives $\sqrt{0.5/2} = 0.5$ and Bretagnolle–Huber gives $\sqrt{1-e^{-0.5}}$.

Table 3.14.: Exact total variation between n samples of $\mathcal{N}(0,1)$ and of $\mathcal{N}(0.1,1)$, and the two bounds computed from KL.

n	$D_{\mathrm{KL}}(P^n\|Q^n)$	Exact TV	Pinsker	Bretagnolle–Huber
100	0.50	0.3829	0.5000	0.6273
400	2.00	0.6827	1.0000	0.9299

At $n = 100$ Pinsker overstates TV by 31% ($0.5000/0.3829 = 1.31$). At $n = 400$ it is vacuous, and Bretagnolle–Huber still gives a non-trivial bound. Figure 3.6 (right) shows the Pinsker bound on accuracy over the whole range of n. The same comparison for single pairs: Gaussian $\mu = 1$, TV 0.3829 against Pinsker 0.5000; Laplace $t = 1$, TV 0.3935 against 0.4289; the die, TV 0.3333 against 0.3833.

3.11.6. Check yourself

- Why is the reduction to two outcomes in step 1 of the Pinsker derivation free? *(TV is attained by the single event A^*, so processing the data into the bit "$x \in A^*$?" keeps TV exactly, and the DPI says it can only lower KL.)*
- Pinsker bounds TV by KL. Can you bound KL by TV? *(Not in general. Let Q move probability 10^{-9} from P onto an outcome where P puts none. Then TV $= 10^{-9}$, but $D_{\mathrm{KL}}(Q\|P) = \infty$.)*

3.12. Code: check every divergence by computation and simulation

The script code/divergences.py computes every number in this chapter and draws every figure. Each divergence is a small typed function. The closed forms for Gaussian and Laplace pairs are checked against Monte Carlo averages and against each other, and the figures loop the same functions over parameters. From the repository root:

```
uv run python code/part01-prerequisites/divergences.py
```

Output (seed 0), summarized in Table 3.15:

Table 3.15.: The script's output with the default seed.

Experiment	Result
Die, loaded ‖ fair	KL 0.2939; reverse KL 0.2426; TV 0.3333; χ^2 0.8000; H^2 0.1317; E_2 0.1667; E_3 0; Rényi orders in Table 3.6
Die, power means of r under P	Harmonic 1.0000; geometric 1.3416; arithmetic 1.8000; maximum 3.0000
Die, evidence per roll	Loaded die: mean 0.2939, standard deviation 0.8047, $(\text{sd}/\text{mean})^2 = 7.50$. Fair die: evidence for "loaded" has mean -0.2426, standard deviation 0.5998
Die, KL rebuilt from the E_γ curves (Equation 3.27)	0.2939
Die, after processing	Parity: KL 0.0823. "Is it a six?": KL 0.2939
Gaussians, $\mu = 1$	KL 0.5000 (Monte Carlo 0.4990); D_2 1.0000; D_{10} 5.0000; TV 0.3829; best accuracy 0.6915; E_2 0.1906 (Monte Carlo 0.1892); E_4 0.0692
Gaussians, $\mu = 1$, $\Pr_Q[L \geq 2]$	Exact 0.0062; Markov 0.1353; Rényi–Chernoff 0.0439 at $\alpha = 2.5$
Gaussians, $\mu = 1$, binned	Width 0.5: 0.4898; width 1: 0.4618; width 2: 0.3781; one bit: 0.3090
Laplace, $t = 1$	KL 0.3679 (Monte Carlo 0.3684); $D_{0.5}$ 0.1891; D_2 0.6191; D_{10} 0.9287; D_∞ 1; TV 0.3935; E_2 0.1422
n samples, $\mu = 0.1$	$n = 100$: accuracy 0.6915, simulated 0.6916. $n = 400$: accuracy 0.8413, simulated 0.8424
Fitting one Gaussian to two bumps	Forward: $\mu = 0.00$, $\sigma = 2.06$. Reverse: $\mu = 2.00$, $\sigma = 0.50$

tests/test_divergences.py checks that the output still matches.

What to take from it. First, the closed forms are right. Every Monte Carlo average agrees with its formula to within 0.0015, about the sampling error of a million draws, and KL rebuilt from the hockey-stick curves matches KL computed directly. Second, Rényi divergences really are means of one ratio: on the die, the harmonic, geometric and arithmetic means and the maximum of r give D_0, KL, D_2 and D_∞.

Third, processing only loses. Parity throws away more than 70% of the KL of the die, while the sufficient bit "is it a six?" keeps all of it. Fourth, the bulk and the worst case can disagree. The Laplace pair is further apart than the Gaussian pair at low orders and closer at high orders, so which pair is "more different" depends on the divergence you ask. Finally, direction matters: forward and reverse KL give opposite fits to the same data.

3.14. Cheat sheet

$r = p/q$ is the likelihood ratio and $L = \ln r$ the log-likelihood ratio, the evidence for P. Gaussian pair: $\mathcal{N}(0, \sigma^2) \parallel \mathcal{N}(s, \sigma^2)$ with $\mu = s/\sigma$. Laplace pair: $\mathrm{Lap}(0, b) \parallel \mathrm{Lap}(s, b)$ with $t = s/b$. Table 3.16 collects every divergence.

Table 3.16.: Every divergence in this chapter, with its closed form for the shifted Gaussian and Laplace pairs.

Divergence	Definition	Gaussian pair	Laplace pair	Key property
KL	$\mathbb{E}_P[L]$	$\mu^2/2$	$t + e^{-t} - 1$	≥ 0; additive; maximum likelihood minimizes it
Rényi D_α	$\frac{1}{\alpha-1} \ln \mathbb{E}_Q[r^\alpha] = \ln \left(\mathbb{E}_P[r^{\alpha-1}]\right)^{1/(\alpha-1)}$	$\alpha\mu^2/2$	Equation 3.19	Log of a power mean of r; non-decreasing in α; additive; \$D_1 = \$ KL
Max-divergence D_∞	$\ln \max r = \ln \max_A \frac{P(A)}{Q(A)}$	∞	t	Worst-case ratio over all events

Divergence	Definition	Gaussian pair	Laplace pair	Key property
TV	$\max_A \lvert\Pr_P[A] - \Pr_Q[A]\rvert = \frac{1}{2}\sum\lvert p-q\rvert$	$2\Phi(\mu/2) - 1$	$1 - e^{-t/2}$	Best accuracy $\frac{1}{2} + \frac{1}{2}$TV; \$1 - \$ overlap; a metric
Hockey-stick E_γ	$\max_A[\Pr_P[A] - \gamma \Pr_Q[A]] = \mathbb{E}_Q[(r-\gamma)_+]$	$\Phi(\frac{\mu}{2} - \frac{\ln\gamma}{\mu}) - \gamma\Phi(-\frac{\mu}{2} - \frac{\ln\gamma}{\mu})$	$(1 - e^{-(t-\ln\gamma)/2})_+$	\$E_1 = \$ TV; 0 for $\gamma \geq e^{D_\infty}$
f-divergence D_f	$\mathbb{E}_Q[f(r)]$, f convex, $f(1) = 0$	—	—	Contains KL, TV, E_γ, χ^2, H^2

Inequalities

- Data processing: $D_f(PK\|QK) \leq D_f(P\|Q)$ for every f-divergence, and the same for every D_α; equality for sufficient statistics.
- Pinsker: $\mathrm{TV}(P,Q) \leq \sqrt{D_{\mathrm{KL}}(P\|Q)/2}$. Bretagnolle–Huber: $\mathrm{TV}(P,Q) \leq \sqrt{1 - e^{-D_{\mathrm{KL}}(P\|Q)}}$.
- Log-likelihood tail: $\Pr_Q[L \geq c] \leq \exp(-\alpha c + (\alpha-1)D_\alpha(P\|Q))$ for every $\alpha > 0$.
- Skew symmetry: $D_\alpha(P\|Q) = \frac{\alpha}{1-\alpha} D_{1-\alpha}(Q\|P)$ for $0 < \alpha < 1$.

Rules of thumb

- KL is the rate at which evidence accumulates; telling two distributions apart takes about $1/D_{\mathrm{KL}}(P\|Q)$ samples.
- Compute in KL or Rényi, where independent samples add; convert to TV at the end.
- The Rényi order is a dial from typical evidence ($\alpha \to 1$) to the worst case ($\alpha \to \infty$).
- A bounded likelihood ratio (Laplace) gives a finite max-divergence; an unbounded one (Gaussian) gives finite D_α for every finite α but $D_\infty = \infty$.
- Processing averages likelihood ratios together, so it can never increase a divergence.
- Maximum likelihood minimizes forward KL and covers all modes; variational inference minimizes reverse KL and picks one.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

4. Hypothesis testing

4.1. Why this matters

A spam filter sees an email and must say "ham" or "spam". A fraud detector sees a transaction and must say "normal" or "fraud". A medical test reads a biomarker and must say "healthy" or "ill". A monitoring job sees a batch of sensor readings and must say "calibrated" or "drifted". Each one is the same problem: **an observation came from one of two distributions, and you must decide which.** Hypothesis testing is the mathematics of that decision. It starts by naming the two kinds of mistake a decision rule can make and measuring how often it makes each. It then asks what the best possible rule is and how good it can be. Finally, it asks how to summarize and compare real rules, and how to estimate their error rates from a finite amount of data.

The whole chapter rests on one idea. Write $p(x)$ for the probability of observing x under the first distribution and $q(x)$ for its probability under the second. The ratio $q(x)/p(x)$, called the **likelihood ratio**, says how many times more likely the observation is under the second distribution than under the first, and **it is the only thing about the observation that matters.** The Neyman–Pearson lemma, proved below, says that the best rule compares this ratio with a threshold. Moving the threshold trades one kind of mistake for the other, and the best rules at all thresholds together trace a curve that is fixed by the two distributions alone. Every one-number summary of a rule, from the best advantage to the area under the curve (AUC) to the probability that an alarm is right, is read off that curve. Table 4.1 lists the results and where each is used. Later parts ask how well *any* test can distinguish two distributions; the trade-off curve built here is the answer.

Table 4.1.: The results in this chapter and where they are used.

Result	Typical use
Type I/II errors, power	Reading any detector's confusion matrix
Neyman–Pearson lemma	Designing the optimal detector; proving that nothing beats it
Likelihood-ratio test	Score thresholds, sequential and multi-sample tests
Trade-off function $T(P, Q)$	The whole error trade-off between two distributions, as one curve
Gaussian and Laplace trade-off curves	Closed-form reference curves for shifted noise
Best advantage = total variation	A one-number summary of distinguishability

Result	Typical use
Receiver operating characteristic (ROC) curve, AUC, true positive rate at a low false positive rate	Comparing classifiers and detectors honestly
Bayesian view	Turning error rates into posterior probabilities at a given base rate
Confidence intervals for rates	Reporting measured error rates with their uncertainty

The distributions used here are in Probability distributions, the tail bounds and confidence intervals in Concentration inequalities, and total variation and Kullback–Leibler (KL) divergence in Divergences. Each is restated below where it is used.

4.2. Toolkit: four facts every derivation uses

The derivations below reuse four facts. Each is stated and proved once here, with a small running example.

The running example. A spam filter counts suspicious words in an email, capped at 3. The default assumption is that an email is ham; this is the **null hypothesis** H_0, under which the count X has distribution P. The **alternative** H_1 is that the email is spam, under which X has distribution Q. Table 4.2 gives both, and their likelihood ratio $\Lambda(x) = q(x)/p(x)$, with the alternative on top so that large values point to H_1. (Divergences writes the ratio the other way up, as $r(x) = p(x)/q(x)$, and its logarithm as $L(x)$; here Λ is always the plain ratio q/p.) Spam tends to have more suspicious words, so the ratio grows with the count: a count of 3 is four times as likely in spam as in ham, a count of 0 a quarter as likely.

Table 4.2.: Word-count distributions under ham (P) and spam (Q), and their likelihood ratio.

x	0	1	2	3
$p(x)$, ham	0.4	0.3	0.2	0.1
$q(x)$, spam	0.1	0.2	0.3	0.4
$\Lambda(x) = q(x)/p(x)$	0.250	0.667	1.500	4.000

4.2.1. Fact 1 — A test is a function, and its errors are expectations

The simplest decision rule picks a set R of outcomes, its **rejection region**, and says "spam" (rejects H_0) exactly when x lands in R. It is useful to allow a little more: on some outcomes the rule may say "spam" only with some probability, by flipping a biased coin. So a **test** is a function $\phi : \mathcal{X} \to [0, 1]$ on the set $\mathcal{X}$ of possible outcomes, where $\phi(x)$ is the probability of rejecting H_0 after observing x. A **deterministic test** takes only the values 0 and 1, so it is the indicator of its rejection region: $\phi(x) = 1$ on R and 0 off it. A **randomized test** may take values strictly between 0 and 1.

A test makes two kinds of mistake, and both are averages of ϕ. The first is to reject when the email is ham. Given $X = x$, the test rejects with probability $\phi(x)$, so averaging over X drawn from P gives the probability of rejecting under H_0. The second is to keep H_0 when the email is spam: averaging ϕ over X drawn from Q gives the probability of rejecting under H_1, and one minus that is the probability of failing to. Writing $\mathbb{E}_P$ and $\mathbb{E}_Q$ for averages under P and Q, the two error probabilities are

$$\alpha_\phi = \mathbb{E}_P[\phi(X)], \qquad \beta_\phi = 1 - \mathbb{E}_Q[\phi(X)]. \tag{4.1}$$

For a deterministic test this is the familiar fact that the probability of an event is the average of its indicator, $\Pr[X \in R] = \mathbb{E}[\mathbf{1}[X \in R]]$: the indicator is 1 on the event and 0 off it, so its average is the probability mass of the event (Concentration inequalities builds Markov's inequality on the same fact).

For example, the test "reject when $X \geq 2$" has $\phi = (0, 0, 1, 1)$ on the outcomes $0, 1, 2, 3$. Its first error is the ham mass on $\{2, 3\}$, $\alpha_\phi = 0.2 + 0.1 = 0.3$. It rejects spam with probability $\mathbb{E}_Q\phi = 0.3 + 0.4 = 0.7$, so its second error is $\beta_\phi = 0.3$.

4.2.2. Fact 2 — Change of measure

The likelihood ratio converts averages under P into averages under Q. The reason is simple: wherever $p(x) > 0$, the spam probability $q(x)$ equals the ham probability $p(x)$ multiplied by $\Lambda(x) = q(x)/p(x)$. So any average under Q can be computed as an average under P in which each outcome is reweighted by Λ. The one catch is outcomes that P never produces, where $p(x) = 0$ and the ratio is undefined; those have to be counted separately. For any function $g \geq 0$,

$$\mathbb{E}_Q[g(X)] = \mathbb{E}_P[g(X)\Lambda(X)] + \mathbb{E}_Q\big[g(X)\mathbf{1}[p(X) = 0]\big]. \tag{4.2}$$

To prove it, split the sum (or integral) $\sum_x g(x)q(x)$ into the points with $p(x) > 0$, where $q(x) = \Lambda(x)p(x)$ turns the sum into $\sum_x g(x)\Lambda(x)p(x) = \mathbb{E}_P[g\Lambda]$, and the points with $p(x) = 0$, which give the second term.

In the spam example $p > 0$ everywhere, so only the first term appears. For "reject when $X = 3$", $\phi = (0, 0, 0, 1)$ and $\mathbb{E}_P[\phi\Lambda] = 0.1 \times 4 = 0.4$, which is exactly $\mathbb{E}_Q\phi$, the spam mass at 3. One consequence is used later: taking $g = 1$, the left side is 1 and the second term is $\Pr_Q[p = 0]$, the Q-probability of the outcomes P never produces, so $\mathbb{E}_P[\Lambda] = 1 - \Pr_Q[p = 0] = \Pr_Q[p > 0] \leq 1$.

4.2.3. Fact 3 — Mixing tests mixes their errors

Suppose you flip a coin that lands heads with probability $\lambda \in [0, 1]$, and run test ϕ_1 on heads and ϕ_2 on tails. On outcome x this rejects with probability $\lambda\phi_1(x) + (1 - \lambda)\phi_2(x)$, so it is the test $\phi = \lambda\phi_1 + (1 - \lambda)\phi_2$, which takes values in $[0, 1]$. Its errors are the same mixture of the two tests' errors,

$$\alpha_\phi = \lambda\alpha_{\phi_1} + (1 - \lambda)\alpha_{\phi_2}, \qquad \beta_\phi = \lambda\beta_{\phi_1} + (1 - \lambda)\beta_{\phi_2}, \tag{4.3}$$

because by Fact 1 both errors are averages of ϕ, and the average of a weighted sum is the weighted sum of the averages. Geometrically, if you plot each test as a point $(\alpha_\phi, \beta_\phi)$, every point on the segment between two achievable points is achievable too. So the set of achievable error pairs is convex, and randomization fills in the segments between deterministic tests.

4.2.4. Fact 4 — The inverse normal distribution function

Write Φ for the standard normal cumulative distribution function (CDF): $\Phi(x)$ is the probability that a standard normal variable is at most x. Write Φ^{-1} for its inverse, so $\Phi^{-1}(u)$ is the point below which a standard normal has probability u. The normal density is symmetric about 0, so the area above x equals the area below $-x$: $1-\Phi(x) = \Phi(-x)$. Applying Φ^{-1} to both sides of this identity, with $x = \Phi^{-1}(\alpha)$, gives $\Phi^{-1}(1-\alpha) = -\Phi^{-1}(\alpha)$. The values used below are $\Phi^{-1}(0.9) = 1.2816$, $\Phi^{-1}(0.95) = 1.6449$, $\Phi^{-1}(0.975) = 1.9600$, $\Phi^{-1}(0.99) = 2.3263$ and $\Phi^{-1}(0.999) = 3.0902$.

Φ has no closed-form inverse, so these values are computed numerically. The script solves $1-\Phi(x) = \alpha$ by bisection, evaluating the upper tail as $\frac{1}{2}\operatorname{erfc}(x/\sqrt{2})$ with the complementary error function erfc. Solving for the tail directly, rather than computing Φ^{-1} at $1-\alpha$, keeps full precision when α is tiny, because $1-\alpha$ then rounds to a number very close to 1 and loses the digits that matter.

4.3. Simple-versus-simple testing

4.3.1. Context

The simplest testing problem has exactly two candidate distributions, each fully specified: **simple** hypotheses, as opposed to composite ones such as "the mean is positive", which allow a whole family of distributions. Most practical detection problems reduce to it once you fix what "normal" and "abnormal" data look like. This section fixes the vocabulary.

4.3.2. Definitions

You observe X and test whether it came from P or from Q:

$$H_0 : X \sim P \qquad \text{against} \qquad H_1 : X \sim Q. \tag{4.4}$$

A test can go wrong in two ways, and each has a name. A **type I error**, or false positive, is rejecting H_0 when it is true: flagging a ham email as spam. Its probability is α_ϕ from Fact 1, also called the **size** of the test or its **false positive rate (FPR)**. A **type II error**, or false negative, is keeping H_0 when H_1 is true: letting spam through. Its probability is β_ϕ, the **false-negative rate**. (These are the letters of Neyman and Pearson; a page where α or β already means something else writes the two errors as FPR and FNR.)

The complement of each error is a success rate. The **power** $1-\beta_\phi$ is the probability of detecting H_1 when it holds; in classification it is called the **true positive rate (TPR)**, **recall** or **sensitivity**. The complement of the first error, $1-\alpha_\phi$, is the **specificity**, the probability of correctly passing a ham email. Finally, a test has **level** α if its false positive rate is at most α, $\alpha_\phi \le \alpha$: the level is a budget, the size is what the test actually spends.

The convention is asymmetric on purpose. H_0 is the default ("this email is fine", "this patient is healthy"), and a false alarm is the error you control first. You fix the level, then look for the most powerful test at that level.

4.3.3. The two errors pull in opposite directions

For each rejection region in the spam example, Fact 1 gives the errors directly: α is the ham mass p summed over the region, and the power is the spam mass q summed over it. For the region $\{2, 3\}$, $\alpha = 0.2 + 0.1 = 0.3$ and the power is $0.3 + 0.4 = 0.7$, so $\beta = 0.3$. Table 4.3 lists the threshold tests "reject when $X \geq k$" and two regions that are not thresholds.

Table 4.3.: Errors of deterministic tests in the spam example. The first five are thresholds on the count; the last two are not.

Rejection region	α	β	Power
none	0.00	1.00	0.00
$\{3\}$	0.10	0.60	0.40
$\{2, 3\}$	0.30	0.30	0.70
$\{1, 2, 3\}$	0.60	0.10	0.90
all	1.00	0.00	1.00
$\{0\}$	0.40	0.90	0.10
$\{0, 3\}$	0.50	0.50	0.50

Going down the first five rows, the rejection region grows: each added outcome adds its ham mass to α and its spam mass to the power, so α rises and β falls. You cannot lower both errors by changing the region; you can only trade one for the other.

The last two rows are bad regions, and a useful yardstick shows why. A test that ignores the email and rejects with probability α by flipping a coin has, by Fact 1, size α and power α, so $\beta = 1 - \alpha$. Any test worth using must beat this. The region $\{0\}$ does not: at $\alpha = 0.4$ it has $\beta = 0.9$, worse than the coin flip's $1 - 0.4 = 0.6$, because it rejects on the outcome most typical of ham. The region $\{0, 3\}$ does exactly as well as the coin flip, $\beta = 0.5 = 1 - 0.5$.

4.3.4. Why randomize

The threshold tests reach only $\alpha \in \{0, 0.1, 0.3, 0.6, 1\}$. If your spam policy allows a false-positive rate of 0.25, no deterministic threshold test uses that budget: $\{3\}$ spends only 0.1, and $\{2, 3\}$ overspends at 0.3. A randomized test spends it exactly: reject on $\{3\}$ always and on $\{2\}$ with probability 0.75. This is the same as flipping a coin that picks the region $\{3\}$ with probability 0.25 and the region $\{2, 3\}$ with probability 0.75 (count 3 is then rejected either way, and count 2 with probability 0.75). So it is the mixture $0.25 \cdot \mathbf{1}[x \in \{3\}] + 0.75 \cdot \mathbf{1}[x \in \{2, 3\}]$, and by Fact 3 its size is $\alpha = 0.25 \times 0.1 + 0.75 \times 0.3 = 0.25$ exactly. In practice, randomization matters for discrete data, where the threshold can only jump from one outcome to the next. For continuous data such as scores, moving a threshold changes α smoothly, so a threshold can hit any α on its own.

Figure 4.1 shows the two errors for a continuous problem: a biomarker that is $\mathcal{N}(0, 1)$ in healthy patients and $\mathcal{N}(2, 1)$ in ill ones, with the test "reject when $x > \tau$". The false positive rate α is the area under the healthy curve to the right of τ, and the miss rate β is the area under the ill curve to the left of τ. Moving τ right shrinks the blue area α and grows the orange area β.

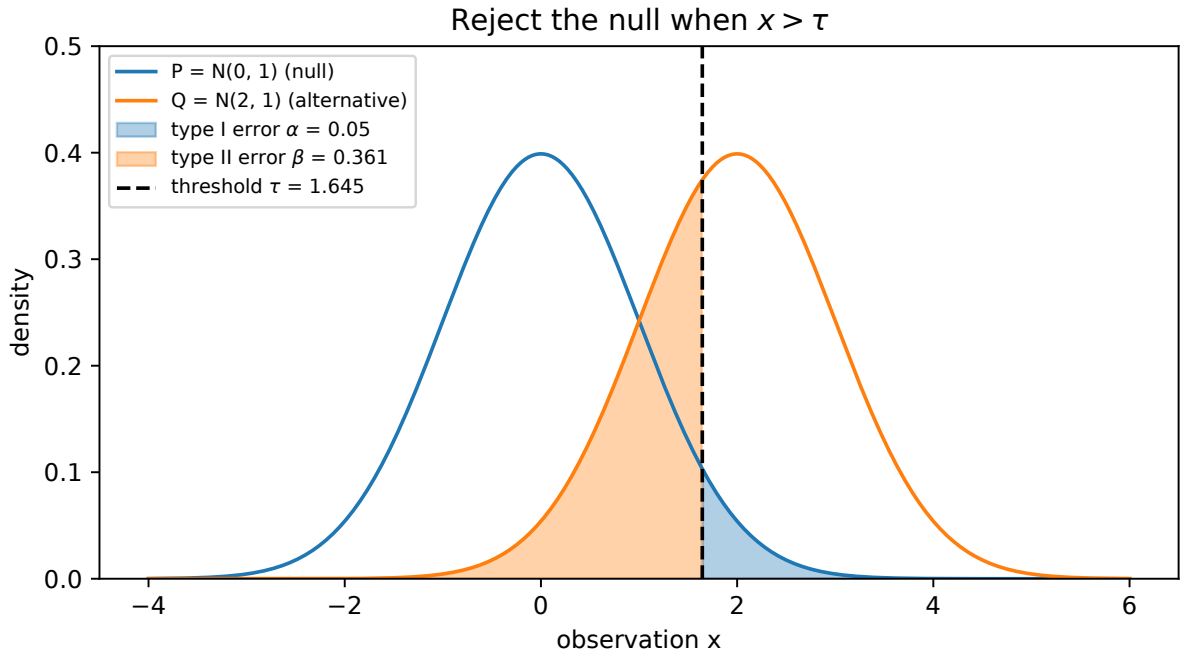

Figure 4.1.: The two errors of the threshold test "reject when $x > \tau$" for $P = \mathcal{N}(0, 1)$ against $Q = \mathcal{N}(2, 1)$, with τ set so that $\alpha = 0.05$. The blue area under P beyond τ is α; the orange area under Q before τ is $\beta = 0.361$.

4.3.5. Example: a medical screening test

A screening test flags a patient when the biomarker exceeds $\tau = 1.645$, the threshold drawn in Figure 4.1. A healthy patient's biomarker is standard normal, so it exceeds τ with probability $1 - \Phi(1.645)$, and by Fact 4 that is 0.05 because $\Phi^{-1}(0.95) = 1.6449$. So one healthy patient in 20 is sent for a follow-up. An ill patient's biomarker is centred at 2, so it falls below τ with probability $\beta = \Phi(\tau - 2) = \Phi(-0.355) = 0.361$. The test's sensitivity is therefore $1 - \beta = 0.6388$: about two ill patients in three are caught. Lowering the threshold catches more ill patients and alarms more healthy ones. Which point to pick is a policy decision. What the mathematics can say is which points are *achievable*, and that is the subject of Section 4.4.

4.3.6. Check yourself

- A test rejects with probability α regardless of the data. What are its errors? *($\alpha_\phi = \alpha$ and $\beta_\phi = 1 - \alpha$. This "coin flip" test is the baseline every useful test must beat.)*
- Why is the test that rejects on $\{0\}$ in Table 4.3 worse than the coin flip at the same α? *(It rejects where $\Lambda(x) = 0.25 < 1$: on that region ham is four times as likely as spam, so it spends false-positive budget where spam is rare.)*

4.4. The Neyman–Pearson lemma

4.4.1. Context

Among all tests at level α, which one is the most powerful? The space of tests is huge: every function $\phi : \mathcal{X} \to [0, 1]$. The Neyman–Pearson lemma says that you only need to look at one family, thresholds of the likelihood ratio, and that the best test in that family beats every other test.

The intuition is a budget. Each outcome x you decide to reject costs $p(x)$ of false-positive budget and buys $q(x)$ of power. The exchange rate at x is $q(x)/p(x) = \Lambda(x)$, units of power per unit of budget. If you want the most power for a fixed budget, you should spend it on the outcomes with the best exchange rate first, and that means rejecting exactly where $\Lambda(x)$ is above some cut-off.

4.4.2. Statement

Let P and Q have densities (or probability mass functions) p and q. A **likelihood ratio (LR) test** with threshold $\tau \geq 0$ rejects wherever $q(x)$ is more than τ times $p(x)$, keeps H_0 wherever it is less, and on the tie set, where $q(x) = \tau\, p(x)$ exactly, may reject with any probability $\gamma(x) \in [0, 1]$:

$$\phi^*(x) = \begin{cases} 1 & \text{if } q(x) > \tau\, p(x), \\ \gamma(x) & \text{if } q(x) = \tau\, p(x), \\ 0 & \text{if } q(x) < \tau\, p(x). \end{cases} \tag{4.5}$$

Writing the condition as $q > \tau p$ rather than $\Lambda > \tau$ also covers points where $p(x) = 0$: there any $q(x) > 0$ counts as above every threshold. The lemma has two parts.

1. **Optimality.** Every test ϕ with $\alpha_\phi \leq \alpha_{\phi^*}$ has $\beta_\phi \geq \beta_{\phi^*}$: no test that spends at most as much false-positive budget misses less.
2. **Existence.** For every $\alpha \in (0, 1]$ there is an LR test with a constant γ and size exactly α.

Together they say that the most powerful level-α test is the LR test of size α. (For $\alpha = 0$ the best test is $\mathbf{1}[p(x) = 0]$: with no budget at all, you can only reject where H_0 is impossible.)

4.4.3. Derivation of optimality

The plan is to compare ϕ^* with any other test ϕ outcome by outcome, weighting each outcome by $q(x) - \tau\, p(x)$, which is positive exactly where the LR test rejects. A pointwise comparison then adds up to a comparison of the errors.

1. **A pointwise inequality.** For every x,

$$(\phi^*(x) - \phi(x))(q(x) - \tau\, p(x)) \geq 0. \tag{4.6}$$

   To see it, check the three cases of Equation 4.5. If $q > \tau p$, then $\phi^* = 1 \geq \phi$, so both factors are ≥ 0. If $q < \tau p$, then $\phi^* = 0 \leq \phi$, so both are ≤ 0. If $q = \tau p$, the second factor is 0. This is the only place the form of ϕ^* is used, and it does not care what γ is.

2. **Sum (or integrate) over x.** A sum of non-negative terms is non-negative. Expanding the product, $\sum_x \phi(x)q(x) = \mathbb{E}_Q[\phi]$ and $\sum_x \phi(x)p(x) = \mathbb{E}_P[\phi]$ by Fact 1, and the same for ϕ^*, so
$$\mathbb{E}_Q[\phi^*] - \mathbb{E}_Q[\phi] \geq \tau(\mathbb{E}_P[\phi^*] - \mathbb{E}_P[\phi]). \tag{4.7}$$
3. **Use the level constraint.** The other test spends no more budget: $\mathbb{E}_P[\phi] = \alpha_\phi \leq \alpha_{\phi^*} = \mathbb{E}_P[\phi^*]$. Together with $\tau \geq 0$, the right side is ≥ 0.
4. **Read off the errors.** So $\mathbb{E}_Q[\phi^*] \geq \mathbb{E}_Q[\phi]$. Both sides are powers, $1 - \beta_{\phi^*} \geq 1 - \beta_\phi$, which is $\beta_\phi \geq \beta_{\phi^*}$.

Step 2 is the budget intuition of the Context written out. τ is the exchange rate at the cut-off: every unit of false-positive probability spent at x buys $\Lambda(x)$ units of power. The LR test spends its budget only where the exchange rate is at least τ, so no other allocation of the same budget buys more power.

4.4.4. Derivation of existence

The idea is to lower the cut-off on Λ until the outcomes strictly above it use at most α of the budget, while including the outcomes at the cut-off would use at least α. Then randomizing on the outcomes exactly at the cut-off fills the gap. To make this precise, let $X \sim P$ and let $G(c) = \Pr_P[\Lambda(X) > c]$ for $c \geq 0$ be the ham probability of the outcomes whose ratio exceeds c, which is the size of the test that rejects strictly above c. (Points with $p(x) = 0$ have probability 0 under P, so $\Lambda(X)$ is finite.)

1. **How G behaves.** Raising c removes outcomes from $\{\Lambda > c\}$, so G is non-increasing. It is right-continuous, because as $c' \downarrow c$ the sets $\{\Lambda > c'\}$ grow to $\{\Lambda > c\}$, and the probability of a growing sequence of sets tends to the probability of their union. In the same way, as $c' \uparrow c$ the sets $\{\Lambda > c'\}$ shrink to $\{\Lambda \geq c\}$, so the left limit is $G(c^-) = \Pr_P[\Lambda(X) \geq c]$.
2. **Choose the cut-off.** Set $\tau = \inf\{c \geq 0 : G(c) \leq \alpha\}$, the smallest cut-off whose strict rejection region fits in the budget. Right-continuity gives $G(\tau) \leq \alpha$. Just left of τ, $G > \alpha$, so $\Pr_P[\Lambda \geq \tau] \geq \alpha$ (when $\tau = 0$ this reads $1 \geq \alpha$).
3. **Randomize on the ties.** The LR test with constant γ rejects $\{\Lambda > \tau\}$ always and $\{\Lambda = \tau\}$ with probability γ, so its size is $G(\tau) + \gamma \Pr_P[\Lambda = \tau]$. If $\Pr_P[\Lambda = \tau] > 0$, pick $\gamma = (\alpha - G(\tau))/\Pr_P[\Lambda = \tau]$ to make the size exactly α. It lies in $[0, 1]$: it is ≥ 0 because $G(\tau) \leq \alpha$, and ≤ 1 because $G(\tau) + \Pr_P[\Lambda = \tau] = \Pr_P[\Lambda \geq \tau] \geq \alpha$, both by step 2. If $\Pr_P[\Lambda = \tau] = 0$, step 2 gives $G(\tau) = \alpha$ and any γ works.

Concrete: the spam example at $\alpha = 0.25$. The distinct ratios, from the largest, are 4 (mass 0.1 under P), 1.5 (mass 0.2), 0.667 and 0.25. For any cut-off c with $1.5 \leq c < 4$, only the count 3 has a ratio above c, so $G(c) = 0.1$, which fits in the budget. Just below 1.5 the count 2 joins, and $G = 0.1 + 0.2 = 0.3$, which does not. So $\tau = 1.5$. The test rejects the count 3 always and must spend the remaining $0.25 - 0.1 = 0.15$ on the tie set $\{2\}$, whose ham mass is 0.2: $\gamma = (0.25 - 0.1)/0.2 = 0.75$. This is the randomized test of Section 4.3. Its power is the spam mass it rejects, $0.4 + 0.75 \times 0.3 = 0.625$, so $\beta = 0.375$.

The script checks the lemma by brute force. It draws 200,000 random tests, $\phi(x)$ uniform on $[0, 1]$ for each x; 11,727 of them have size at most 0.25, and the most powerful of those has power 0.587, below 0.625. Figure 4.2 plots 400 random tests: every one lies on or above the curve traced by the LR tests.

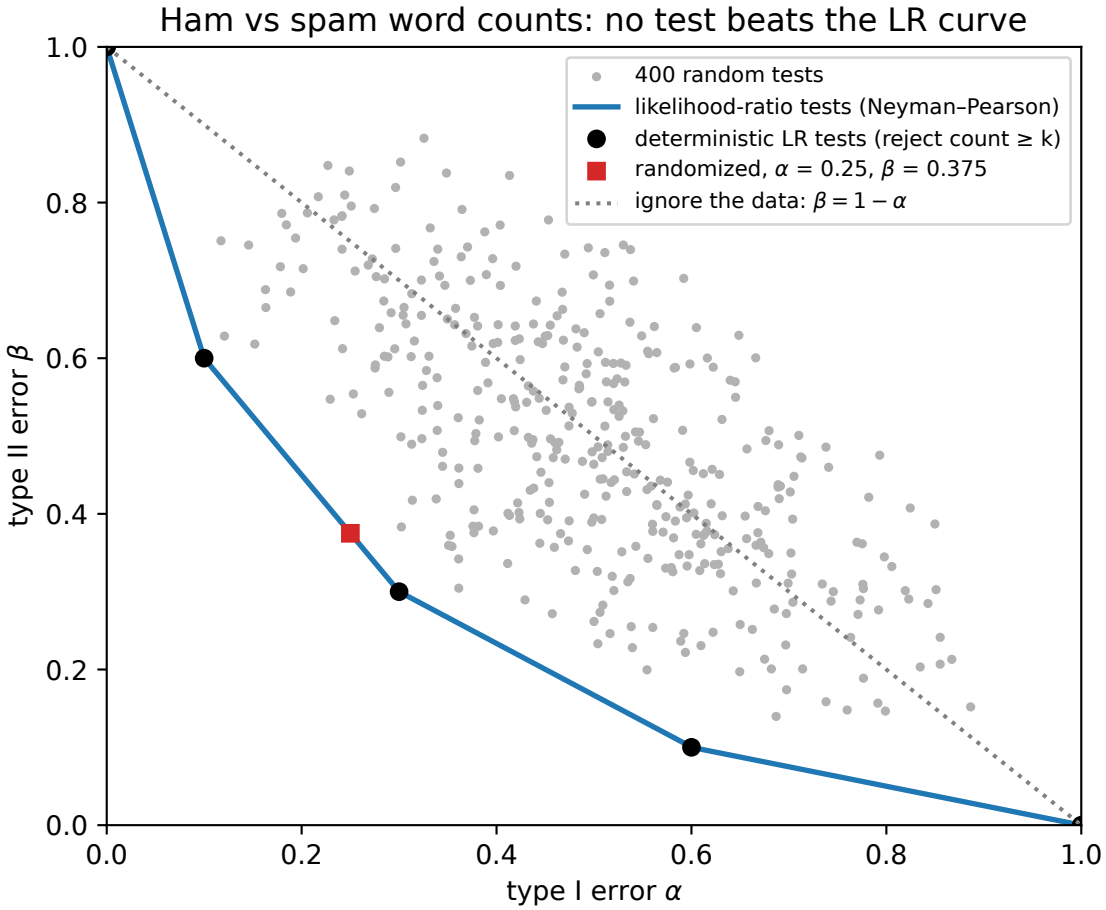

Figure 4.2.: Errors (α, β) of 400 random tests on the spam example (grey), against the curve of likelihood-ratio tests. Black dots are the deterministic thresholds, the red square is the randomized test of size 0.25, and the dotted line is the coin-flip test.

4.4.5. Interpretation

Only the likelihood ratio matters. The optimal test looks at x only through $\Lambda(x)$, so two observations with the same likelihood ratio are interchangeable for testing. Everything else about x is noise.

Monotone ratios give thresholds on x. Often $\Lambda(x)$ increases with some simple statistic $s(x)$, such as the word count in the spam example. Then "the ratio is above its threshold" is the same event as "the statistic is above some threshold τ", $\{s > \tau\}$, and the optimal test is a plain threshold on s. The word count, the Gaussian biomarker and the Laplace shift below all work this way. This is why thresholding a well-calibrated score is the right thing to do.

The slope of the curve is $-\tau$. Plot the LR tests as points (α, β). Moving along a segment of this curve means rejecting one more outcome x with a little more probability. That spends $p(x)$ of false-positive budget per unit of extra rejection probability and gains $q(x)$ of power, so β falls by $\Lambda(x)$ for each unit α rises: the slope of the segment is $-\Lambda(x)$. In Figure 4.2 the segments have slopes -4, -1.5, -0.667 and -0.25: the likelihood ratios, largest first. Because the LR test adds outcomes in decreasing order of exchange rate, each segment is less steep than the last, and a curve whose slope keeps increasing is convex.

Many observations. For n independent observations the joint probability of the sample is the product of the individual probabilities, under P and under Q. So the likelihood ratio of the whole sample is $\prod_i \Lambda(x_i)$, and the LR test thresholds its logarithm $\sum_i \ln \Lambda(x_i)$, a sum of independent terms. Sums of independent terms concentrate, so the errors decay exponentially in n. With the false positive rate held fixed, the type II error decays like $e^{-n\, D_{\mathrm{KL}}(P\|Q)}$, where the KL divergence $D_{\mathrm{KL}}(P\|Q) = \mathbb{E}_P[\ln(p(X)/q(X))]$ is the average log-ratio by which a ham observation favours ham over spam (the Chernoff–Stein lemma; Cover & Thomas, ch. 11, Section F.2 in the appendices, and Exercise 8 in the exercise book).

What the lemma needs. Both hypotheses must be simple. A composite alternative such as "the mean is positive" contains many distributions, each with its own LR test, and one test is optimal against all of them at once only in special cases. The main one is a one-sided test in a family with a monotone likelihood ratio, where every member's LR test is the same threshold on one statistic (Karlin–Rubin; Casella & Berger, §8.3).

4.4.6. Example: why a classifier's score should be a likelihood ratio

A fraud model outputs a score $s(x)$. Suppose the score is calibrated, $s(x) = \Pr[\text{fraud} \mid x]$, with a base rate π of fraud. Bayes' rule says that the odds of fraud after seeing x are the odds before seeing it, multiplied by the likelihood ratio (Section 4.10 derives this): $s/(1-s) = \frac{\pi}{1-\pi}\Lambda(x)$. The odds $s/(1-s)$ grow with s, so s is an increasing function of $\Lambda(x)$. Thresholding s is then an LR test, and Neyman–Pearson says no other use of x can catch more fraud at the same false-alarm rate. If the score is not monotone in Λ, re-ranking the transactions by an estimate of Λ can only help.

4.4.7. Check yourself

- Where did the proof use that ϕ takes values in $[0,1]$? *(In step 1: when $q > \tau p$ it needs $\phi \le 1 = \phi^*$, and when $q < \tau p$ it needs $\phi \ge 0 = \phi^*$.)*
- In the spam example, what is the most powerful test at level $\alpha = 0.3$, and does it need randomization? *(Reject $\{2,3\}$, with power 0.70. No: 0.3 is exactly the P-mass of the outcomes with $\Lambda \ge 1.5$.)*

4.5. Trade-off functions and ROC curves

4.5.1. Context

A single test gives one point (α, β). To compare two *problems* (how hard is it to tell P from Q?) you want the best β at every α at once. That is a curve, and it depends only on P and Q, not on any particular test.

4.5.2. Definition

For each false positive budget α, look at every test that stays within it and record the smallest miss rate any of them achieves. As a function of α, that is the **trade-off function** of P and Q:

$$T(P,Q)(\alpha) = \inf\{\beta_\phi : \alpha_\phi \le \alpha\}, \qquad \alpha \in [0,1]. \tag{4.8}$$

The infimum (inf) is the largest number that is at most every β_ϕ in the set; it is the minimum when the minimum is attained. By the Neyman–Pearson lemma it is attained, by the LR test of size α, so in practice you compute T by sweeping the LR threshold. Write T for $T(P,Q)$ when the pair is clear.

The **ROC curve** of the optimal test plots its TPR against its FPR, that is, power against size: $\alpha \mapsto 1 - T(\alpha)$. It holds the same information as T, turned upside down. A particular *score*, thresholded at every possible value, also traces an ROC curve, and by Neyman–Pearson that curve lies on or below the optimal one.

4.5.3. Statement: four properties

Every trade-off function is

1. **non-increasing,**
2. **at most** $1-\alpha$**:** $T(\alpha) \le 1-\alpha$,
3. **convex,**
4. **continuous** on $[0,1]$.

In words: a bigger budget never hurts, the coin flip is always available, mixing tests fills in segments, and there are no jumps.

Conversely, every function $f : [0,1] \to [0,1]$ with these four properties is $T(P,Q)$ for some pair P, Q, so these four properties are exactly what "a possible error trade-off" means. The standard construction takes P uniform on $[0,1]$, so that any test rejecting an interval of length α has size α, and designs Q so that rejecting the top interval $(1-\alpha, 1]$ misses exactly $f(\alpha)$. Concretely, let Q have CDF $G(x) = f(1-x)$ on $[0,1]$ (so $G(1) = f(0)$, and $G(0) = f(1) = 0$ since property 2 forces $f(1) \le 0$), and put its remaining mass $1 - f(0)$ at a point outside $[0,1]$, where P has no mass. The slope of G at x is minus the slope of f at $1-x$. Because f is convex its slope increases with its argument, so as x grows and $1-x$ shrinks, the slope of G, which is the density of Q on $[0,1]$, is non-decreasing. The likelihood ratio is that density on $[0,1]$ (since $p = 1$ there) and infinite at the outside point, so it is non-decreasing, and the tests "reject the outside point and every $x > 1-\alpha$" are LR tests. Each has size α, and its type II error is the Q-mass it does not reject, $\Pr_Q[0 \le X \le 1-\alpha] = G(1-\alpha) = f(\alpha)$.

4.5.4. Derivation

1. **Non-increasing.** If $\alpha \le \alpha'$, every test with $\alpha_\phi \le \alpha$ also has $\alpha_\phi \le \alpha'$. The infimum in Equation 4.8 is over a larger set at α', so it is no larger.

2. **At most $1-\alpha$.** The coin-flip test $\phi \equiv \alpha$ is always within budget, with $\alpha_\phi = \alpha$ and $\beta_\phi = 1-\alpha$ (Fact 1), so the infimum is at most $1-\alpha$.

3. **Convex.** Convexity says the curve at a mixed budget is no higher than the same mixture of the curve's values, and Fact 3 provides exactly that mixture. Fix $\alpha_1, \alpha_2, \lambda \in [0,1]$ and a small $h > 0$. Pick tests ϕ_i with $\alpha_{\phi_i} \le \alpha_i$ and $\beta_{\phi_i} \le T(\alpha_i) + h$, which exist by the definition of the infimum. By Fact 3, the mixture $\lambda\phi_1 + (1-\lambda)\phi_2$ has size at most $\lambda\alpha_1 + (1-\lambda)\alpha_2$ and type II error at most $\lambda T(\alpha_1) + (1-\lambda)T(\alpha_2) + h$. So $T(\lambda\alpha_1 + (1-\lambda)\alpha_2) \le \lambda T(\alpha_1) + (1-\lambda)T(\alpha_2) + h$. Let $h \to 0$.

4. **Continuous.** Inside $(0,1)$ this comes free from convexity: a convex function on an interval is continuous at every interior point, because its chords pin it between two lines on either side of the point (any analysis text, e.g. Rockafellar, *Convex Analysis*, §10). At $\alpha = 1$, the test $\phi \equiv 1$ has $\beta = 0$, so $T(1) = 0$, and property 2 squeezes $0 \le T(\alpha) \le 1 - \alpha \to 0$.

   At $\alpha = 0$ convexity alone allows a jump, so the argument needs Fact 2. First, $T(0) = 1 - \Pr_Q[p = 0]$: a test of size 0 must have $\phi = 0$ wherever $p > 0$, so the most it can do is reject everywhere $p = 0$. Now take any test with $\alpha_\phi \le \alpha$ and any cut-off $K > 0$, and bound its power. By Fact 2 the power is $\mathbb{E}_Q[\phi] = \mathbb{E}_P[\phi\Lambda] + \mathbb{E}_Q[\phi\,\mathbf{1}[p = 0]]$, and the second term is at most $\Pr_Q[p = 0]$. Split $\mathbb{E}_P[\phi\Lambda]$ by whether $\Lambda \le K$: where $\Lambda \le K$ it is at most $K\,\mathbb{E}_P[\phi] \le K\alpha$, and where $\Lambda > K$ it is at most $\mathbb{E}_P[\Lambda\,\mathbf{1}[\Lambda > K]]$ because $\phi \le 1$. So

$$1 - \beta_\phi = \mathbb{E}_Q[\phi] \le \Pr_Q[p = 0] + \mathbb{E}_P[\phi\Lambda] \le \Pr_Q[p = 0] + K\alpha + \mathbb{E}_P[\Lambda\,\mathbf{1}[\Lambda > K]]. \tag{4.9}$$

   Hence $T(\alpha) \ge T(0) - K\alpha - \mathbb{E}_P[\Lambda\,\mathbf{1}[\Lambda > K]]$. Since $\mathbb{E}_P[\Lambda] \le 1$ is finite (Fact 2), the part of that average coming from $\Lambda > K$ tends to 0 as $K \to \infty$. So choose K large to make the last term small, then α small to make $K\alpha$ small: $T(\alpha) \to T(0)$.

4.5.5. Interpretation

The two extremes of the curve are the two extremes of difficulty. $T(\alpha) = 1 - \alpha$ for all α means no test beats a coin flip, which happens exactly when $P = Q$. $T \equiv 0$ means some test makes no errors at all, which happens when P and Q live on disjoint sets.

Between the extremes, the further T bends below the diagonal, the easier the problem. A pair (P, Q) is **harder to distinguish** than (P', Q') if $T(P, Q) \geq T(P', Q')$ everywhere: at every budget, the best test misses more. This is only a partial order, because two curves can cross, and then neither problem is uniformly harder.

The curve need not start at 1. If Q puts mass where P has none, a test catches that mass with no false alarms, so $T(0) = 1 - \Pr_Q[p = 0]$ is below 1 (Exercise 6 in the exercise book). And the curve depends on which distribution is the null: swapping the roles of P and Q reflects the curve across the diagonal, so $T(Q, P)$ is the inverse function of $T(P, Q)$ when $T(P, Q)$ is strictly decreasing (Exercise 2 in the exercise book).

4.5.6. Check yourself

- Why can a trade-off function never be concave and below the diagonal on part of $[0, 1]$ and above it elsewhere? *(Property 2 forbids it from ever being above the diagonal $1 - \alpha$.)*
- A deterministic score gives a staircase ROC on a finite test set. Why can you always join adjacent points with straight segments? *(Fact 3: randomizing between the two thresholds achieves every point on the segment.)*

4.6. The Gaussian trade-off curve

4.6.1. Context

The most common pair in practice is a shift of a normal distribution: a score, a biomarker or a sample mean that is normal under both hypotheses with the same spread but different centres. Its trade-off curve has a closed form, worked out here in full.

4.6.2. Statement

For a unit-variance normal under H_0 and the same normal shifted right by μ under H_1, the best test is a threshold on x. At budget α the threshold sits where P has upper tail α, which is $\Phi^{-1}(1 - \alpha)$, and the miss rate is the probability that Q, centred μ higher, falls below it. So for $P = \mathcal{N}(0, 1)$ and $Q = \mathcal{N}(\mu, 1)$ with $\mu \geq 0$,

$$T(P, Q)(\alpha) = \Phi\big(\Phi^{-1}(1 - \alpha) - \mu\big). \tag{4.10}$$

More generally, $\mathcal{N}(m_0, \sigma^2)$ against $\mathcal{N}(m_1, \sigma^2)$ has this curve with $\mu = |m_1 - m_0|/\sigma$. The reason is that standardizing the observation, $x \mapsto (x - m_0)/\sigma$, is a one-to-one relabelling of the outcomes, so every test on the original scale is a test on the new scale with the same two errors, and on the new scale the pair is $\mathcal{N}(0, 1)$ against $\mathcal{N}(\pm\mu, 1)$.

4.6.3. Derivation

The plan is to compute the likelihood ratio, see that it increases with x, and then read both errors of the threshold test off normal tails.

1. **The likelihood ratio.** With the standard normal density $\varphi(x) = e^{-x^2/2}/\sqrt{2\pi}$, the density of Q is $\varphi(x-\mu)$. The constants cancel in the ratio, and expanding the square, $x^2-(x-\mu)^2 = 2\mu x - \mu^2$:
$$\Lambda(x) = \frac{\varphi(x-\mu)}{\varphi(x)} = \exp\Big(\frac{x^2-(x-\mu)^2}{2}\Big) = \exp\Big(\mu x - \frac{\mu^2}{2}\Big). \tag{4.11}$$
2. **The LR test is a threshold on x.** For $\mu > 0$, Λ is strictly increasing in x, so the likelihood ratio exceeds a cut-off c exactly when $x > \tau$, where $\tau = (\ln c + \mu^2/2)/\mu$ solves $\mu\tau - \mu^2/2 = \ln c$. Ties $\Lambda(x) = c$ happen only at the single point $x = \tau$, which has probability 0, so no randomization is needed. By Neyman–Pearson, the tests $\phi_\tau(x) = \mathbf{1}[x > \tau]$ are optimal.
3. **Size fixes the threshold.** $\alpha = \Pr_P[X > \tau] = 1 - \Phi(\tau)$, so $\tau = \Phi^{-1}(1-\alpha)$.
4. **Type II error.** Under Q, $X - \mu \sim \mathcal{N}(0,1)$, so the test misses with probability $\beta = \Pr_Q[X \le \tau] = \Pr[X - \mu \le \tau - \mu] = \Phi(\tau - \mu)$.
5. **Substitute** step 3 into step 4 to get Equation 4.10.

Checks. At $\mu = 0$ the two hypotheses coincide, and indeed $\Phi(\Phi^{-1}(1-\alpha)) = 1-\alpha$, the diagonal. As $\mu \to \infty$, $T \to 0$ for every $\alpha > 0$. And T is symmetric about the diagonal, $T(T(\alpha)) = \alpha$ (Exercise 1 in the exercise book). In short: Fact 4 turns $\Phi^{-1}(1-T(\alpha))$ into $-\Phi^{-1}(T(\alpha)) = -(\Phi^{-1}(1-\alpha)-\mu)$, so $T(T(\alpha)) = \Phi(-\Phi^{-1}(1-\alpha)) = 1-(1-\alpha) = \alpha$.

4.6.4. Interpretation

One number describes the problem. The curve depends on the two normals only through μ, the distance between the means in units of the standard deviation. Figure 4.3 shows the family. Crosses mark simulated thresholds at $\mu = 1$, with 20,000 draws per point.

Near $\alpha = 0$ the curve is vertical. The slope of the curve at the point with threshold τ is $-\Lambda(\tau)$, as in the slope rule of Section 4.4. Here it follows from the two errors: moving the threshold from τ to $\tau + \mathrm{d}\tau$ lowers α by $p(\tau)\,\mathrm{d}\tau$ and raises β by $q(\tau)\,\mathrm{d}\tau$, so $T'(\alpha) = d\beta/d\alpha = -q(\tau)/p(\tau) = -\Lambda(\tau)$. Small α means a large threshold, and $\Lambda(\tau) = e^{\mu\tau-\mu^2/2} \to \infty$ as $\tau \to \infty$. So the first sliver of false-positive budget buys power at an unbounded exchange rate. The Laplace pair of Section 4.7 behaves differently.

Averaging n observations. Take n independent draws from $\mathcal{N}(0,\sigma^2)$ against $\mathcal{N}(h,\sigma^2)$. Step 1, with the spread σ put back, gives each draw a log likelihood ratio $(hx_i - h^2/2)/\sigma^2$, and the log ratios of independent draws add up to $\sum_i (hx_i - h^2/2)/\sigma^2$. This depends on the data only through $\sum_i x_i$, that is, through the sample mean $\bar{x}$, so the best test thresholds $\bar{x}$. The sample mean is $\mathcal{N}(0,\sigma^2/n)$ against $\mathcal{N}(h,\sigma^2/n)$, a shift of h with standard deviation $\sigma/\sqrt{n}$. So the curve is Equation 4.10 with
$$\mu = \frac{h\sqrt{n}}{\sigma}. \tag{4.12}$$
Distinguishability grows like $\sqrt{n}$, the same rate at which a sample mean concentrates.

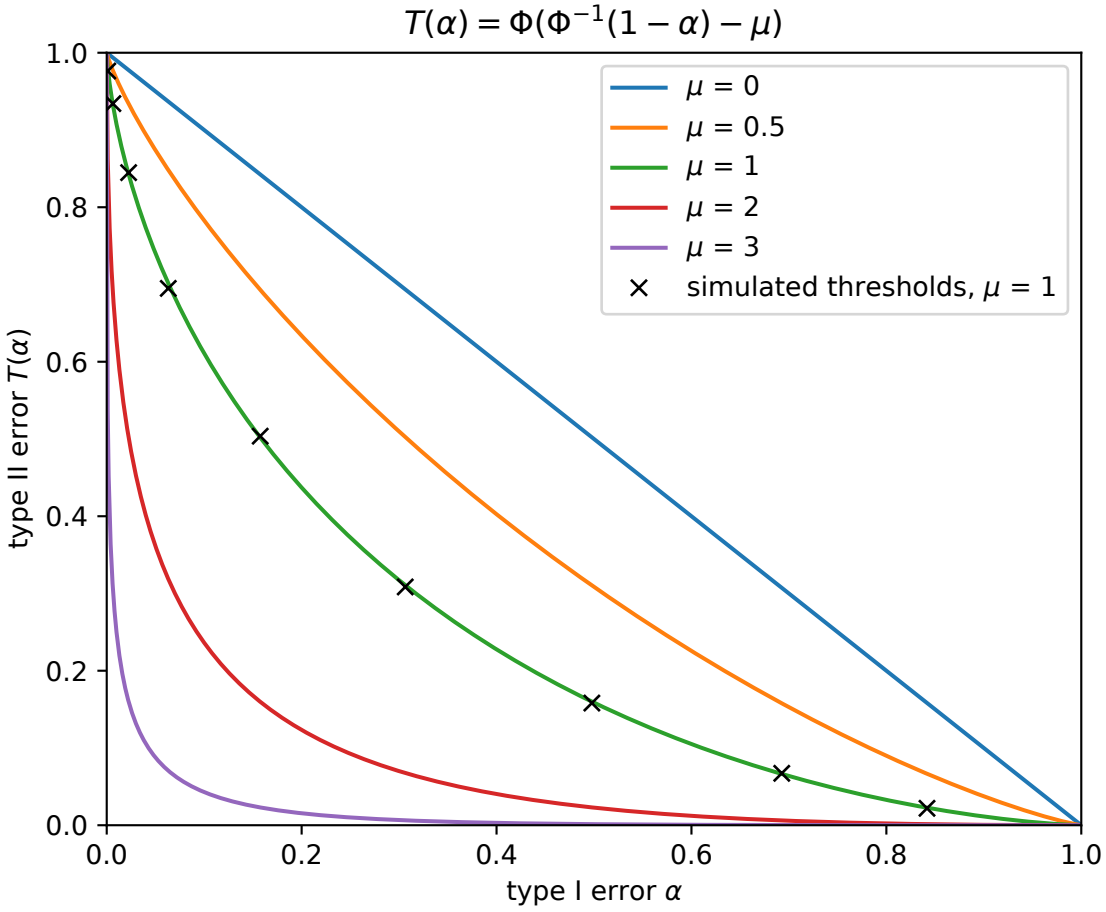

Figure 4.3.: The Gaussian trade-off curve $\Phi(\Phi^{-1}(1-\alpha) - \mu)$ for $\mu = 0, 0.5, 1, 2, 3$. Crosses are simulated errors of threshold tests at $\mu = 1$.

4.6.5. Example: detecting sensor drift

A monitoring job averages $n = 100$ readings from a sensor with noise σ and must detect a drift of $h = 0.2\sigma$ in the mean. Then $\mu = h\sqrt{n}/\sigma = 0.2 \times 10 = 2$. Table 4.4 evaluates Equation 4.10 at this shift and at $\mu = 1$, for two levels. Each row sets the threshold from the level by Fact 4 and subtracts μ; for example, at $\mu = 2$ and $\alpha = 0.05$, $\beta = \Phi(1.6449 - 2) = \Phi(-0.3551) = 0.3612$.

Table 4.4.: The Gaussian trade-off curve at two shifts and two levels.

μ	α	Threshold $\Phi^{-1}(1-\alpha)$	$\beta = T(\alpha)$	Power
1	0.05	1.6449	0.7405	0.2595
1	10^{-3}	3.0902	0.9817	0.0183
2	0.05	1.6449	0.3612	0.6388
2	10^{-3}	3.0902	0.8622	0.1378

At a 5% false-alarm rate the job catches the drift with probability 0.6388 (Table 4.4). A simulation with 1,000,000 draws per hypothesis gives $\hat{\alpha} = 0.0503$ and $\hat{\beta} = 0.3617$. If false alarms must be rare, $\alpha = 10^{-3}$, the threshold moves out to 3.0902 and the power drops to $1 - \Phi(3.0902 - 2) = 0.1378$: a stricter threshold costs a lot of power when μ is moderate.

How many readings? Turn the question around: what shift μ, and so what n, gives power at least $1 - \beta'$ at level α? The power target is $T(\alpha) \le \beta'$, that is, $\Phi(\Phi^{-1}(1-\alpha) - \mu) \le \beta'$. Applying the increasing function Φ^{-1} to both sides gives $\Phi^{-1}(1-\alpha) - \mu \le \Phi^{-1}(\beta')$, and by Fact 4, $\Phi^{-1}(\beta') = -\Phi^{-1}(1-\beta')$. So the condition is $\mu \ge \Phi^{-1}(1-\alpha) + \Phi^{-1}(1-\beta')$. Substituting $\mu = h\sqrt{n}/\sigma$ and solving for n,

$$n \ge \left(\frac{\Phi^{-1}(1-\alpha) + \Phi^{-1}(1-\beta')}{h/\sigma} \right)^2 . \tag{4.13}$$

For power 0.9 at $\alpha = 0.01$ and $h/\sigma = 0.25$, the two quantiles are $\Phi^{-1}(0.99) = 2.3263$ and $\Phi^{-1}(0.9) = 1.2816$, so $n \ge ((2.3263 + 1.2816)/0.25)^2 = 208.3$, and you need $n = 209$ readings.

4.6.6. Check yourself

- Two classifiers produce normal scores with equal spread. Classifier A separates the class means by 2 standard deviations, classifier B by 1. How many independent B-scores must you average to match one A-score? *(Four: μ grows like $\sqrt{n}$, and $1 \times \sqrt{4} = 2$.)*
- Why does step 2 need $\mu > 0$, and what changes for $\mu < 0$? *(For $\mu < 0$ the ratio is decreasing in x, so the optimal test rejects for small x. The curve is the same with $|\mu|$.)*

4.7. The Laplace trade-off curve

4.7.1. Context

Replace the normal by a Laplace distribution: the same shift problem, but with exponential tails. The Laplace distribution $\mathrm{Lap}(m, b)$ with centre m and scale b has density $\frac{1}{2b} e^{-|x-m|/b}$. The

trade-off curve changes shape at the ends, and the reason is the likelihood ratio. Shifting a Laplace density changes its exponent $-|x-m|/b$ by at most m_1/b for a shift of m_1 (moving the centre by m_1 changes the distance $|x-m|$ by at most m_1), so the shifted density is within a factor $e^{m_1/b}$ of the original everywhere (Probability distributions). A shifted normal is not: its likelihood ratio, computed in Section 4.6, grows without bound.

4.7.2. Statement

Because the likelihood ratio is capped, no test can buy power faster than the cap allows, and the curve's two ends are straight lines with the cap as their slope. In between, where the ratio does vary, the curve bends. For $P = \mathrm{Lap}(0, b)$ and $Q = \mathrm{Lap}(m_1, b)$ with $m_1 > 0$, write $\kappa = m_1/b$ for the shift in units of the scale. Then

$$T(P,Q)(\alpha) = \begin{cases} 1 - e^{\kappa}\alpha, & \alpha < \frac{1}{2}e^{-\kappa}, \\ \dfrac{e^{-\kappa}}{4\alpha}, & \frac{1}{2}e^{-\kappa} \le \alpha \le \frac{1}{2}, \\ e^{-\kappa}(1-\alpha), & \alpha > \frac{1}{2}. \end{cases} \tag{4.14}$$

The three pieces correspond to a threshold above the spam-side centre m_1, between the two centres, and below the ham-side centre 0.

4.7.3. Derivation

Rescale x by b, which changes no test's errors (as for the normal), so that $b = 1$ and $m_1 = \kappa$. The CDF of $\mathrm{Lap}(0, 1)$ is $F(x) = \frac{1}{2}e^{x}$ for $x < 0$ and $1 - \frac{1}{2}e^{-x}$ for $x \ge 0$, obtained by integrating the density $\frac{1}{2}e^{-|x|}$ on each side of 0. The plan is the same as for the normal: find the likelihood ratio, see that thresholds on x are LR tests, and read the errors off F, now in three cases.

1. **The likelihood ratio.** The normalizing constants cancel, so $\ln \Lambda(x) = -|x-\kappa| + |x| = |x| - |x-\kappa|$. Removing the absolute values on each side of 0 and κ gives

$$\ln \Lambda(x) = \begin{cases} -\kappa, & x \le 0, \\ 2x - \kappa, & 0 < x < \kappa, \\ \kappa, & x \ge \kappa. \end{cases} \tag{4.15}$$

   It is non-decreasing in x and clipped to $[-\kappa, \kappa]$ (Figure 4.4, left).
2. **Thresholds on x are LR tests.** Because Λ is non-decreasing, the region $\{x > \tau\}$ always consists of every point with $\Lambda > c$, for the cut-off $c = \Lambda(\tau)$, plus part of the tie set $\{\Lambda = c\}$. When τ falls in a flat piece, the tie set is a whole half-line with positive probability, and rejecting only the part of it with $x > \tau$ is one allowed choice of $\gamma(x)$ in Equation 4.5. So every threshold test is optimal, and its errors $\alpha = 1 - F(\tau)$ and $\beta = \Pr_Q[X \le \tau] = F(\tau - \kappa)$ trace T.
3. **Case $\tau \ge \kappa$.** Both τ and $\tau - \kappa$ are ≥ 0. Then $\alpha = \frac{1}{2}e^{-\tau} \le \frac{1}{2}e^{-\kappa}$, and $\beta = 1 - \frac{1}{2}e^{-(\tau-\kappa)} = 1 - e^{\kappa} \cdot \frac{1}{2}e^{-\tau} = 1 - e^{\kappa}\alpha$.
4. **Case $0 \le \tau < \kappa$.** Now $\tau \ge 0$ but $\tau - \kappa < 0$. Then $\alpha = \frac{1}{2}e^{-\tau} \in (\frac{1}{2}e^{-\kappa}, \frac{1}{2}]$, and $\beta = \frac{1}{2}e^{\tau-\kappa}$. Substituting $e^{\tau} = 1/(2\alpha)$ from the first equation: $\beta = \frac{1}{2}e^{-\kappa}/(2\alpha) = e^{-\kappa}/(4\alpha)$.

5. **Case $\tau < 0$.** Both are negative. Then $\alpha = 1 - \frac{1}{2}e^{\tau} > \frac{1}{2}$, so $\frac{1}{2}e^{\tau} = 1 - \alpha$, and $\beta = \frac{1}{2}e^{\tau-\kappa} = e^{-\kappa}(1-\alpha)$.

Checks. The pieces agree at the joins: at $\alpha = \frac{1}{2}e^{-\kappa}$ both give $\frac{1}{2}$, and at $\alpha = \frac{1}{2}$ both give $\frac{1}{2}e^{-\kappa}$. At $\kappa = 0$ all three pieces are $1 - \alpha$, the diagonal of two identical distributions.

4.7.4. Interpretation

The ends are straight lines. Their slopes are $-e^{\kappa}$ and $-e^{-\kappa}$. That is the slope rule of Section 4.4 at work: the slope of T is $-\Lambda$ at the threshold, and on the two flat pieces of the likelihood ratio Λ is the constant e^{κ} or $e^{-\kappa}$. Because $\Lambda \le e^{\kappa}$ everywhere, no test can buy power faster than e^{κ} per unit of false-positive rate. Reading the first piece as power: for small α, the best power is exactly $1 - T(\alpha) = e^{\kappa}\alpha$.

Gaussian against Laplace. To compare the two shapes fairly, match the two problems by their best advantage, the largest gap $\mathrm{TPR} - \mathrm{FPR}$ any test achieves. Section 4.8 shows that it equals $1 - e^{-\kappa/2}$ for the Laplace pair and $2\Phi(\mu/2) - 1$ for the Gaussian pair. At $\kappa = 1$ the Laplace value is $1 - e^{-1/2} = 0.3935$, and solving $2\Phi(\mu/2) - 1 = 0.3935$ gives a Gaussian pair with $\mu = 1.0301$. In the bulk the two curves nearly coincide. At small α they do not, as Table 4.5 shows: the Laplace power is $e\alpha$, and the Gaussian power is $1 - \Phi(\Phi^{-1}(1-\alpha) - 1.0301)$.

Table 4.5.: Best power at small false-positive rates for two pairs with the same total variation.

α	Laplace power, $\kappa = 1$	Gaussian power, $\mu = 1.0301$
10^{-3}	2.718×10^{-3}	1.969×10^{-2}
10^{-6}	2.718×10^{-6}	9.829×10^{-5}

At $\alpha = 10^{-6}$ the Gaussian test is 36 times more powerful, $9.829 \times 10^{-5} / 2.718 \times 10^{-6} = 36.2$ (Table 4.5). Its unbounded likelihood ratio lets a test find rare observations that are overwhelmingly more likely under Q; the clipped Laplace ratio forbids that. Figure 4.4 plots both on log axes.

4.7.5. Example: absolute-error residuals

A regression model with absolute-error loss has residuals that are roughly Laplace with scale b. You suspect a batch of inputs carries a systematic offset of $m_1 = b$, so $\kappa = 1$. The first breakpoint of Equation 4.14 is $\frac{1}{2}e^{-1} = 0.1839$ and the second is $\frac{1}{2}$, so each level falls on a different piece. At $\alpha = 0.05$, below the first breakpoint, the first piece gives $\beta = 1 - e \times 0.05 = 0.8641$, power 0.1359. At $\alpha = 0.25$, between the breakpoints, the middle piece gives $\beta = e^{-1}/(4 \times 0.25) = e^{-1} = 0.3679$, power 0.6321. At $\alpha = 0.75$, above $\frac{1}{2}$, the last piece gives $\beta = e^{-1} \times 0.25 = 0.0920$.

A simulation of the threshold test at $\alpha = 0.25$ with 1,000,000 draws per hypothesis gives $\hat{\alpha} = 0.2498$ and $\hat{\beta} = 0.3685$.

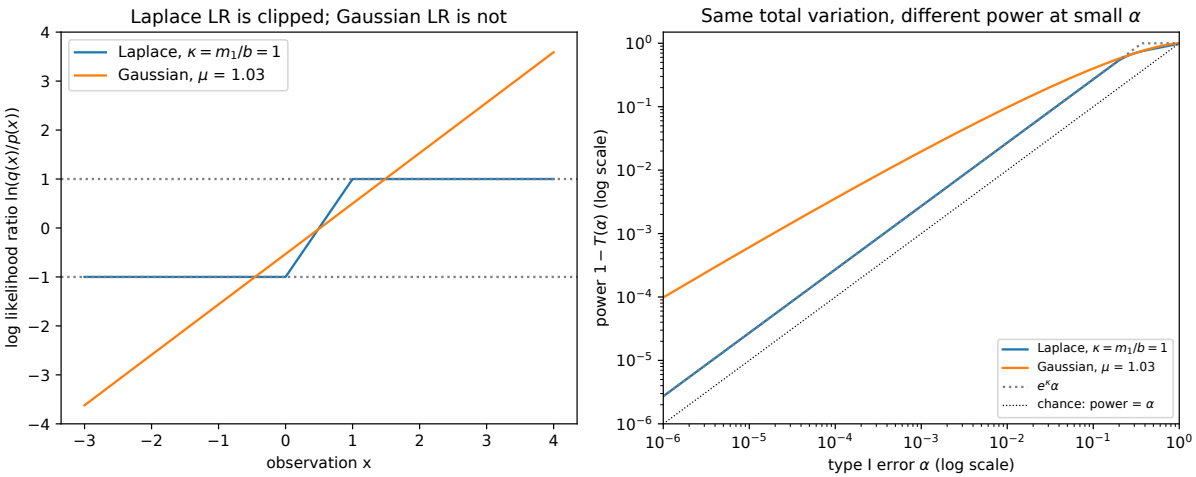

Figure 4.4.: Left: the log likelihood ratio of $\mathrm{Lap}(1,1)$ against $\mathrm{Lap}(0,1)$ is clipped at ± 1, while the Gaussian one with the same total variation is a straight line. Right: best power $1 - T(\alpha)$ on log axes. The Laplace curve follows $e\alpha$ for small α; the Gaussian curve rises far above it.

4.7.6. Check yourself

- On which piece of Equation 4.14 does the threshold τ lie between the two medians 0 and m_1? *(The middle piece, $\frac{1}{2}e^{-\kappa} \le \alpha \le \frac{1}{2}$, where Λ is strictly increasing.)*
- Why can a test on the Laplace pair at level $\alpha = 10^{-3}$ never have power above $e^{\kappa} \times 10^{-3}$? *(Fact 2: power $= \mathbb{E}_P[\phi\Lambda] \le e^{\kappa}\,\mathbb{E}_P[\phi] \le e^{\kappa}\alpha$, since $\Lambda \le e^{\kappa}$ everywhere.)*

4.8. Best advantage equals total variation

4.8.1. Context

Sometimes you want one number for "how distinguishable are P and Q?". A natural one is the **advantage** of a test, $1 - \alpha_\phi - \beta_\phi = \mathrm{TPR} - \mathrm{FPR}$: how much more often it fires under Q than under P. A test that ignores the data, such as the coin flip, fires equally often under both and has advantage 0. (In medicine, $\mathrm{TPR} - \mathrm{FPR}$ at a threshold is Youden's index.) Its maximum over all tests turns out to be the total variation (TV) distance of Divergences. That distance is half the total absolute difference between the two probability tables, $\frac{1}{2}\sum_x |q(x) - p(x)|$, or equivalently the largest difference $\Pr_Q[A] - \Pr_P[A]$ in the probability the two distributions give to any one event A.

4.8.2. Statement

The advantage of a test is a sum over outcomes of $\phi(x)$ times $q(x) - p(x)$, so the best test fires exactly on the outcomes where q exceeds p, and its advantage is the total excess of q over p. That

excess is the total variation distance:

$$\max_{\phi}(1-\alpha_\phi-\beta_\phi)=\mathrm{TV}(P,Q)=\sup_A\,(\Pr_Q[A]-\Pr_P[A])=\frac{1}{2}\sum_x|q(x)-p(x)|, \tag{4.16}$$

with the sum replaced by an integral for densities. The maximum is attained by the LR test with $\tau=1$: reject where $q>p$.

4.8.3. Derivation

1. **Advantage as one sum.** By Fact 1, the power is $\mathbb{E}_Q\phi$ and the false positive rate is $\mathbb{E}_P\phi$, so $1-\alpha_\phi-\beta_\phi=\mathbb{E}_Q\phi-\mathbb{E}_P\phi=\sum_x\phi(x)(q(x)-p(x))$.
2. **Maximize term by term.** Each $\phi(x)$ appears in one term only, so each can be chosen separately. A term is largest with $\phi(x)=1$ where $q(x)>p(x)$ and $\phi(x)=0$ where $q(x)<p(x)$. So the maximum is $\sum_{x:q>p}(q(x)-p(x))=\Pr_Q[A^*]-\Pr_P[A^*]$ with $A^*=\{q>p\}$. A deterministic $\phi(x)=\mathbf{1}[x\in A]$ gives $\Pr_Q[A]-\Pr_P[A]$, and the best of these is A^*, so the maximum is also $\sup_A(\Pr_Q[A]-\Pr_P[A])$.
3. **Rewrite as half the L^1 distance.** Both tables sum to 1, so $\sum_x(q-p)=1-1=0$, and the positive and negative parts of $q-p$ are equal: $\sum_{q>p}(q-p)=\sum_{q<p}(p-q)$. Their sum is $\sum_x|q-p|$, so each is half of it.

On the trade-off curve, the advantage at level α is $1-\alpha-T(\alpha)$: the vertical gap between the diagonal and the curve. Its derivative is $-1-T'(\alpha)$, which is zero where the slope of T is -1. By the slope rule of Section 4.4 the slope is $-\Lambda$ at the threshold, so this is the point where the LR threshold is $\tau=1$ (Figure 4.5).

4.8.4. Example: three pairs

Spam words. The differences $|q-p|$ in Table 4.2 are 0.3, 0.1, 0.1 and 0.3, so TV $=\frac{1}{2}(0.3+0.1+0.1+0.3)=0.40$. Spam is more likely than ham at the counts 2 and 3, so the best test rejects $\{2,3\}$, and indeed its advantage is $1-0.3-0.3=0.4$ (Table 4.3).

Gaussian. The best test rejects where $q>p$, that is, where $\Lambda(x)=e^{\mu x-\mu^2/2}>1$, which is $x>\mu/2$: the point halfway between the two means, where the two bell curves cross. That test has $\alpha=1-\Phi(\mu/2)$ and $\beta=\Phi(\mu/2-\mu)=\Phi(-\mu/2)=1-\Phi(\mu/2)$, so TV $=1-2(1-\Phi(\mu/2))=2\Phi(\mu/2)-1$. At $\mu=1$ this is $2\Phi(0.5)-1=0.3829$, reached at $\alpha=1-\Phi(0.5)=0.3085$. Maximizing $1-\alpha-T(\alpha)$ over a grid of 100,001 values of α gives the same 0.3829 at $\alpha=0.3085$.

Laplace. Here it is easiest to maximize the gap on the curve directly. On the middle piece of Equation 4.14 the gap is $1-\alpha-\frac{e^{-\kappa}}{4\alpha}$, and setting its derivative to zero, $-1+\frac{e^{-\kappa}}{4\alpha^2}=0$, gives $\alpha=\frac{1}{2}e^{-\kappa/2}$. There $\frac{e^{-\kappa}}{4\alpha}=\frac{1}{2}e^{-\kappa/2}$ as well, so TV $=1-e^{-\kappa/2}$. At $\kappa=1$ that is 0.3935, at $\alpha=0.3033$; the grid search agrees.

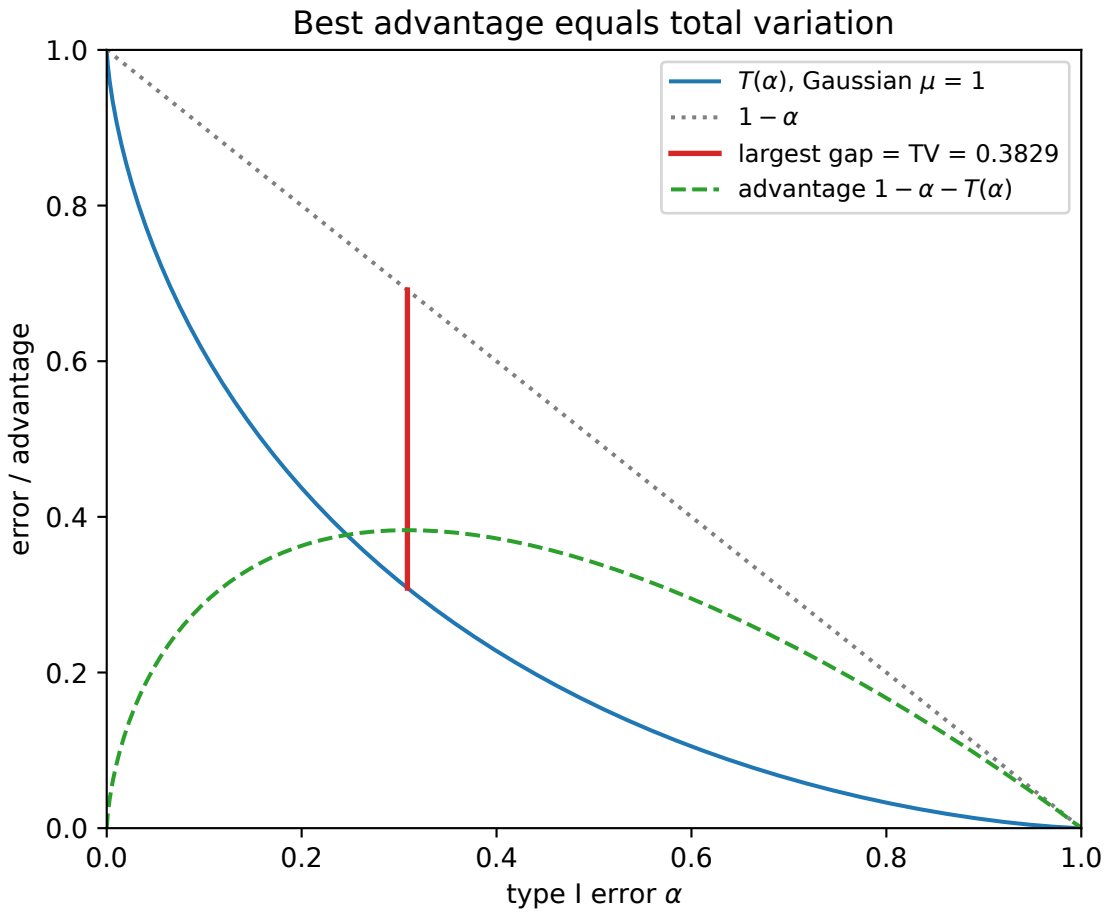

Figure 4.5.: The Gaussian trade-off curve at $\mu = 1$, the diagonal $1 - \alpha$, and the advantage $1 - \alpha - T(\alpha)$ (dashed). The red segment is the largest gap, at $\alpha = 0.3085$, and its length is the total variation 0.3829.

4.8.5. Interpretation

TV is the best that a summary using a single threshold, and weighting the two errors equally, can say. It measures the problem at one point of the curve, where $\tau = 1$, and says nothing about the ends. Table 4.5 is the warning: two pairs with the same TV, 0.3935, differ by a factor of 36 in power at $\alpha = 10^{-6}$. If the regime you care about is "very few false alarms", TV is the wrong summary, and the whole curve is the right one.

4.8.6. Check yourself

- Why is the advantage of any test at most 1, and when is it exactly 1? *(It is at most* $\Pr_Q[A^*] - \Pr_P[A^*] \le 1$*, with equality only if* $\Pr_Q[A^*] = 1$ *and* $\Pr_P[A^*] = 0$*: the distributions have disjoint supports.)*
- Is the coin-flip test's advantage ever negative? Is any test's? *(The coin flip has advantage 0. A test can have negative advantage, like rejecting* $\{0\}$ *in the spam example, but then its complement* $1 - \phi$ *has positive advantage.)*

4.9. ROC summaries: why AUC hides the low-FPR regime

4.9.1. Context

Real detectors are compared on held-out data by their ROC curves, the plot of TPR against FPR as the detector's threshold sweeps from strict to lenient. The curve is usually summarized by the **AUC**, the area under it. In many applications only a small corner of the curve matters: a fraud team can review a tiny fraction of transactions, a screening programme can afford few false alarms, a spam filter must almost never discard real mail. This section shows that two detectors with the same AUC can differ by an order of magnitude in that corner.

4.9.2. Statement: AUC is a ranking probability

The area under the ROC curve has a direct meaning: it is the probability that the detector scores a randomly chosen positive above a randomly chosen negative. For a score S that is $S_- \sim P$ on negatives and $S_+ \sim Q$ on positives (continuous and independent),

$$\mathrm{AUC} = \int_0^1 \mathrm{TPR}\, d(\mathrm{FPR}) = \Pr[S_+ > S_-]. \tag{4.17}$$

4.9.3. Derivation

The idea is to parametrize the curve by the threshold and recognize the area integral as an average over a negative's score.

1. **Parametrize the curve by the threshold.** The test "positive when $S > \tau$" has $\mathrm{FPR}(\tau) = \Pr[S_- > \tau]$ and $\mathrm{TPR}(\tau) = \Pr[S_+ > \tau]$. As τ goes from $+\infty$ to $-\infty$, the FPR goes from 0 to 1.

2. **Change variables.** $\mathrm{FPR}(\tau) = \int_{\tau}^{\infty} p_-(s)\,\mathrm{d}s$, where p_- is the density of S_-, so $\mathrm{d}\,\mathrm{FPR}(\tau) = -p_-(\tau)\,\mathrm{d}\tau$. Substituting, and flipping the limits to absorb the minus sign,

$$\mathrm{AUC} = \int_{+\infty}^{-\infty} \Pr[S_+ > \tau]\,(-p_-(\tau))\,\mathrm{d}\tau = \int_{-\infty}^{\infty} \Pr[S_+ > \tau]\,p_-(\tau)\,\mathrm{d}\tau. \tag{4.18}$$

3. **Read it as an average.** Fix a negative's score τ. The chance that an independent positive beats it is $\Pr[S_+ > \tau]$. The last integral averages that chance over τ drawn from the negatives' density, so it is $\mathbb{E}[\Pr[S_+ > S_- \mid S_-]] = \Pr[S_+ > S_-]$: the probability that a random positive outscores a random negative.

The binormal model. A common model has normal scores in both classes, $S_- \sim \mathcal{N}(0,1)$ and $S_+ \sim \mathcal{N}(m, \sigma^2)$. The difference of two independent normals is normal, with the means subtracted and the variances added, so $S_+ - S_- \sim \mathcal{N}(m, 1+\sigma^2)$. The AUC is the probability that this difference is positive, and the ROC curve follows by setting the threshold from the FPR:

$$\mathrm{AUC} = \Phi(m/\sqrt{1+\sigma^2}), \qquad \mathrm{TPR}(\mathrm{FPR}) = 1 - \Phi\Big(\frac{\Phi^{-1}(1-\mathrm{FPR}) - m}{\sigma}\Big). \tag{4.19}$$

The second formula repeats steps 3 and 4 of the Gaussian derivation in Section 4.6: the threshold is $\tau = \Phi^{-1}(1-\mathrm{FPR})$, and a positive exceeds it when $(S_+ - m)/\sigma > (\tau - m)/\sigma$, now with spread σ under Q.

4.9.4. Example: same AUC, different detectors

Detector A has positives that score $\mathcal{N}(1,1)$, so $m = 1$, $\sigma = 1$ and $\mathrm{AUC} = \Phi(1/\sqrt{2}) = 0.7602$. Detector B has positives that score $\mathcal{N}(m, 2^2)$, more spread out, with m chosen to give the same AUC: $m/\sqrt{5} = 1/\sqrt{2}$ gives $m = \sqrt{5/2} = 1.5811$ and the same AUC, 0.7602. Table 4.6 compares them using the binormal ROC formula. For example, at FPR 10^{-3} the threshold is 3.0902; A's TPR is $1 - \Phi(3.0902 - 1) = 0.0183$, and B's is $1 - \Phi((3.0902 - 1.5811)/2) = 1 - \Phi(0.7546) = 0.2253$.

Table 4.6.: Two binormal detectors with equal AUC. The simulated AUC counts correctly ranked pairs among 1,000,000.

Detector	AUC (formula / simulated)	TPR at FPR = 0.1	TPR at FPR = 10^{-3}
A, $\mathcal{N}(1,1)$	0.7602 / 0.7605	0.3891	0.0183
B, $\mathcal{N}(1.5811, 2^2)$	0.7602 / 0.7601	0.5595	0.2253

At an FPR of 10^{-3}, detector B catches 12 times as many positives, $0.2253/0.0183 = 12.3$ (Table 4.6). On linear axes the two ROC curves cross and look like comparable detectors; on log axes the gap at low FPR is obvious (Figure 4.6). B's positives are more spread out, so a few of them score far above every negative. Those are exactly the cases a strict threshold catches.

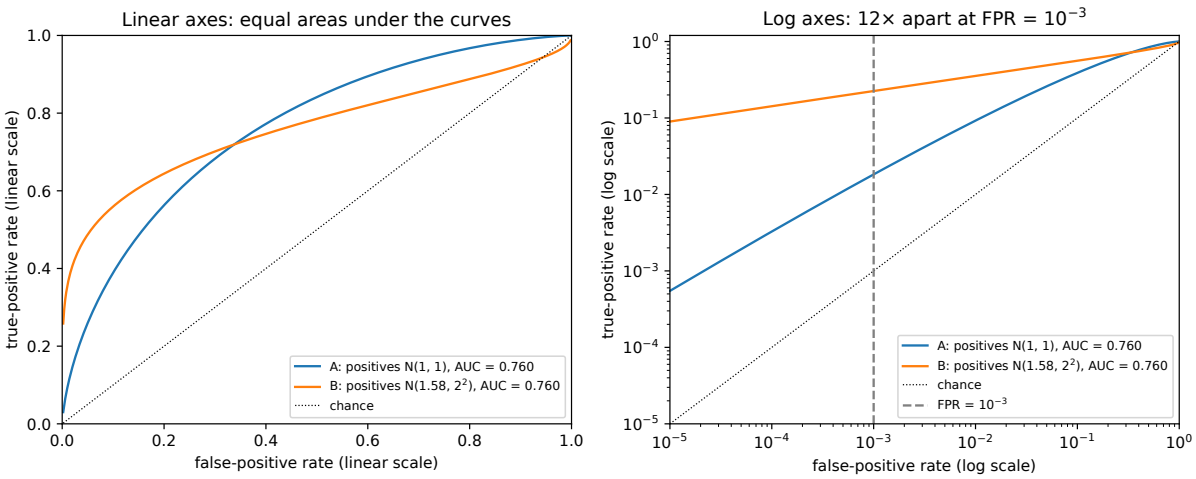

Figure 4.6.: ROC curves of two detectors with the same AUC of 0.760. Left, linear axes: the curves cross and enclose equal areas. Right, log axes: at FPR $= 10^{-3}$ detector B has 12 times the TPR of detector A.

4.9.5. Interpretation

The AUC hides this because it averages over all FPRs equally. The region FPR $\leq 10^{-3}$ is a tenth of a percent of the horizontal axis, so it barely affects the area, and most of the AUC comes from FPRs nobody would operate at. The remedy is to report the TPR at a fixed low FPR, chosen by the application, and to plot ROC curves on log–log axes. A log–log ROC curve shows exactly the behaviour near zero that separated the Gaussian and Laplace curves in Section 4.7.

Neither curve here is the best possible for its detector. B's score threshold is not the optimal test for its own P and Q: with unequal variances the log likelihood ratio, ln of the $\mathcal{N}(m, \sigma^2)$ density over the $\mathcal{N}(0, 1)$ density, has the term $\frac{1}{2}(1 - 1/\sigma^2)s^2$, which is quadratic in the score s and positive for $\sigma = 2$. So the ratio is large at both ends, and the optimal test also flags very *low* scores. Neyman–Pearson says the optimal ROC is at least as good as the one plotted.

An extreme case is in Exercise 5 in the exercise book: a detector with AUC only 0.525 that catches 5% of positives at FPR 10^{-3}.

4.9.6. Check yourself

- A detector's ROC curve lies on the diagonal except for a jump to TPR 0.05 at FPR 0. What is its AUC, and is it useless? *(About* $0.5 + 0.05 \times 0.5 \approx 0.525$*. It is not useless: it catches 5% of positives with no false alarms.)*
- Why does the AUC not depend on any threshold, while TPR at FPR 10^{-3} does? *(The AUC integrates over all thresholds. TPR at a fixed FPR evaluates one threshold, the one whose FPR is* 10^{-3}*.)*

4.10. The Bayesian view

4.10.1. Context

Neyman–Pearson treats the two hypotheses asymmetrically and uses no prior. In many problems you do know a base rate: 1% of patients are ill, one transaction in a thousand is fraud. Then the question becomes "given this observation, how likely is H_1?", and the likelihood ratio answers it.

4.10.2. Statement

Bayes' rule says how evidence updates a belief, and in terms of odds it is a single multiplication. Write $\pi = \Pr[H_1]$ for the prior probability of H_1, the base rate. The odds of H_1 against H_0 after seeing x are the odds before seeing it, multiplied by the likelihood ratio of x:

$$\underbrace{\frac{\Pr[H_1 \mid x]}{\Pr[H_0 \mid x]}}_{\text{posterior odds}} = \underbrace{\frac{\pi}{1-\pi}}_{\text{prior odds}} \times \underbrace{\frac{q(x)}{p(x)}}_{\Lambda(x)}. \tag{4.20}$$

If you want to make as few mistakes as possible, you should say H_1 whenever the posterior odds exceed 1, that is, exactly when $\Lambda(x) > (1-\pi)/\pi$. So the decision that minimizes the probability of error is again an LR test, with the threshold set by the prior.

4.10.3. Derivation

1. **Bayes' rule.** The probability of H_1 and x together is $\pi q(x)$, and of H_0 and x together is $(1-\pi)p(x)$. Dividing each by the total probability of x, $m(x) = \pi q(x) + (1-\pi)p(x)$, gives $\Pr[H_1 \mid x] = \pi q(x)/m(x)$ and $\Pr[H_0 \mid x] = (1-\pi)p(x)/m(x)$. Dividing one by the other cancels $m(x)$ and gives Equation 4.20.
2. **Error of a test.** A test errs when H_0 holds and it rejects, with probability $(1-\pi)\alpha_\phi$, or when H_1 holds and it misses, with probability $\pi\beta_\phi$. By Fact 1, writing $\alpha_\phi = \sum_x \phi p$ and $\beta_\phi = 1 - \sum_x \phi q$,

$$(1-\pi)\alpha_\phi + \pi\beta_\phi = \pi + \sum_x \phi(x)((1-\pi)p(x) - \pi q(x)). \tag{4.21}$$

3. **Minimize term by term.** Each $\phi(x)$ appears in one term, so set $\phi(x) = 1$ where the bracket is negative and 0 where it is positive. The bracket is negative where $\pi q(x) > (1-\pi)p(x)$, or $\Lambda(x) > (1-\pi)/\pi$.
4. **The minimum error on the curve.** Because the optimal test is an LR test, it lies on the trade-off curve, so the minimum error is $\min_\alpha [(1-\pi)\alpha + \pi T(\alpha)]$. With equal priors, $\pi = \frac{1}{2}$, it is $\frac{1}{2}\min_\alpha(\alpha + T(\alpha))$. Minimizing $\alpha + T(\alpha)$ is maximizing the advantage $1 - \alpha - T(\alpha)$, whose maximum is TV by Equation 4.16, so the minimum error is $\frac{1}{2}(1 - \mathrm{TV})$. For the Gaussian pair at $\mu = 1$ that is $\frac{1}{2}(1 - 0.3829) = 0.3085$.

The same holds for any outcome you observe, not only for x. If the evidence is just "the test fired", its likelihood ratio is the probability of firing under H_1 over that under H_0, $\Pr[\text{fire} \mid H_1]/\Pr[\text{fire} \mid H_0] = (1-\beta)/\alpha$, the power divided by the false positive rate.

4.10.4. Example: screening at 1% prevalence

Use the biomarker test with $\mu = 2$ from Table 4.4, in a population where 1% are ill (prior odds 1/99). To get the probability of illness after a positive result, multiply the prior odds by the likelihood ratio of a positive, then turn odds o back into a probability $o/(1 + o)$.

At $\alpha = 0.05$ the power is 0.6388, so a positive result has likelihood ratio $0.6388/0.05 = 12.8$. The posterior odds are $12.8/99 = 0.129$, so $\Pr[\text{ill} \mid \text{positive}] = 0.129/1.129 = 0.114$. Nine in ten positives are false alarms. At $\alpha = 10^{-3}$ the power is 0.1378, the likelihood ratio is $0.1378/0.001 = 137.8$, the posterior odds are $137.8/99 = 1.392$, and $\Pr[\text{ill} \mid \text{positive}] = 1.392/2.392 = 0.582$.

The stricter threshold catches fewer ill patients but makes a positive result far more informative (Figure 4.7). This is the second reason low-FPR behaviour matters: when positives are rare, the false-positive rate, not the power, decides whether an alarm is worth acting on.

The Bayes rule here. Minimizing the error probability at $\pi = 0.01$ means rejecting when $\Lambda(x) > (1 - \pi)/\pi = 99$. For the Gaussian, $\Lambda(x) = e^{\mu x - \mu^2/2} > 99$ means $x > \mu/2 + \ln(99)/\mu = 1 + 4.5951/2 = 3.2976$. That test has $\alpha = 1 - \Phi(3.2976) = 4.88 \times 10^{-4}$ and power only $1 - \Phi(3.2976 - 2) = 0.0972$: when errors of both kinds count equally and the disease is rare, it is cheapest to rarely say "ill". If missing a case costs c times as much as a false alarm, the quantity to minimize becomes $(1 - \pi)\alpha + c\pi\beta$, the same argument gives the threshold $(1 - \pi)/(c\pi)$, and the test moves along the same curve.

4.10.5. Check yourself

- If the prior doubles from 1% to 2%, roughly how does the posterior odds after a positive change? *(It roughly doubles: posterior odds scale linearly with prior odds,* 2/98 *against* 1/99*.)*
- Why is the Bayes-optimal test an LR test even though Bayes and Neyman–Pearson ask different questions? *(Both trade off the two errors linearly: Bayes with fixed weights* $1 - \pi$ *and* π*, Neyman–Pearson with the exchange rate* τ*, which plays the role of a Lagrange multiplier on the false-positive budget. Each linear trade-off is minimized by a threshold on* Λ*.)*

4.11. Estimating error rates from finite trials

4.11.1. Context

Everything so far assumed you know P and Q. In practice you measure a detector's FPR and TPR on test data: k false positives among n negatives. Each negative is falsely flagged independently with probability p, so the count k is $\mathrm{Bin}(n, p)$, the number of successes in n independent trials that each succeed with probability p (Probability distributions). The measured rate k/n is therefore uncertain, and at low rates the uncertainty is large relative to the rate itself. A claim such as "TPR at FPR 10^{-3}" is only as good as the interval around it.

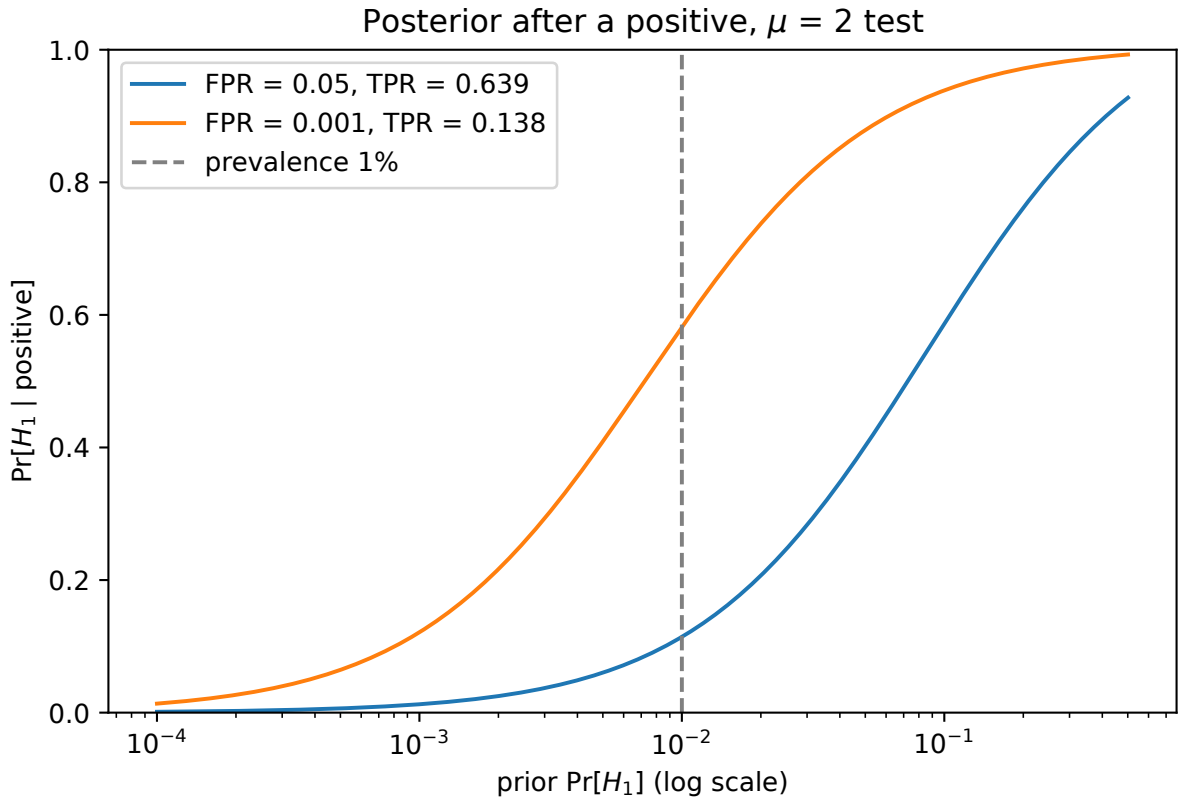

Figure 4.7.: Posterior probability of illness after a positive result, as a function of the prior, for the $\mu = 2$ biomarker test at two thresholds. At 1% prevalence (dashed line) the stricter test gives 0.582 against 0.114.

4.11.2. Statement: the Clopper–Pearson interval

The interval is built by asking which true rates would make the observed count unsurprising. A true rate far above k/n would make a count as small as k very unlikely; the upper end u is the rate at which seeing k or fewer has probability exactly $\alpha/2$. Likewise the lower end l is the rate at which seeing k or more has probability $\alpha/2$. For k successes in n trials and confidence level $1-\alpha$, let l and u solve

$$\Pr[\mathrm{Bin}(n,l) \geq k] = \frac{\alpha}{2}, \qquad \Pr[\mathrm{Bin}(n,u) \leq k] = \frac{\alpha}{2}, \tag{4.22}$$

with $l = 0$ if $k = 0$ and $u = 1$ if $k = n$. Then $\Pr[l \leq p \leq u] \geq 1-\alpha$ for every true rate p.

4.11.3. Derivation (upper end; the lower end is symmetric)

The interval is random, because it depends on the observed count, and the claim is about how often it misses the fixed true rate p. The plan is to show that it misses above, $p > u$, with probability at most $\alpha/2$. Write $F_p(k) = \Pr[\mathrm{Bin}(n,p) \leq k]$ for the probability of at most k successes at rate p, and let $K \sim \mathrm{Bin}(n,p)$ be the observed count.

1. **Monotonicity.** $F_p(k)$ is continuous and strictly decreasing in p for $k < n$: a larger success probability makes small counts less likely (Section F.3 in the appendices proves it). So for each k there is a single rate $u(k)$ with $F_{u(k)}(k) = \alpha/2$, and the true rate lies at or above the upper end, $p \geq u(K)$, exactly when $F_p(K) \leq F_{u(K)}(K) = \alpha/2$.
2. **A CDF evaluated at its own draw is rarely small.** It remains to show $\Pr[F_p(K) \leq \alpha/2] \leq \alpha/2$. Let k^* be the largest k with $F_p(k) \leq \alpha/2$. Since F_p is increasing in k, $F_p(K) \leq \alpha/2$ exactly when $K \leq k^*$, so $\Pr[F_p(K) \leq \alpha/2] = \Pr[K \leq k^*] = F_p(k^*) \leq \alpha/2$. (If no such k^* exists, the probability is 0.)
3. **Combine.** So $\Pr[p \geq u(K)] \leq \alpha/2$, and the same argument gives $\Pr[p \leq l(K)] \leq \alpha/2$ at the lower end. The probability that at least one of two events happens is at most the sum of their probabilities (the union bound), so the interval misses with probability at most α, and its coverage is at least $1-\alpha$.

The interval is **exact** in the sense that it uses the binomial distribution itself rather than an approximation, and **conservative**: its coverage is at least $1-\alpha$, often more.

Zero counts and the rule of three. If $k = 0$, the probability of seeing no successes at rate u is $(1-u)^n$, so the one-sided upper bound at level 0.95 solves $(1-u)^n = 0.05$. That gives $u = 1 - 0.05^{1/n}$. For large n, $0.05^{1/n} = e^{-\ln(20)/n} \approx 1 - \ln(20)/n$, so $u \approx \ln(20)/n \approx 3/n$, since $\ln 20 = 3.00$ to two decimals. With $n = 3{,}000$ negatives and no false positives, $u = 9.981 \times 10^{-4}$. Turning this around, to certify an FPR below 10^{-3} at 95% confidence you need $(1-10^{-3})^n \leq 0.05$, that is, at least $\ln 20/(-\ln(1-10^{-3})) = 2{,}994.2$, so 2,995, negatives with *no* false positive at all.

4.11.4. Example: measuring TPR at FPR 10^{-3}

Take the $\mu = 2$ biomarker, with the threshold $\tau = 3.0902$ that gives a true FPR of 10^{-3} and a true TPR of 0.1378. Test it on $n = 10{,}000$ negatives and 10,000 positives. One simulated run gives Table 4.7.

Table 4.7.: One simulated evaluation of the $\mu = 2$ test at its 10^{-3} threshold, with 10,000 examples per class.

Quantity	Count	Estimate	95% Clopper–Pearson interval
False positives	10	0.0010	$[0.00048, 0.00184]$
True positives	1,350	0.1350	$[0.1284, 0.1419]$

The TPR is pinned down to about ± 0.007, half the interval's width of $0.1419 - 0.1284 = 0.0135$. The FPR is not: the data are consistent with a true FPR anywhere from about half to almost twice the target (Table 4.7). The number of negatives limits what a low-FPR claim can mean.

Two other common ways to build the FPR interval from $k = 10$, $n = 10{,}000$ do worse. The **Wald** interval uses the normal approximation to the binomial, $\hat{p} \pm 1.96\sqrt{\hat{p}(1-\hat{p})/n}$ with $\hat{p} = k/n$, where 1.96 is $\Phi^{-1}(0.975)$. Here the half-width is $1.96\sqrt{0.001 \times 0.999/10{,}000} = 0.00062$, giving $[0.00038, 0.00162]$. That is too narrow and symmetric for a skewed count, and at $k = 0$ it collapses to $[0, 0]$, claiming certainty from no data. The **Hoeffding** interval comes from Hoeffding's inequality (Concentration inequalities), which says that the average of n independent variables in $[0, 1]$ strays from its mean by at least v with probability at most $2e^{-2nv^2}$. Setting that to 0.05 gives the two-sided half-width $v = \sqrt{\ln(2/0.05)/(2n)} = \sqrt{\ln(40)/20{,}000} = 0.0136$, more than 13 times the rate being measured. A bound that uses only the range $[0, 1]$ ignores the tiny variance $p(1-p)$.

Clopper–Pearson is conservative, not loose: over 2,000 simulated evaluations with true FPR 10^{-3} and $n = 10{,}000$, its interval covered the true rate 97.20% of the time, above the nominal 95%. Figure 4.8 shows how slowly the interval tightens with n when the observed rate stays at 10^{-3}.

4.11.5. Interpretation

What sets the relative width of the interval is mainly the expected count $k = np$, the number of false positives you expect to see, not n alone. A count of k fluctuates by about $\sqrt{k}$, so its relative uncertainty is about $1/\sqrt{k}$. Ten events give a factor-of-two uncertainty, $[0.00048, 0.00184]$ around 10^{-3}. A hundred events, at $n = 100{,}000$, give about $\pm 20\%$: $[0.00081, 0.00122]$. This gives a rule of thumb: to measure an FPR of p to within a factor of about 1.2, you need on the order of $100/p$ negatives, 10^5 for $p = 10^{-3}$.

The threshold is also estimated. If you choose the threshold on the same data so that the empirical FPR is 10^{-3}, the true FPR of that threshold is uncertain in exactly the way shown above. Choose thresholds on one split and measure rates on another.

4.11.6. Check yourself

- You see 0 false positives in 300 negatives. What can you claim at 95% confidence? *(FPR $\leq$ about $3/300 = 0.01$, by the rule of three. Nothing about 10^{-3}.)*
- Why is Hoeffding so much wider than Clopper–Pearson at low rates? *(Hoeffding assumes the worst-case variance $\frac{1}{4}$ for a variable in $[0, 1]$; the true variance of a false-positive indicator is $p(1-p) \approx 10^{-3}$.)*

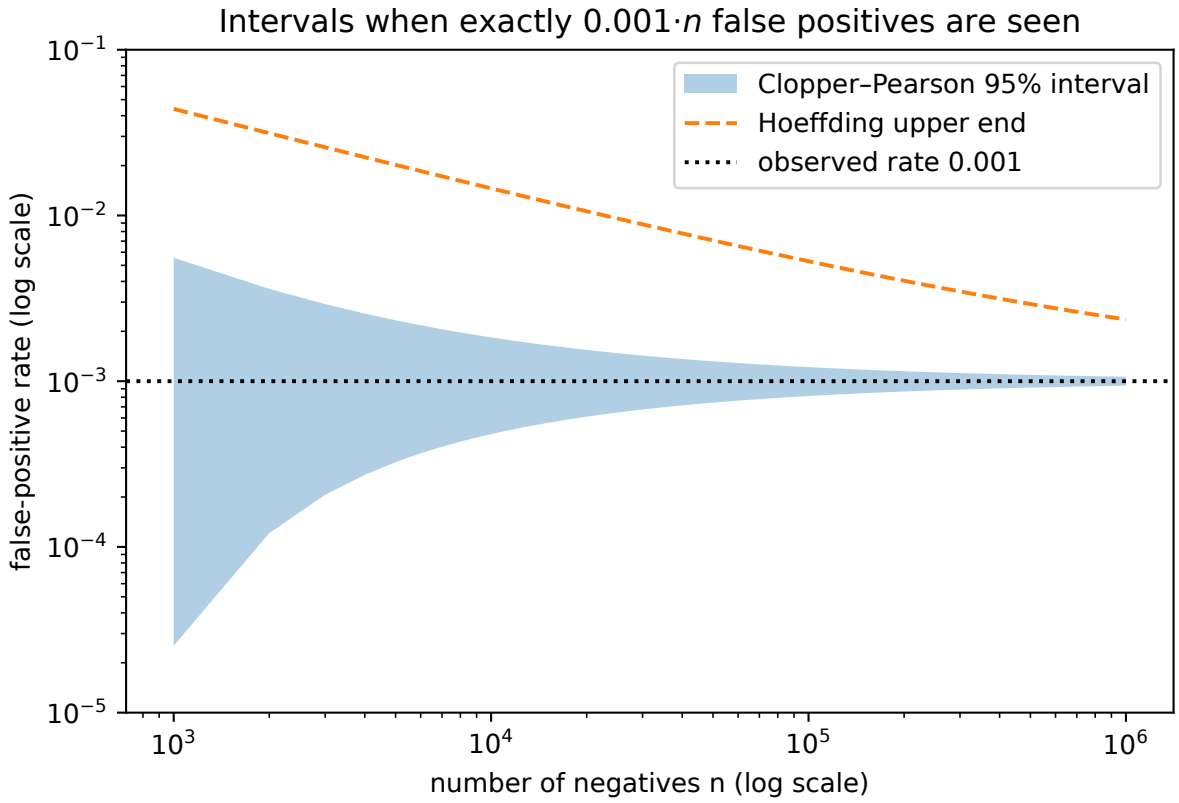

Figure 4.8.: 95% Clopper–Pearson intervals for an observed false-positive rate of exactly 10^{-3}, as the number of negatives grows from 10^3 to 10^6, with the upper end of the two-sided Hoeffding interval for comparison.

4.12. Code: check every result by computation and simulation

The script code/hypothesis_testing.py computes every number quoted in this chapter and draws every figure. Each error rate, trade-off curve, interval and simulation is a small typed function; the script calls them once for the table and loops them over parameters for the figures. It uses only the standard library and NumPy: Φ comes from `math.erfc`, and Φ^{-1} and the Clopper–Pearson ends are found by bisection. From the repository root:

```
uv run python code/part01-prerequisites/hypothesis_testing.py
```

Output (seed 0), summarized in Table 4.8:

Table 4.8.: Results printed by the script with seed 0.

Experiment	Result
Spam example, LR test at $\alpha = 0.25$	$\tau = 1.5$, $\gamma = 0.75$, power 0.625
200,000 random tests on the spam example	11,727 with size ≤ 0.25; best power 0.587
Gaussian $\mu = 2$, $\alpha = 0.05$	$\beta = 0.3612$ exact; simulated $\hat{\alpha} = 0.0503$, $\hat{\beta} = 0.3617$
Gaussian $\mu = 2$, $\alpha = 10^{-3}$	power 0.1378
Laplace $\kappa = 1$, $\alpha = 0.25$	$\beta = 0.3679$ exact; simulated $\hat{\alpha} = 0.2498$, $\hat{\beta} = 0.3685$
Same TV 0.3935, $\alpha = 10^{-6}$	Laplace power 2.718×10^{-6}; Gaussian ($\mu = 1.0301$) 9.829×10^{-5}
Best advantage, Gaussian $\mu = 1$	Formula 0.3829; grid maximum 0.3829 at $\alpha = 0.3085$
Equal-AUC detectors A and B	AUC 0.7602 both; TPR at 10^{-3}: 0.0183 and 0.2253
Screening at 1% prevalence, $\mu = 2$	Posterior after a positive: 0.114 at $\alpha = 0.05$; 0.582 at $\alpha = 10^{-3}$
Clopper–Pearson, $k = 10$, $n = 10{,}000$	$[0.00048, 0.00184]$; coverage over 2,000 runs 0.9720

tests/test_hypothesis_testing.py checks that the output still matches Table 4.8 and every other number in the text.

Four things stand out. First, Neyman–Pearson is not just a theorem: a random search over 200,000 tests never comes close to the LR test at the same level. Second, the closed-form curves match simulation to within sampling error, for both the Gaussian and the Laplace pairs, so the derivations can be trusted at the levels where simulation is too expensive. Third, summaries can agree while the curves differ: equal TV or equal AUC says nothing about power at 10^{-3} or 10^{-6}, which is why the whole curve is the object to look at. Fourth, low rates are expensive to measure: ten false positives pin the FPR down only to a factor of two.

4.14. Cheat sheet

Table 4.9 collects every result in the chapter.

Table 4.9.: Every result in this chapter.

Result	Statement	Where it comes from
Errors of a test ϕ	$\alpha_\phi = \mathbb{E}_P\phi$, $\beta_\phi = 1 - \mathbb{E}_Q\phi$, power $= 1 - \beta_\phi$	Fact 1
Neyman–Pearson	The size-α test that rejects when $q/p > \tau$ (randomizing at $=$) is most powerful at level α	$(\phi^* - \phi)(q - \tau p) \geq 0$ pointwise
Trade-off function	$T(\alpha) = \inf\{\beta_\phi : \alpha_\phi \leq \alpha\}$; non-increasing, $\leq 1 - \alpha$, convex, continuous	Mixing tests; change of measure
Slope of T	$T'(\alpha) = -\Lambda$ at the threshold	$\mathrm{d}\beta/\mathrm{d}\alpha = -q(\tau)/p(\tau)$
Gaussian $\mathcal{N}(0,1)$ vs $\mathcal{N}(\mu,1)$	$T(\alpha) = \Phi(\Phi^{-1}(1-\alpha) - \mu)$; n draws: $\mu = h\sqrt{n}/\sigma$	LR increasing in x
Laplace $\mathrm{Lap}(0,b)$ vs $\mathrm{Lap}(m_1,b)$	$1 - e^{\kappa}\alpha$; $e^{-\kappa}/(4\alpha)$; $e^{-\kappa}(1-\alpha)$, with $\kappa = m_1/b$	LR clipped to $[e^{-\kappa}, e^{\kappa}]$
Best advantage	$\max_\phi(1-\alpha_\phi-\beta_\phi) = \mathrm{TV}(P,Q)$; Gaussian $2\Phi(\mu/2) - 1$; Laplace $1 - e^{-\kappa/2}$	Reject where $q > p$
AUC	$\Pr[S_+ > S_-]$; binormal $\Phi(m/\sqrt{1+\sigma^2})$	Change of variables in $\int \mathrm{TPR}\,\mathrm{dFPR}$

Result	Statement	Where it comes from
Bayes	Posterior odds = prior odds $\times\Lambda(x)$; minimum error at $\pi = \frac{1}{2}$ is $\frac{1}{2}(1 - \mathrm{TV})$	Bayes' rule
Clopper–Pearson	$\Pr[\mathrm{Bin}(n, l) \geq k] = \Pr[\mathrm{Bin}(n, u) \leq k] = \alpha/2$; zero counts: $u \approx 3/n$	Inverting binomial tails

Rules of thumb

- To find the best test, compute the likelihood ratio and threshold it. If it is monotone in a statistic, threshold the statistic.
- Look at the whole trade-off curve, on log axes if false positives must be rare. TV and AUC are single points or averages of it.
- A bounded likelihood ratio caps power at small α: power $\leq \Lambda_{\max}\,\alpha$.
- To measure a rate near p, plan for about $100/p$ trials, and report a Clopper–Pearson interval.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

5. Information theory

5.1. Why this matters

You observe something, and you want to know how much it tells you about something else you cannot see. A word in an email says something about whether the email is spam. A noisy sensor reading says something about the true state. A model's prediction says something about the label. Information theory turns "how much" into a number, and it does so in two different ways, because there are two different questions you might be asking.

The first question is: **how many bits, on average, does the observation save you when you describe the hidden value?** Shannon entropy and mutual information answer it. They are the language of compression, of the cross-entropy loss you train classifiers with, of decision-tree splits and of sending data over noisy links. The second question is: **how much more likely is a single best guess to be right once you have seen the observation?** Min-entropy and vulnerability answer that one. They are the language of password strength, and of anyone who gets only one try.

The idea that organizes the chapter is that **every quantity here is built from the logarithm of a probability, either averaged or maximized.** Shannon entropy is the average of $-\log_2 p(x)$ over the outcomes x; min-entropy uses only the most likely outcome instead. Because of this, almost every derivation below is one of two moves. Either it applies Jensen's inequality, which compares the average of a logarithm with the logarithm of an average, or it takes the product rule $p(x, y) = p(y)\, p(x \mid y)$ (the probability of both equals the probability of y times the probability of x given y) and turns it, by taking logs, into a sum.

Table 5.1.: The results of this chapter and where they are used.

Result	Where it is used
Entropy, $0 \le H(X) \le \log_2 \lvert\mathcal{X}\rvert$	Cross-entropy loss, compression, the scale of everything below
Chain rule, conditional entropy	Splitting the uncertainty of several variables into pieces
Mutual information $I(X;Y)$ as a Kullback–Leibler (KL) divergence	Feature selection, information gain; the link to Divergences
Data-processing inequality	Processing an observation cannot add information about its source
Channel capacity, binary symmetric channel $1 - h(p)$	The most information a noisy channel can carry

Result	Where it is used
Vulnerability and min-entropy	One-guess success; password strength
Conditional min-entropy, min-entropy leakage, min-capacity	How much an observation helps a guesser, and its worst case over priors
Fano's inequality	Lower bounds: no estimator can beat a given error rate

Table 5.1 lists the results. Later parts of the book measure what an observation reveals about a hidden value. They need both views, the average one and the one-guess one, and they need to know where the two disagree.

Logarithms in this chapter are base 2, written $\log_2$, so quantities are in **bits**; ln is the natural logarithm. Divergences uses natural logarithms, whose unit is the **nat**, so the KL divergence D_{KL} of this chapter is the one there divided by $\ln 2$. To convert, note that $\log_2 x = \ln x / \ln 2$, so one nat is $1/\ln 2 = \log_2 e \approx 1.443$ bits.

5.2. Toolkit: three facts every derivation uses

5.2.1. Fact 1 — Jensen's inequality for the logarithm

The logarithm grows more and more slowly: going from 1 to 2 adds one bit, going from 2 to 3 adds much less. Because of this bend, if you average some positive numbers and then take the log, you get more than if you take the logs first and then average. Concretely, the numbers 1 and 4 have logs 0 and 2, whose average is 1, while their average 2.5 has $\log \log_2 2.5 \approx 1.32$. In general, for a positive random variable Z,

$$\mathbb{E}[\log_2 Z] \leq \log_2 \mathbb{E}[Z], \tag{5.1}$$

with equality if and only if Z is constant (with probability 1), since only then is there nothing for the bend to act on.

The proof uses the fact that a curve that bends downward, a **concave** function, lies below each of its tangent lines. Take the tangent to $\log_2$ at the point $m = \mathbb{E}Z$. Its slope is the derivative of $\log_2 z$ at m, which is $1/(m \ln 2)$, so for every $z > 0$

$$\log_2 z \leq \log_2 m + \frac{z - m}{m \ln 2}. \tag{5.2}$$

Now put Z in place of z and average both sides. The left side becomes $\mathbb{E}[\log_2 Z]$. On the right, $\log_2 m$ stays as it is and the second term averages to zero, because $\mathbb{E}[Z - m] = 0$ by the choice of m. That leaves $\mathbb{E}[\log_2 Z] \leq \log_2 m = \log_2 \mathbb{E}Z$. The tangent touches $\log_2$ only at m, so equality needs $Z = m$ wherever Z has probability: Z must be constant.

This fact turns "an average of logs" into "a log of an average", and that is how every bound in this chapter is proved. Multiplying both sides by -1 gives the mirror version for $-\log_2$, which bends the other way (it is **convex**): $-\log_2 \mathbb{E}Z \leq \mathbb{E}[-\log_2 Z]$.

5.2.2. Fact 2 — Gibbs' inequality: KL divergence is non-negative

To say how different two distributions p and q on the same finite set are, information theory uses the **Kullback–Leibler (KL) divergence** $D_{\mathrm{KL}}(p \,\|\, q)$. It is the average, over outcomes drawn from p, of the log of how much more likely each outcome is under p than under q. If p and q are the same, every ratio is 1, every log is 0, and the divergence is 0. Gibbs' inequality says that it can never be negative:

$$D_{\mathrm{KL}}(p \,\|\, q) = \sum_x p(x) \log_2 \frac{p(x)}{q(x)} \geq 0, \tag{5.3}$$

with equality if and only if $p = q$. This is not obvious, because individual log ratios can be negative (wherever $q(x) > p(x)$). The point is that on average, weighted by p, they cannot be.

The proof is Jensen's inequality (Fact 1) applied to the ratio $Z = q(X)/p(X)$, with X drawn from p. The average of this ratio is easy: the $p(x)$ in the weight cancels the $p(x)$ in the denominator, leaving $\sum q(x)$ over the outcomes that p can produce, which is at most 1. So, summing only over x with $p(x) > 0$,

$$-D_{\mathrm{KL}}(p \,\|\, q) = \mathbb{E}\left[\log_2 \frac{q(X)}{p(X)}\right] \leq \log_2 \sum_{x:\, p(x)>0} p(x) \frac{q(x)}{p(x)} = \log_2 \sum_{x:\, p(x)>0} q(x) \leq \log_2 1 = 0. \tag{5.4}$$

Both inequalities in this line must be equalities for $D_{\mathrm{KL}} = 0$. The first needs the ratio q/p to be constant where p has mass (the equality case of Fact 1), and the second needs q to put no mass outside that set. Together these force $q = p$.

Every "≥ 0" and every "$\leq \log_2 |\mathcal{X}|$" below is this fact in disguise. Divergences studies D_{KL} itself in more detail.

5.2.3. Fact 3 — Conventions

Three conventions keep the formulas short. First, $0 \log_2 0 = 0$. The expression $0 \log_2 0$ is not defined on its own, but $t \log_2 t \to 0$ as $t \to 0$, and this choice says that outcomes of probability zero contribute nothing, which is what you want from a measure of uncertainty.

Second, a joint distribution of two variables with finitely many values is a table $p(x, y)$, with one row for each value of X and one column for each value of Y. Adding up a row gives the **marginal** probability $p(x)$ that $X = x$, whatever Y is; adding up a column gives $p(y)$.

Third, a **channel** from X to Y is a rule that, for each input x, says how likely each output y is. It is also a table, $K[x, y] = p(y \mid x)$, and each row sums to 1 because, given the input, some output must occur. A channel alone does not say how likely each input is. That comes from a **prior** $\pi(x)$, and the two together give the joint table by the product rule, $p(x, y) = \pi(x)\, K[x, y]$: the probability that the input is x, times the probability that the channel then produces y.

5.3. Shannon entropy

5.3.1. Context

How uncertain is a random variable? A fair coin should count as one unit of uncertainty, two fair coins as two, and a coin that always lands heads as zero. Shannon entropy is the measure with these properties, and it is also the average number of bits that the best possible code needs per symbol. You meet it every time you train a classifier. The cross-entropy loss, averaged over the data, equals $H(p) + D_{\mathrm{KL}}(p \,\|\, q)$: the entropy of the true label distribution p, which no model can remove, plus the KL divergence from p to the model's predicted distribution q, which training drives down.

5.3.2. Statement

The rarer an outcome, the more it tells you when it happens. So measure the information in an outcome x by its **surprisal** $\log_2(1/p(x))$, which is 0 for a certain outcome and grows as $p(x)$ shrinks: an outcome of probability $\frac{1}{2}$ carries 1 bit, one of probability $\frac{1}{4}$ carries 2 bits. The **entropy** of a discrete random variable X with distribution p is its average surprisal:

$$H(X) = -\sum_x p(x) \log_2 p(x) = \mathbb{E}\left[\log_2 \frac{1}{p(X)}\right]. \tag{5.5}$$

For a variable that is 1 with probability p and 0 otherwise, a $\mathrm{Bern}(p)$ variable, the sum has two terms. It is called the **binary entropy function**:

$$h(p) = -p \log_2 p - (1-p) \log_2 (1-p). \tag{5.6}$$

Bounds. Entropy cannot be negative, because surprisals are not, and it is largest when no outcome is favoured. For X taking values in a finite set $\mathcal{X}$, with $|\mathcal{X}|$ elements,

$$0 \le H(X) \le \log_2 |\mathcal{X}|. \tag{5.7}$$

The lower bound holds with equality exactly when X is constant, the upper bound exactly when X is uniform.

Joint and conditional entropy. For two variables, $H(X, Y)$ is the entropy of the pair, computed from the joint table. Once you observe a particular value $Y = y$, the uncertainty about X is the entropy of the distribution of X given that value, $H(X \mid Y = y) = -\sum_x p(x \mid y) \log_2 p(x \mid y)$. Before you observe Y, you do not know which y you will see, so the natural summary is the average over y. That average is the **conditional entropy**:

$$H(X \mid Y) = \sum_y p(y)\, H(X \mid Y = y). \tag{5.8}$$

Chain rule. The uncertainty in the pair is the uncertainty in Y plus whatever uncertainty about X remains once Y is known, and the same holds with the roles swapped:

$$H(X, Y) = H(Y) + H(X \mid Y) = H(X) + H(Y \mid X). \tag{5.9}$$

5.3.3. Derivation

Lower bound. The idea is that entropy is an average of surprisals, and no surprisal is negative.

1. Each probability satisfies $0 \le p(x) \le 1$, so $1/p(x) \ge 1$ and $\log_2(1/p(x)) \ge 0$. Each term $p(x)\log_2(1/p(x))$ is therefore non-negative (Fact 3 handles $p(x) = 0$).
2. A sum of non-negative terms is zero only if every term is zero. A term $p(x)\log_2(1/p(x))$ is zero only when $p(x) = 0$ or $p(x) = 1$. So $H(X) = 0$ forces one value to have probability 1: X is constant.

Upper bound. The idea is that the gap between $\log_2|\mathcal{X}|$ and $H(X)$ is exactly the KL divergence from p to the uniform distribution, which Fact 2 says is non-negative.

1. Let $u(x) = 1/|\mathcal{X}|$ be the uniform distribution. Since $\sum_x p(x) = 1$, you can write the constant $\log_2|\mathcal{X}|$ as $\sum_x p(x)\log_2|\mathcal{X}|$. Then $\log_2|\mathcal{X}| - H(X) = \sum_x p(x)\log_2|\mathcal{X}| + \sum_x p(x)\log_2 p(x)$.
2. Combine the two logs in each term, using $\log_2|\mathcal{X}| = \log_2(1/u(x))$: the sum becomes $\sum_x p(x)\log_2 \frac{p(x)}{u(x)} = D_{\mathrm{KL}}(p \,\|\, u)$.
3. By Gibbs' inequality (Fact 2), $D_{\mathrm{KL}}(p \,\|\, u) \ge 0$, with equality iff $p = u$. So $H(X) \le \log_2|\mathcal{X}|$, with equality iff X is uniform.

Chain rule. The idea is that the product rule for probabilities becomes a sum rule for surprisals, and averaging preserves sums.

1. For every pair with $p(x, y) > 0$, the product rule gives $p(x, y) = p(y)\,p(x \mid y)$. Taking $\log_2(1/\cdot)$ of both sides turns the product into a sum: $\log_2 \frac{1}{p(x,y)} = \log_2 \frac{1}{p(y)} + \log_2 \frac{1}{p(x|y)}$.
2. Average both sides over the pair (X, Y). The left side is the average surprisal of the pair, $H(X, Y)$. The first term on the right is $H(Y)$. The second term, grouped by y, is $\sum_y p(y) \sum_x p(x \mid y)\log_2 \frac{1}{p(x|y)}$, which is the average over y of $H(X \mid Y = y)$, that is $H(X \mid Y)$.
3. Starting from $p(x, y) = p(x)\,p(y \mid x)$ instead, the same steps give the second form.

5.3.4. Interpretation

Figure 5.1 shows the binary entropy $h(p)$. It is 1 bit at $p = \frac{1}{2}$, where the coin is fair and you have no idea which way it will land, and zero at $p \in \{0, 1\}$, where you know the outcome. It is very steep near the ends, so even a quite lopsided coin keeps a lot of uncertainty: $h(0.11) = 0.4999$, so a coin with an 11% chance of heads still carries half a bit. The figure also shows the min-entropy of the same coin, a one-guess measure that Section 5.6 defines and that is always below h.

The chain rule splits uncertainty into pieces: first reveal Y, then what remains of X. Applying Equation 5.9 repeatedly, peeling off one variable at a time, extends it to any number of variables: $H(X_1, \ldots, X_n) = \sum_i H(X_i \mid X_1, \ldots, X_{i-1})$, the uncertainty of the first variable, plus that of the second given the first, and so on.

Entropy depends only on the probabilities, not on the values themselves. Relabelling the outcomes, for instance calling them "red" and "blue" instead of 0 and 1, does not change it.

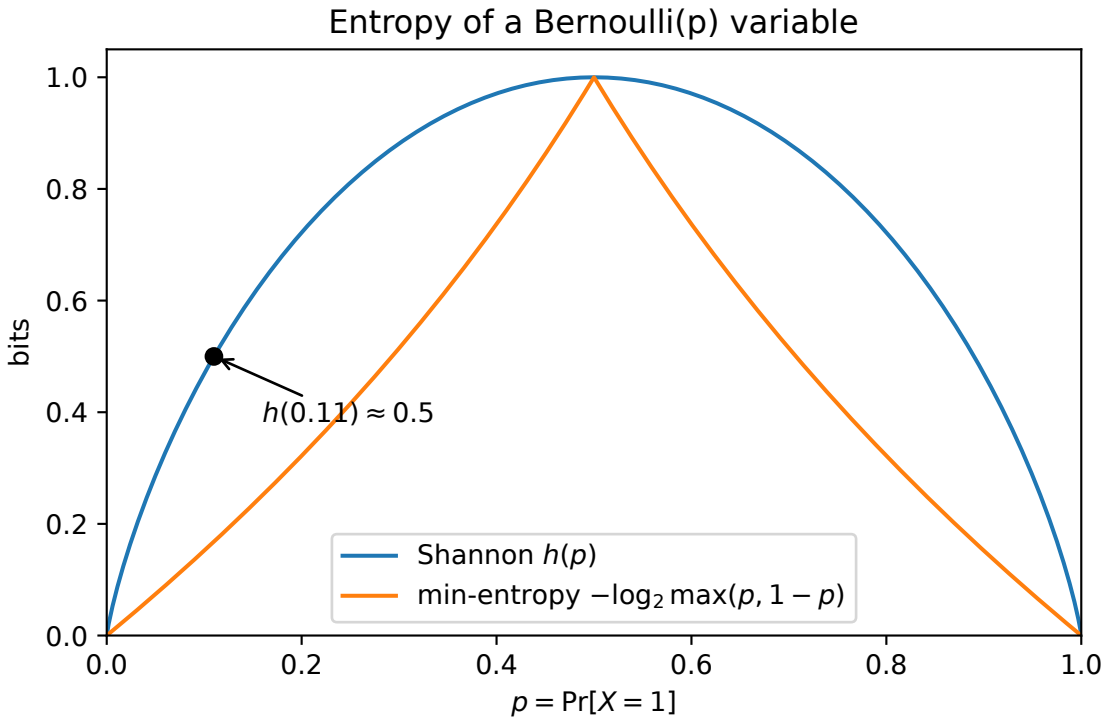

Figure 5.1.: The binary entropy $h(p)$ against the min-entropy $-\log_2 \max(p, 1-p)$ of the same Bernoulli variable. Both are 1 bit at $p = \frac{1}{2}$; the min-entropy is lower everywhere else.

5.3.5. Conditioning reduces entropy on average, not pointwise

Intuitively, learning something should not make you more uncertain. That is true on average: averaged over what you might observe, observing Y cannot increase the uncertainty about X,

$$H(X \mid Y) \leq H(X), \tag{5.10}$$

with equality if and only if X and Y are independent. The proof is short once mutual information is defined in the next section. There the gap $H(X) - H(X \mid Y)$ turns out to be a KL divergence (Equation 5.11), and KL divergences are non-negative by Gibbs' inequality (Fact 2).

But a *particular* observation can increase the uncertainty. $H(X \mid Y = y) > H(X)$ is perfectly possible, as the next example shows: if an observation is rare, it can push you from a confident belief into a toss-up, and the average stays low only because the common observations make up for it.

5.3.6. Example: a spam filter's keyword

Let X be the label of an email (ham or spam) and Y whether it contains the word "offer". One email in eight is spam. Every spam email contains the word, and so does one ham email in seven. Since ham emails are $\frac{7}{8}$ of the total, the ham emails with the word are $\frac{1}{7} \cdot \frac{7}{8} = \frac{1}{8}$ of all emails, and the ham emails without it are $\frac{7}{8} - \frac{1}{8} = \frac{3}{4}$. Table 5.2 gives the full joint distribution.

Table 5.2.: Joint distribution of an email's label and whether it contains the keyword.

	$Y = 0$ (absent)	$Y = 1$ (present)	$p(x)$
ham	3/4	1/8	7/8
spam	0	1/8	1/8
$p(y)$	3/4	1/4	

Work out each quantity from Table 5.2. Before you look at the email, the label is spam with probability $\frac{1}{8}$, so $H(X) = h(1/8) = \frac{1}{8}\log_2 8 + \frac{7}{8}\log_2 \frac{8}{7} = 0.375 + 0.1686 = 0.5436$ bits: the label is fairly predictable, because most email is ham.

If the word is absent, you are in the first column. Its only non-zero entry is ham, so the email is certainly ham and $H(X \mid Y = 0) = 0$.

If the word is present, you are in the second column, where ham and spam each have probability $\frac{1}{8}$ out of $\frac{1}{4}$. Given the word, they are equally likely, so $H(X \mid Y = 1) = h(1/2) = 1$ bit. **Seeing the word made you more uncertain** than you were before: from 0.5436 bits up to a full bit.

On average, though, the word helps. You see it absent with probability $\frac{3}{4}$ and present with probability $\frac{1}{4}$, so $H(X \mid Y) = \frac{3}{4} \cdot 0 + \frac{1}{4} \cdot 1 = 0.25$ bits, less than $H(X)$.

The chain rule can be checked on the same table. The word is present with probability $\frac{1}{4}$, so $H(Y) = h(1/4) = 0.8113$, and $H(Y) + H(X \mid Y) = 0.8113 + 0.25 = 1.0613$. That equals the entropy of the pair computed directly from the three non-zero cells $(\frac{3}{4}, \frac{1}{8}, \frac{1}{8})$.

Figure 5.2 draws the four numbers. The common observation (word absent) removes all uncertainty; the rare one (word present) increases it; the average goes down. That is the general pattern: conditioning reduces entropy only in expectation.

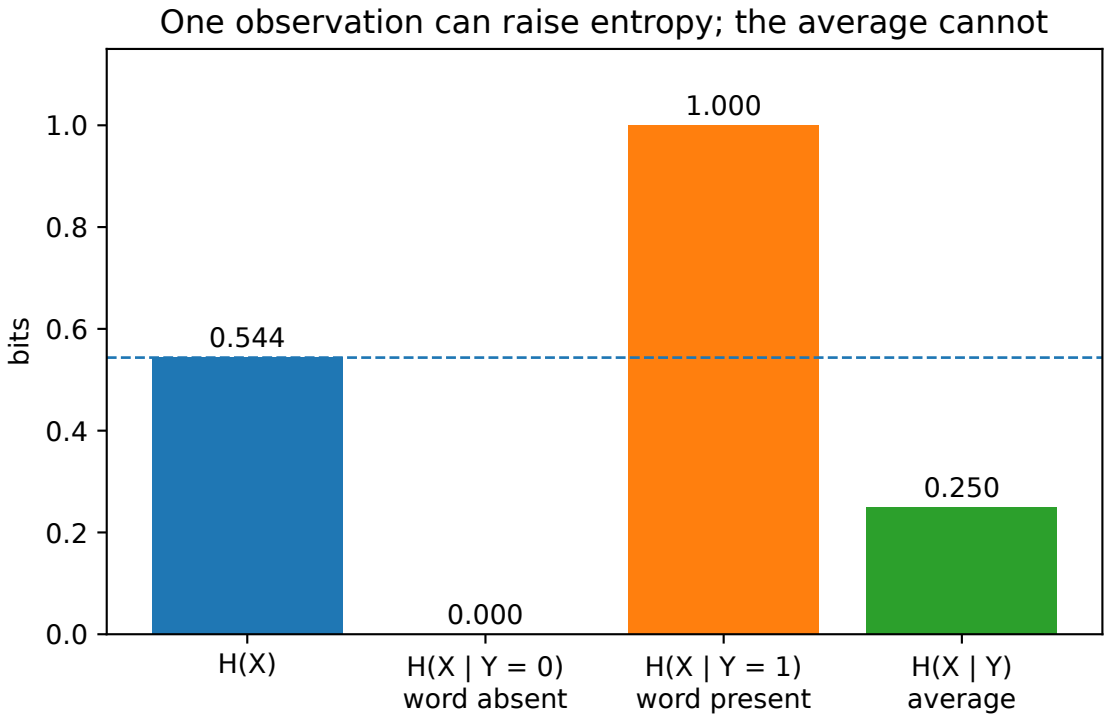

Figure 5.2.: Entropy of the spam label before observing the keyword, after each of the two possible observations, and on average. The rare observation raises the entropy above $H(X)$ (dashed line); the average falls below it.

5.3.7. Check yourself

- What is the entropy of a uniformly random 4-digit PIN, and why? *(There are 10,000 equally likely PINs, so* $H = \log_2 10{,}000 = 13.2877$ *bits: the upper bound* $\log_2|\mathcal{X}|$*, attained because the distribution is uniform.)*
- Using the chain rule, show that $H(X,Y) \le H(X) + H(Y)$, with equality iff X and Y are independent. *(*$H(X,Y) = H(Y) + H(X \mid Y)$*, and* $H(X \mid Y) \le H(X)$ *with equality iff independent.)*

5.4. Mutual information

5.4.1. Context

How much does observing Y tell you about X? A natural answer is the drop in uncertainty it causes on average, $H(X) - H(X \mid Y)$. This is the **information gain** a decision tree uses to choose a split, and the criterion many feature-selection methods use to rank features. It turns out to be a KL divergence, which makes it symmetric and non-negative, and it obeys a rule that drives a great deal of later reasoning: processing cannot create information.

5.4.2. Statement

The **mutual information** between X and Y is the average drop in uncertainty about X from seeing Y. It can also be read as a measure of dependence: the KL divergence from the true joint distribution P_{XY} to the product $P_X P_Y$ of its marginals, which is what the joint distribution would be if X and Y were independent. The two readings give the same number:

$$I(X;Y) = H(X) - H(X \mid Y) = D_{\mathrm{KL}}(P_{XY} \,\|\, P_X P_Y) = \sum_{x,y} p(x,y) \log_2 \frac{p(x,y)}{p(x)\,p(y)}. \tag{5.11}$$

It follows that mutual information is symmetric, $I(X;Y) = I(Y;X) = H(Y) - H(Y \mid X)$: Y tells you as much about X as X tells you about Y. It is non-negative, and it is zero if and only if X and Y are independent.

Sometimes a third variable Z is already known. The **conditional mutual information** is the same quantity computed with every distribution conditioned on $Z = z$, then averaged over z. It measures what Y adds about X beyond what Z already told you, and it is non-negative because it is an average of KL divergences:

$$I(X;Y \mid Z) = H(X \mid Z) - H(X \mid Y,Z) = \sum_{z} p(z)\, D_{\mathrm{KL}}(P_{XY|z} \,\|\, P_{X|z} P_{Y|z}) \ge 0. \tag{5.12}$$

Chain rule for mutual information. What a pair (Y,Z) tells you about X is what Y tells you, plus what Z adds once Y is known:

$$I(X;Y,Z) = I(X;Y) + I(X;Z \mid Y). \tag{5.13}$$

Data-processing inequality. Suppose Z is computed from Y alone, possibly with fresh randomness, so that once you know Y, also knowing X tells you nothing more about Z. In

other words, X and Z are independent given Y. This is called a **Markov chain** and written $X \to Y \to Z$. Then Z cannot know more about X than Y does:

$$I(X;Z) \leq I(X;Y). \tag{5.14}$$

5.4.3. Derivation

Mutual information is a KL divergence. The idea is to write both entropies as averages over the same pairs (x, y), so that they can be combined term by term.

1. Start from $H(X) - H(X \mid Y)$. The entropy $H(X)$ is an average over x, but since $\sum_y p(x,y) = p(x)$ it can be written as an average over pairs: $H(X) = \sum_{x,y} p(x,y) \log_2 \frac{1}{p(x)}$. The conditional entropy is already an average over pairs, $H(X \mid Y) = \sum_{x,y} p(x,y) \log_2 \frac{1}{p(x|y)}$.
2. Subtract, combining the logs in each term: $\sum_{x,y} p(x,y) \log_2 \frac{p(x|y)}{p(x)}$.
3. Multiply the fraction inside the log by $p(y)/p(y)$ and use $p(x \mid y)\, p(y) = p(x,y)$: $\frac{p(x|y)}{p(x)} = \frac{p(x,y)}{p(x)\, p(y)}$. The sum is now $\sum_{x,y} p(x,y) \log_2 \frac{p(x,y)}{p(x)\, p(y)}$, which is the definition of $D_{\mathrm{KL}}(P_{XY} \,\|\, P_X P_Y)$.

Symmetry, non-negativity, independence. The expression at the end of step 3 does not change when you swap the roles of X and Y, so $I(X;Y) = I(Y;X)$, and running the same steps with the roles swapped gives $H(Y) - H(Y \mid X)$. Gibbs' inequality (Fact 2) gives $I \geq 0$, with equality iff $p(x,y) = p(x)\, p(y)$ for all pairs, which is the definition of independence. Since $I(X;Y) = H(X) - H(X \mid Y) \geq 0$, this also proves $H(X \mid Y) \leq H(X)$.

Chain rule for mutual information. The idea is to pass from knowing nothing to knowing (Y, Z) through the intermediate stage of knowing only Y.

1. By definition, $I(X; Y, Z) = H(X) - H(X \mid Y, Z)$: the total drop in uncertainty.
2. Add and subtract the uncertainty at the intermediate stage, $H(X \mid Y)$: $\big[H(X) - H(X \mid Y)\big] + \big[H(X \mid Y) - H(X \mid Y, Z)\big]$.
3. The first bracket is the drop from learning Y, which is $I(X;Y)$. The second is the further drop from learning Z when Y is already known, which is $I(X; Z \mid Y)$.

Data-processing inequality. The idea is to expand what the pair (Y, Z) tells you about X in two orders. In one order, the part Z adds after Y is zero, because Z was computed from Y.

1. Apply the chain rule with Z first and with Y first:

$$I(X;Z) + I(X;Y \mid Z) = I(X;Y,Z) = I(X;Y) + I(X;Z \mid Y). \tag{5.15}$$

2. The Markov chain says X and Z are independent given Y, so the conditional mutual information $I(X; Z \mid Y)$ is zero (it is an average of KL divergences between identical distributions).
3. Hence $I(X;Z) = I(X;Y) - I(X;Y \mid Z) \leq I(X;Y)$, since conditional mutual information is non-negative.

Equality holds iff $I(X; Y \mid Z) = 0$: once you know Z, Y tells you nothing more about X. Such a Z has kept everything in Y that matters for X, and is called a **sufficient statistic** for X.

5.4.4. Interpretation

Mutual information measures dependence of any kind, not only linear correlation. Two variables can have zero correlation and still be strongly dependent, as Y and Y^2 are when Y is symmetric around zero. Their mutual information is positive in that case, and it is zero only under full independence.

The data-processing inequality says that no function of the data, however clever, can contain more information about the source than the data itself. Denoising, feature extraction and training a model are all processing steps. They can make information easier to use, but never larger.

Because $I(X;Y) = D_{\mathrm{KL}}(P_{XY} \,\|\, P_X P_Y)$, every property of KL divergence in Divergences applies to mutual information. In particular, KL divergence has its own data-processing inequality there: passing two distributions through the same channel cannot increase the divergence between them. That inequality implies the one here.

Mutual information is an average over both x and y. A small value can therefore hide a few outcomes in which Y reveals X completely, because those outcomes carry little weight in the average. Section 5.8 shows how far apart the average and the worst case can be.

5.4.5. Example: the keyword, then a noisy detector

In the spam table, the word reduced the uncertainty from $H(X) = 0.5436$ bits to $H(X \mid Y) = 0.25$ bits on average, so $I(X;Y) = 0.5436 - 0.25 = 0.2936$ bits. The script computes the same value from the KL formula of Equation 5.11 and from $H(Y) - H(Y \mid X)$.

Now suppose the keyword is detected by a sloppy tokenizer that gets the answer wrong with probability 0.1, whatever the email. Call its output Z. A channel on $\{0, 1\}$ that flips its input with a fixed probability is a **binary symmetric channel**, studied in the next section, so Z is Y passed through a binary symmetric channel with flip probability 0.1. The tokenizer looks only at the word, not at the label, so $X \to Y \to Z$ is a Markov chain, and the data-processing inequality predicts $I(X;Z) \le I(X;Y)$. The script finds $I(X;Z) = 0.1668$ bits. Since $0.1668/0.2936 \approx 0.57$, the noisy feature carries 57% of the information of the clean one: a 10% error rate in the detector costs over 40% of the information.

5.4.6. Check yourself

- If $Z = g(Y)$ for an invertible function g, what is $I(X;Z)$? *(Equal to $I(X;Y)$. Apply the data-processing inequality to $X \to Y \to Z$, which gives $\le$, and to $X \to Z \to Y$, which is also a Markov chain because $Y = g^{-1}(Z)$ is computed from Z, and gives $\ge$.)*
- Can $I(X;Y)$ exceed $H(X)$? *(No. $I(X;Y) = H(X) - H(X \mid Y)$ and $H(X \mid Y) \ge 0$: an observation cannot remove more uncertainty than there was.)*

5.5. Channels and capacity

5.5.1. Context

A channel turns an input X into a random output Y: a noisy storage device, a communication link, a lossy sensor. You control the input distribution but not the noise. How much information can one use of the channel carry at best? That maximum is the **capacity**. Shannon's channel coding theorem says it is exactly the rate, in bits per channel use, at which you can send data with an error probability as small as you like, using long enough codes. This chapter does not prove that theorem; it computes the capacity, which is the number the theorem is about.

5.5.2. Statement

A channel is fixed, but how much information passes through it depends on how often you send each input, the prior π. So the capacity is the mutual information between input and output, maximized over the input prior. For a channel $K[x, y] = p(y \mid x)$,

$$\mathcal{C} = \max_{\pi} I(X;Y), \qquad X \sim \pi,\ Y \mid X = x \sim K[x, \cdot]. \tag{5.16}$$

The **binary symmetric channel** $\mathrm{BSC}(p)$ has inputs and outputs in $\{0, 1\}$ and flips the input with probability p. Its capacity is one bit, the most a binary output can carry, minus the entropy of the noise:

$$\mathcal{C}_{\mathrm{BSC}}(p) = 1 - h(p), \tag{5.17}$$

attained by the uniform input.

5.5.3. Derivation

The idea is to use the form $I(X;Y) = H(Y) - H(Y \mid X)$: the uncertainty in the output, minus the part of it that comes from the noise. The noise part turns out not to depend on the input prior, so you only have to make the output as uncertain as possible. Let the input prior be $\pi_1 = \Pr[X = 1]$.

1. Use the symmetric form of mutual information: $I(X;Y) = H(Y) - H(Y \mid X)$.
2. Given $X = x$, the output equals x with probability $1-p$ and is flipped with probability p, so $H(Y \mid X = x) = h(p)$ for both inputs. Averaging over x gives $H(Y \mid X) = h(p)$, whatever π_1 is.
3. Y takes two values, so by the entropy upper bound $H(Y) \le \log_2 2 = 1$, with equality iff Y is uniform.
4. The output is 1 if the input is 1 and not flipped, or the input is 0 and flipped, so $\Pr[Y = 1] = \pi_1(1-p) + (1-\pi_1)p$. At $\pi_1 = \frac{1}{2}$ this is $\frac{1}{2}(1-p) + \frac{1}{2}p = \frac{1}{2}$, so the uniform input makes Y uniform and the bound in step 3 is attained.
5. Hence $\max_{\pi_1} I(X;Y) = 1 - h(p)$.

5.5.4. Interpretation

Figure 5.3 (left) shows $I(X;Y)$ as a function of the input prior π_1: a concave hump peaking at $\pi_1 = \frac{1}{2}$ for every p. Away from the peak you lose a lot. At $p = 0.11$ and $\pi_1 = 0.2$, the output is 1 with probability $0.2(0.89) + 0.8(0.11) = 0.266$, so $H(Y) = h(0.266) = 0.8357$ and the channel carries only $0.8357 - 0.4999 = 0.3358$ bits, against 0.5001 at the uniform input.

The right panel shows the capacity against p. It is zero at $p = \frac{1}{2}$, where the output is a fair coin flip whatever the input, so the output is independent of the input. It is symmetric about $\frac{1}{2}$, because $h(p) = h(1-p)$: a channel that flips almost always is as good as one that never flips, since the receiver can flip every output back.

For channels without this symmetry, the maximum over π has no closed form. The **Blahut–Arimoto** algorithm computes it numerically, by alternately improving the prior and the receiver's best reading of the output until neither changes. The script uses it to check Equation 5.17, and to compute two capacities in the exercises in the exercise book.

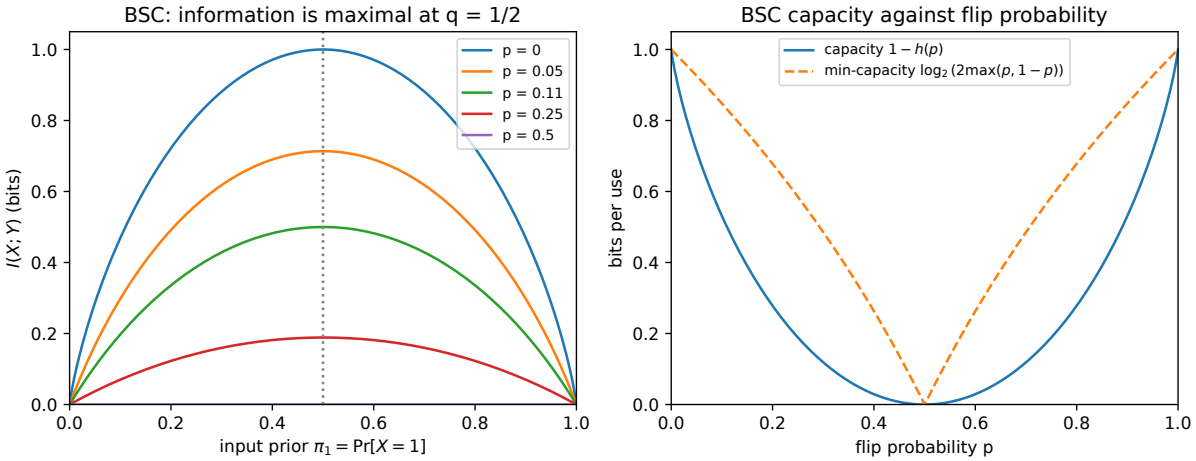

Figure 5.3.: Left: mutual information of a binary symmetric channel as a function of the input prior, for several flip probabilities; every curve peaks at $\pi_1 = \frac{1}{2}$. Right: the capacity $1 - h(p)$ against p, with the min-capacity of Section 5.7 for comparison.

5.5.5. Example: a storage medium that flips bits

A cheap storage medium flips each stored bit independently with probability $p = 0.11$. Its capacity is $1 - h(0.11) = 1 - 0.4999 = 0.5001$ bits per stored bit. So with good error-correcting codes you can store about one bit of data per two raw bits, with an error rate as small as you like, and by the channel coding theorem no code can do better. At $p = 0.25$ the capacity drops to $1 - h(0.25) = 1 - 0.8113 = 0.1887$. Since $1/0.1887 \approx 5.3$, that is about five raw bits per data bit.

5.5.6. Check yourself

- Why does the derivation not need to compute $H(Y)$ for a general π_1? *(Because $H(Y \mid X)$ does not depend on π_1, so maximizing I means maximizing $H(Y)$, and its largest possible value 1 is attainable.)*
- What is the capacity of a channel whose output is independent of its input? *(Zero: $I(X;Y) = 0$ for every prior, because mutual information is zero exactly under independence.)*

5.6. Min-entropy and guessing

5.6.1. Context

Shannon entropy counts the bits needed to describe a value on average. A different question is how likely you are to guess it in **one try**. A password chosen by a person might have high entropy, because most people choose something unusual, yet be guessed one time in ten, because one popular choice dominates. For the one-try question, all that matters is the probability of the most likely value: that is the best you can do with one guess.

5.6.2. Statement

The **vulnerability** of X is the success probability of the best single guess, the largest probability of any value. To put it on the same bit scale as entropy, take its negative log; that is the **min-entropy**:

$$V(X) = \max_x p(x), \qquad H_\infty(X) = -\log_2 V(X). \tag{5.18}$$

A fair coin has $V = \frac{1}{2}$ and $H_\infty = 1$ bit, the same as its Shannon entropy. In general, min-entropy uses the surprisal of the most likely outcome, which is the smallest surprisal, while Shannon entropy averages all surprisals. So min-entropy is never larger than Shannon entropy:

$$H_\infty(X) \le H(X) \le \log_2 |\mathcal{X}|, \tag{5.19}$$

with equality in the first inequality iff X is uniform on its **support**, the set of values it takes with positive probability.

5.6.3. Derivation

The best single guess. If you guess g, you are right with probability $p(g)$. The best you can do is pick g with the largest $p(g)$, so the optimal success probability is $\max_x p(x)$.

$H_\infty \le H$. The idea is that an average of numbers is at least their smallest value.

1. Every outcome has $p(x) \le \max_{x'} p(x') = V(X)$, so its surprisal satisfies $\log_2 \frac{1}{p(x)} \ge \log_2 \frac{1}{V(X)}$.
2. Average over X: $H(X) = \mathbb{E}[\log_2 \frac{1}{p(X)}] \ge \log_2 \frac{1}{V(X)} = H_\infty(X)$.
3. Equality needs every surprisal to equal the smallest one, $p(x) = V(X)$ for every x with $p(x) > 0$: all outcomes in the support are equally likely.

5.6.4. Interpretation

Min-entropy has a direct reading: H_∞ is the number of bits of a uniform distribution that is exactly as easy to guess as X. A uniform r-bit string is guessed in one try with probability 2^{-r}, so a value with $H_\infty = r$ bits is as hard to guess in one try as a uniform r-bit string, no matter how large $H(X)$ is.

Both entropies belong to one family. The **Rényi entropy** of order α is $H_\alpha(X) = \frac{1}{1-\alpha}\log_2 \sum_x p(x)^\alpha$. As α grows, the sum $\sum_x p(x)^\alpha$ is dominated more and more by the largest probability, and as $\alpha \to \infty$ the formula tends to $-\log_2 \max_x p(x) = H_\infty$. As $\alpha \to 1$ the formula becomes $0/0$, and its limit is Shannon's H (Section F.4 in the appendices derives both limits). This parallels the family of Rényi divergences in Divergences.

For a coin, Figure 5.1 shows the gap. The min-entropy $H_\infty = -\log_2 \max(p, 1-p)$ is smooth on each side of $\frac{1}{2}$ but has a kink there, where the most likely outcome switches from tails to heads, and it lies below $h(p)$.

5.6.5. Example: a PIN with one popular choice

A uniform 4-digit PIN has $H = H_\infty = \log_2 10{,}000 = 13.2877$ bits, and a single guess succeeds with probability 10^{-4}. Now suppose 10% of people choose 1234 and the rest choose uniformly among the other 9,999 PINs. The script gives two very different numbers.

The Shannon entropy is $H = 12.4278$ bits, less than a bit below the uniform case. You can see where it comes from with the chain rule: first reveal whether the PIN is 1234, which costs $h(0.1) = 0.4690$ bits, and then, in the 90% of cases where it is not, reveal which of the 9,999 others it is, which costs $\log_2 9{,}999$ bits. That gives $0.4690 + 0.9\log_2 9{,}999 = 0.4690 + 11.9588 = 12.4278$.

The min-entropy is $H_\infty = \log_2 10 = 3.3219$ bits, because the best guess, "1234", succeeds with probability 0.1, and $-\log_2 0.1 = \log_2 10$.

The Shannon entropy says this PIN distribution is almost as good as uniform. The min-entropy says that one guess in ten succeeds. If the guesser gets one try, only the second number matters.

5.6.6. Check yourself

- Which is larger for any X: $V(X)$ or $2^{-H(X)}$? *($V(X)$. $H_\infty \le H$ means $-\log_2 V \le H$, so $\log_2 V \ge -H$ and $V \ge 2^{-H}$.)*
- Give a distribution on a million values whose Shannon entropy is above 10 bits but whose min-entropy is 1 bit. *(Probability $\frac{1}{2}$ on one value and $\frac{1}{2}$ spread uniformly over the other 999,999. The best guess wins with probability $\frac{1}{2}$, so $H_\infty = 1$, while by the chain rule $H = 1 + \frac{1}{2}\log_2 999{,}999 \approx 10.97$: one bit to say which half, then, half the time, the index among 999,999.)*

5.7. Conditional min-entropy and min-entropy leakage

5.7.1. Context

Now the guesser sees an observation Y before guessing the hidden value X, which this section calls the secret. How much does that help? The natural answer, from Smith (2009), keeps the meaning of vulnerability as a success probability: the posterior vulnerability is the success probability of the best guessing strategy that may depend on what was observed. Comparing it with the vulnerability before the observation gives the **min-entropy leakage**, and maximizing that over priors gives the **min-capacity**, the one-guess analogue of channel capacity.

5.7.2. Statement

The guesser who sees y should guess the value of X that is most likely given y. Its success probability is then the average over y of $\max_x p(x \mid y)$, and since $p(y) \max_x p(x \mid y) = \max_x p(x, y)$, this is the sum of the largest entry in each column of the joint table. For a joint distribution $p(x, y)$, the **posterior vulnerability** and the **conditional min-entropy** are

$$V(X \mid Y) = \sum_y \max_x p(x, y), \qquad H_\infty(X \mid Y) = -\log_2 V(X \mid Y). \tag{5.20}$$

How much the observation helps is the factor by which it multiplies the chance of a correct guess, measured in bits by its log. For a prior π and channel K, the **min-entropy leakage** is

$$\mathcal{L}(\pi, K) = H_\infty(X) - H_\infty(X \mid Y) = \log_2 \frac{V(X \mid Y)}{V(X)}. \tag{5.21}$$

The leakage depends on the prior. Its largest value over all priors, the **min-capacity**, depends only on the channel. It has a closed form, the log of the sum of the column maxima of the channel table, and it is attained at the uniform prior:

$$\mathcal{ML}(K) = \max_\pi \mathcal{L}(\pi, K) = \log_2 \sum_y \max_x K[x, y]. \tag{5.22}$$

It satisfies $0 \le \mathcal{ML}(K) \le \log_2 \min(|\mathcal{X}|, |\mathcal{Y}|)$: an observation never hurts the guesser, and it cannot multiply the chance of success by more than the number of possible secrets or the number of possible observations.

5.7.3. Derivation

Posterior vulnerability is the success of the best strategy. The idea is that the guesser's choice for one observation does not affect its success on any other observation, so it can make the best choice column by column.

1. A strategy assigns a guess $g(y)$ to each observation y. It succeeds when $X = g(Y)$, which happens with probability $\sum_y p(g(y), y)$: the strategy picks one cell from each column of the joint table, and its success is the sum of the picked cells.

2. Each column can be optimized separately, since $g(y)$ affects only the term for y. The best choice in column y is the row with the largest entry. Dividing a column by $p(y)$ does not change which row is largest, so this is also the value of x with the largest posterior probability $p(x \mid y)$, the **maximum a posteriori (MAP) guess** $\arg\max_x p(x, y) = \arg\max_x p(x \mid y)$.
3. So the best success probability is $\sum_y \max_x p(x, y)$, which is Equation 5.20. Writing $p(x, y) = p(y)\, p(x \mid y)$ gives the equivalent form $V(X \mid Y) = \sum_y p(y) \max_x p(x \mid y)$: the average over y of the vulnerability $V(X \mid Y = y)$ of the posterior distribution.

Min-capacity. The idea is to bound the posterior vulnerability by pulling the prior out of each column maximum, and then to notice that the uniform prior loses nothing in that step.

1. Write $p(x, y) = \pi(x)K[x, y]$. In each column, the largest product is at most the largest prior times the largest channel entry: $\max_x \pi(x)K[x, y] \le (\max_x \pi(x))(\max_x K[x, y]) = V(X) \max_x K[x, y]$.
2. Sum over y and divide by $V(X)$: $\frac{V(X|Y)}{V(X)} \le \sum_y \max_x K[x, y]$, for every prior. Taking logs, $\mathcal{L}(\pi, K) \le \log_2 \sum_y \max_x K[x, y]$.
3. At the uniform prior $\pi(x) = 1/|\mathcal{X}|$, the inequality in step 1 is an equality, because the constant factor $\pi(x) = V(X)$ comes out of the max. So the bound is attained, and Equation 5.22 follows.
4. *Range.* For the upper bound, there are two ways to bound the sum of column maxima. Each column maximum is at most 1, so the sum is at most $|\mathcal{Y}|$. Each column maximum is also at most its column sum, and all column sums together add up to $\sum_x \sum_y K[x, y] = |\mathcal{X}|$, because each of the $|\mathcal{X}|$ rows sums to 1. For the lower bound, fix any row x_0: each column maximum is at least $K[x_0, y]$, and these add up to 1 across the row, so the sum of column maxima is at least 1 and $\mathcal{ML} \ge \log_2 1 = 0$.

5.7.4. Interpretation

Leakage is a ratio of success probabilities on a log scale: $\mathcal{L} = 1$ bit means the observation doubles the chance of a correct first guess, and 2 bits means it quadruples it. That is a statement an engineer can act on, and it is why min-entropy is the usual measure in the field of quantitative information flow, which studies how much a program's outputs reveal about its secret inputs.

Smith's definition is not the average of $H_\infty(X \mid Y = y)$. It averages the posterior vulnerabilities and then takes the log, $-\log_2 \sum_y p(y) V(X \mid Y = y)$, rather than averaging the logs, $\sum_y p(y)(-\log_2 V(X \mid Y = y))$. These differ, and Jensen's inequality (Fact 1, in the mirror version for the convex $-\log_2$: the $-\log_2$ of an average is at most the average of $-\log_2$) says Smith's value is never larger. The reason to prefer Smith's version is its meaning: it is the log of an actual success probability, that of the MAP guesser. The average of logs is not the log of any success probability.

The min-capacity is the worst case over the prior. That matters whenever you do not know the prior: a single number, computed from the channel alone, bounds the leakage for every prior. It is also cheap to compute, one maximum per column, where the Shannon capacity needs an iterative algorithm.

5.7.5. Example: walking through a small table

A secret X takes four values with prior $\pi = (0.4, 0.3, 0.2, 0.1)$. An observation Y takes three values, through the channel in Table 5.3.

Table 5.3.: The channel of the guessing walk-through: rows are secret values, columns are observations.

$K[x, y]$	y_1	y_2	y_3
x_1	0.8	0.2	0
x_2	0.1	0.8	0.1
x_3	0	0.5	0.5
x_4	0	0.2	0.8

Multiply each row by its prior to get the joint table, Table 5.4, also drawn in Figure 5.4. For example, the first row is $0.4 \times (0.8, 0.2, 0) = (0.32, 0.08, 0)$.

Table 5.4.: The joint distribution $p(x, y) = \pi(x)K[x, y]$ of the walk-through, with the column maxima in bold.

$p(x, y)$	y_1	y_2	y_3
x_1	**0.32**	0.08	0
x_2	0.03	**0.24**	0.03
x_3	0	0.10	**0.10**
x_4	0	0.02	0.08
$p(y)$	0.35	0.44	0.21

1. **Without the observation**, the best guess is the most likely value x_1, right with probability $V(X) = 0.4$. So $H_\infty(X) = -\log_2 0.4 = 1.3219$ bits.
2. **With the observation**, guess the row with the largest entry in each column (in bold): x_1 on y_1, x_2 on y_2, x_3 on y_3. The success probability is $0.32 + 0.24 + 0.10 = 0.66 = V(X \mid Y)$, and $H_\infty(X \mid Y) = -\log_2 0.66 = 0.5995$ bits. Notice that on y_3 the guesser picks x_3 although the channel entry $K[x_4, y_3] = 0.8$ is larger than $K[x_3, y_3] = 0.5$. The guesser compares joint probabilities, not channel entries, and x_3 is twice as likely as x_4 a priori, which more than makes up the difference: $0.2 \times 0.5 = 0.10$ beats $0.1 \times 0.8 = 0.08$.
3. **Simulation.** The script draws (X, Y) a million times and lets the MAP guesser play; it wins 0.6594 of the time, close to the predicted 0.66.
4. **Leakage.** $\mathcal{L} = \log_2(0.66/0.4) = 0.7225$ bits: the observation multiplies the guessing success by $0.66/0.4 = 1.65$. For comparison, the Shannon leakage of the same table, the mutual information, is $I(X; Y) = 0.6865$ bits out of $H(X) = 1.8464$.
5. **Min-capacity.** The column maxima of the channel K (not of the joint table) are 0.8, 0.8, 0.8, so $\mathcal{ML}(K) = \log_2(0.8 + 0.8 + 0.8) = \log_2 2.4 = 1.2630$ bits. Under the uniform prior, the leakage is exactly this value, and the script confirms that no prior on a grid of step 0.05 does better. The Shannon capacity of the same channel, from Blahut–Arimoto, is 0.8269 bits.

6. **Smith versus the average of logs.** The posterior vulnerabilities are the column maxima divided by the column totals, 0.32/0.35, 0.24/0.44 and 0.10/0.21. Their $-\log_2$ are 0.1293, 0.8745 and 1.0704 bits, and averaging these with weights $p(y) = 0.35, 0.44, 0.21$ gives 0.6548 bits, larger than Smith's 0.5995, as Jensen predicts.

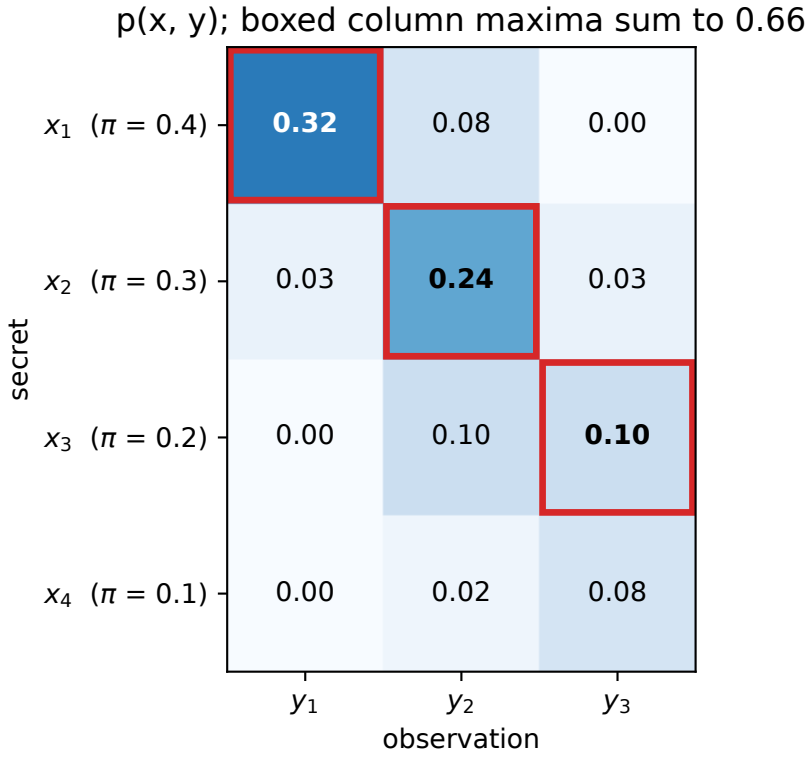

Figure 5.4.: The joint distribution $p(x, y) = \pi(x)K[x, y]$ of the walk-through. The MAP guesser picks the boxed cell in each column, and its success probability is their sum $V(X \mid Y) = 0.66$.

5.7.6. Check yourself

- What is the min-capacity of the binary symmetric channel? *($\log_2(2\max(p, 1-p))$: each of the two columns has maximum $\max(p, 1-p)$. At $p = 0.11$ it is $\log_2 1.78 = 0.8319$ bits, against a Shannon capacity of 0.5001. It is the dashed curve in Figure 5.3.)*
- Why can the min-entropy leakage for a given prior be smaller than the min-capacity? *(A skewed prior already makes the best blind guess good, so the observation adds less. Here 0.7225 bits at the given prior against 1.2630 at the uniform one.)*

5.8. Shannon leakage versus min-entropy leakage

5.8.1. Context

Shannon leakage, the mutual information $I(X;Y)$, and min-entropy leakage $\mathcal{L}$ both measure how much an observation reveals about a secret. They often agree. When they don't, the disagreement is large, and it is always the same kind: a channel that reveals the secret completely on a few outcomes and nothing on the rest. Shannon leakage averages logs, so it gives those rare outcomes little weight; min-entropy leakage asks how much the guesser's success grows, and a rare full reveal can make it grow a lot. This section works through such channels.

5.8.2. Statement

Let X be uniform on n-bit strings, and consider two families of **deterministic** channels, whose output is a fixed function of the input. The first reveals part of the secret every time; the second reveals all of it, but only rarely.

- **reveal-low(m)** always outputs the lowest m bits of X.
- **reveal-if-zero(j)** outputs X itself if its lowest j bits are all zero, which happens with probability 2^{-j}, and a fixed symbol $\perp$ otherwise.

For the first family both leakages equal m. For the second, the Shannon leakage is about n bits times the probability 2^{-j} of a reveal, plus a small term, while the min-entropy leakage is about $n-j$ bits:

$$\text{reveal-low}(m): \quad I(X;Y) = \mathcal{L} = m, \tag{5.23}$$

$$\text{reveal-if-zero}(j),\ j \geq 1: \quad I(X;Y) = 2^{-j}n + (1-2^{-j})\log_2 \frac{1}{1-2^{-j}}, \qquad \mathcal{L} = \log_2\left(2^{n-j}+1\right). \tag{5.24}$$

5.8.3. Derivation

Two observations about deterministic channels make both leakages easy to compute. For Shannon leakage: the output is fixed once the input is known, so $H(Y \mid X) = 0$ and $I(X;Y) = H(Y) - H(Y \mid X) = H(Y)$. For min-entropy leakage: under the uniform prior, $V(X) = 2^{-n}$, and each column of the joint table contains only entries 2^{-n} (for inputs that produce that output) or 0. So each column maximum is 2^{-n}, and $V(X \mid Y) = 2^{-n} \times$ (number of distinct outputs). The ratio is $V(X \mid Y)/V(X) =$ number of distinct outputs, so $\mathcal{L} = \log_2$(number of distinct outputs).

reveal-low(m). The lowest m bits of a uniform string are uniform on 2^m values, so $I(X;Y) = H(Y) = m$. There are 2^m distinct outputs, so $\mathcal{L} = m$.

reveal-if-zero(j).

1. Count the outputs and their probabilities. There are 2^{n-j} strings whose lowest j bits are zero (the other $n-j$ bits are free). Each is output as itself, with probability 2^{-n}. Every other string gives the output $\perp$, which therefore has probability $1 - 2^{n-j} \cdot 2^{-n} = 1 - 2^{-j}$.

2. Compute $H(Y)$ as the average surprisal. The 2^{n-j} revealed outputs each have surprisal $\log_2 2^n = n$, and $\perp$ has surprisal $\log_2 \frac{1}{1-2^{-j}}$. So $H(Y) = 2^{n-j} \cdot 2^{-n} \log_2 2^n + (1 - 2^{-j}) \log_2 \frac{1}{1-2^{-j}} = 2^{-j}n + (1 - 2^{-j}) \log_2 \frac{1}{1-2^{-j}}$.
3. The number of distinct outputs is the 2^{n-j} revealed strings plus $\perp$, which is $2^{n-j} + 1$, and its log gives $\mathcal{L}$.

The script checks both closed forms against the general formulas applied to the explicit channel matrices for $n = 6$; they agree to 7.8×10^{-16}, which is rounding error.

5.8.4. Interpretation

Figure 5.5 plots the two leakages against each other for $n = 64$. The reveal-low family lies on the diagonal: Shannon and min-entropy agree. The reveal-if-zero family hugs the top-left corner: almost no Shannon leakage, almost total min-entropy leakage.

The reason is where the logarithm sits. Shannon leakage averages the log over outcomes, so an outcome of probability 2^{-j} that reveals n bits contributes only $2^{-j}n$. Min-entropy leakage takes the log of an averaged probability. The same outcome raises the guessing success from 2^{-n} to more than 2^{-j}, because the guesser wins whenever the reveal happens, and $\log_2(2^{-j}/2^{-n}) = n - j$: almost $n - j$ bits.

5.8.5. Example: two channels that Shannon ranks the wrong way

Take $n = 64$ and compare reveal-if-zero(3), which outputs the whole secret one time in eight, with reveal-low(9).

For reveal-if-zero(3), the Shannon leakage is $2^{-3} \cdot 64 + \frac{7}{8} \log_2 \frac{8}{7} = 8 + 0.1686 = 8.1686$ bits. The guesser wins whenever the secret is revealed, and otherwise has one chance in $2^{64} - 2^{61}$, so its success is just above $\frac{1}{8} = 0.1250$; in bits, $\log_2(2^{61} + 1)$ is 61 to many decimal places. For reveal-low(9), both leakages are 9 bits, and the guesser, knowing 9 of the 64 bits, must still guess the other 55, so it succeeds with probability $2^{-55} \approx 2.78 \times 10^{-17}$. Table 5.5 puts these side by side.

Table 5.5.: Shannon and min-entropy leakage of two deterministic channels on a uniform 64-bit secret.

Channel	Shannon leakage	Min-entropy leakage	One-guess success
reveal-if-zero(3)	8.1686 bits	61.0000 bits	0.1250
reveal-low(9)	9.0000 bits	9.0000 bits	2.78×10^{-17}

By Shannon leakage, reveal-low(9) is the leakier channel. By one-guess success, reveal-if-zero(3) is worse by a factor of more than 10^{15}: $0.125/(2.78 \times 10^{-17}) \approx 4.5 \times 10^{15}$. Smith (2009) used a pair of programs like these to argue that Shannon leakage is the wrong measure for one-try guessing.

The extreme case: reveal the secret only if it is all zeros. Set $j = n$: the channel outputs X if $X = 0 \cdots 0$ and $\perp$ otherwise. For a 4-bit secret, the output reveals the secret with probability $\frac{1}{16}$, so the Shannon leakage is $H(Y) = h(1/16) = 0.3373$ bits. The min-entropy leakage is exactly

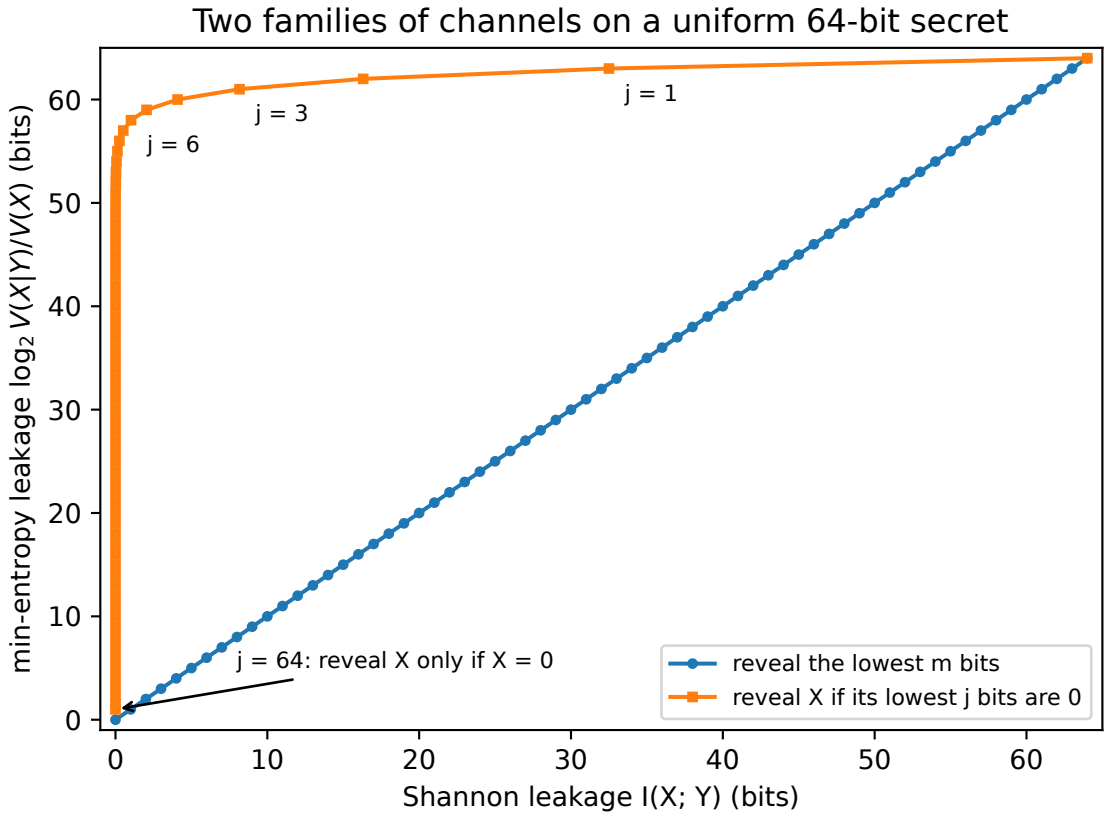

Figure 5.5.: Shannon leakage against min-entropy leakage for two families of deterministic channels on a uniform 64-bit secret. Revealing the low m bits gives equal leakages (diagonal). Revealing the whole secret with probability 2^{-j} gives a small Shannon leakage but a min-entropy leakage close to $64 - j$.

1 bit: the guesser wins if it sees 0000, and otherwise guesses one of the 15 remaining values, winning with probability $\frac{1}{16} + \frac{15}{16} \cdot \frac{1}{15} = \frac{2}{16}$. Its success doubles from $\frac{1}{16}$ to $\frac{2}{16}$, and $\log_2 2 = 1$. For a 32-bit secret the Shannon leakage falls to $h(2^{-32}) = 7.786 \times 10^{-9}$ bits, and the min-entropy leakage stays at 1 bit, by the same doubling argument.

Both numbers are small, and both miss something: for the one secret value 0000, the channel reveals everything, $H_\infty(X \mid Y = 0000) = 0$. Any measure that averages over the secret, Shannon or min-entropy, can hide a value that is fully exposed, because that value carries only its small share of the average. A worst-case question ("how much can the observation reveal about any single secret value?") needs a worst-case measure, and later parts build one.

5.8.6. Check yourself

- For reveal-if-zero(j) at $n = 64$, roughly where does the Shannon leakage drop below 1 bit? *(Between $j = 6$ and $j = 7$: the main term $2^{-j} \cdot 64$ equals 1 at $j = 6$, where the total is just above 1 bit because of the small $\perp$ term. That is the point labelled $j = 6$ in Figure 5.5.)*
- Can a channel have min-entropy leakage 0 but positive Shannon leakage? *(Yes. If the MAP guess is the same for every y, as when one secret value is very likely a priori, then $V(X \mid Y) = V(X)$, even though Y changes the posterior.)*

5.9. Fano's inequality

5.9.1. Context

Mutual information also gives **lower bounds**: statements that *no* estimator can do better than some error rate. You need these whenever you want to show that a problem is hard, rather than that a method is good. Fano's inequality is the basic tool. It says that if X is still uncertain after seeing Y, every guess of X from Y must often be wrong. The reason is that an estimator with a small error rate would leave little uncertainty: if you knew you were usually right, you would be nearly certain of X.

5.9.2. Statement

Let X take values in a finite set of size k, and let $\hat{X}$ be any estimate of X computed from Y (deterministically or with extra randomness), with error probability $P_e = \Pr[\hat{X} \neq X]$. Fano's inequality bounds how much uncertainty a guess with this error rate can leave. Describing X given the guess takes at most two pieces: one binary piece saying whether the guess was right, worth at most $h(P_e)$ bits, and, in the fraction P_e of cases where it was wrong, which of the other $k - 1$ values X is, worth at most $\log_2(k - 1)$ bits. So

$$H(X \mid Y) \leq h(P_e) + P_e \log_2(k - 1). \tag{5.25}$$

Using $h(P_e) \leq 1$ and $\log_2(k - 1) \leq \log_2 k$ gives $H(X \mid Y) \leq 1 + P_e \log_2 k$, and solving for P_e gives the weaker but explicit form

$$P_e \geq \frac{H(X \mid Y) - 1}{\log_2 k}. \tag{5.26}$$

5.9.3. Derivation

Introduce the error indicator $E = \mathbf{1}[\hat{X} \neq X]$, which is 1 when the guess is wrong and 0 when it is right, so $\Pr[E = 1] = P_e$. The idea is to compute the uncertainty of the pair (E, X) given $\hat{X}$, written $H(E, X \mid \hat{X})$, in two ways with the chain rule. Revealing X first makes E free; revealing E first splits X's uncertainty into the "right" and "wrong" cases, which are easy to bound. Every entropy below is conditioned on $\hat{X}$.

1. **First order: X, then E.** $H(E, X \mid \hat{X}) = H(X \mid \hat{X}) + H(E \mid X, \hat{X})$. Given both X and $\hat{X}$, you know whether they differ, so E is determined and the last term is 0.
2. **Second order: E, then X.** $H(E, X \mid \hat{X}) = H(E \mid \hat{X}) + H(X \mid E, \hat{X})$.
3. **Bound $H(E \mid \hat{X})$.** Conditioning reduces entropy on average, so $H(E \mid \hat{X}) \leq H(E)$, and E is a Bernoulli variable with parameter P_e, so $H(E) = h(P_e)$.
4. **Bound $H(X \mid E, \hat{X})$** by splitting on E. If $E = 0$, then $X = \hat{X}$ and there is no uncertainty left. If $E = 1$, then X is one of the $k-1$ values other than $\hat{X}$, so its entropy is at most $\log_2(k-1)$ by the entropy upper bound. Averaging over E: $H(X \mid E, \hat{X}) \leq (1 - P_e) \cdot 0 + P_e \log_2(k-1)$.
5. **Combine** steps 1–4. The two orders give the same quantity, so $H(X \mid \hat{X}) = H(E \mid \hat{X}) + H(X \mid E, \hat{X}) \leq h(P_e) + P_e \log_2(k-1)$.
6. **Replace $\hat{X}$ by Y.** The estimate is computed from Y, so $X \to Y \to \hat{X}$ is a Markov chain, and the data-processing inequality gives $I(X; \hat{X}) \leq I(X; Y)$. Writing both sides as $H(X)$ minus a conditional entropy, this is the same as $H(X \mid Y) \leq H(X \mid \hat{X})$, and the bound of step 5 carries over.

5.9.4. Interpretation

The right side of Equation 5.25 increases with P_e on $[0, (k-1)/k]$, the range from a perfect estimator to one that guesses blindly. So you can invert it numerically: the **Fano bound** is the smallest P_e that satisfies the inequality for the given $H(X \mid Y)$. The script finds it by bisection, halving an interval that contains it until it is small enough.

When it is tight. Equality needs step 4 to be tight: when the guess is wrong, the true value must be uniform over the other $k-1$ values. The k-ary **symmetric channel**, which keeps the input with probability $1-p$ and otherwise outputs one of the other $k-1$ symbols uniformly, has exactly this structure. For it, given the output, the input is the output itself with probability $1-p$ and otherwise uniform over the rest, so $H(X \mid Y) = h(p) + p \log_2(k-1)$, and the MAP guess (the output itself) errs with probability p. Fano's bound is exact (Figure 5.6, left).

When it is loose. If errors are concentrated on a few wrong values, $H(X \mid Y)$ is small even when P_e is not, because the leftover uncertainty after a wrong guess is small. The **shift channel**, which outputs $x + 1 \bmod k$ instead of x with probability p, has the same MAP error p (for $p \leq \frac{1}{2}$). But given the output, the input is one of only two values, so $H(X \mid Y) = h(p)$ only. At $k = 8$ and $p = 0.2$, Fano's bound is 0.2000 for the symmetric channel, equal to the MAP error, but only 0.0954 for the shift channel, against a MAP error of 0.2000 (Figure 5.6, right). The weak form Equation 5.26 gives 0.0945 and 0 respectively. For the symmetric channel, $H(X \mid Y) = h(0.2) + 0.2 \log_2 7 = 0.7219 + 0.5615 = 1.2834$, and $(1.2834 - 1)/3 = 0.0945$. For the shift channel, $H(X \mid Y) = h(0.2) = 0.7219$ is below 1, so the weak form gives a negative number, which says nothing beyond $P_e \geq 0$. The weak form pays for replacing $h(P_e)$ by 1, and is useless whenever $H(X \mid Y) \leq 1$.

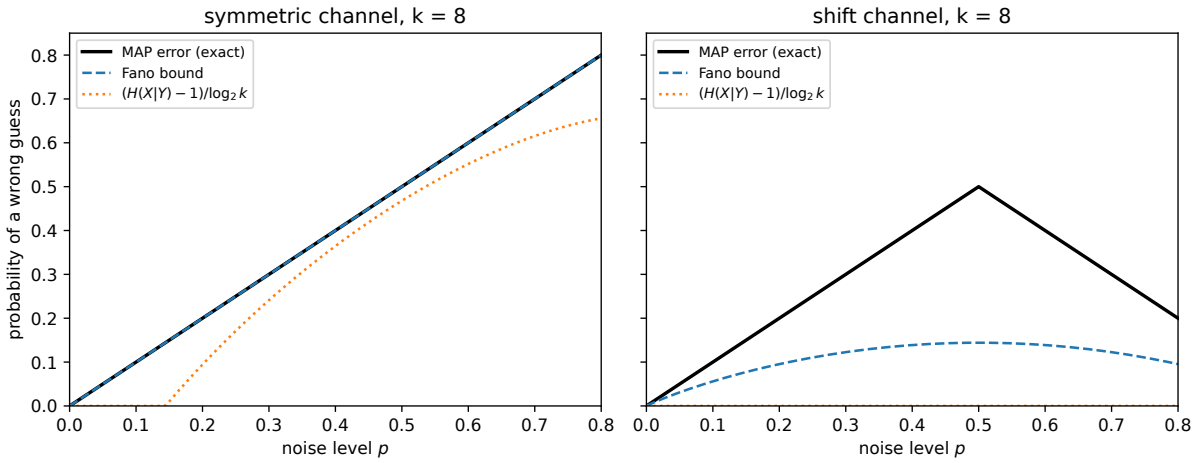

Figure 5.6.: MAP error against Fano's lower bound, for $k = 8$ and a uniform X, as the noise level p grows. Left: on the symmetric channel the bound is exact. Right: on the shift channel, where errors go to a single wrong value, the bound is loose and the weak form is zero.

5.9.5. Example: how hard is a classification problem?

Eight classes and one bit. A label X is uniform over $k = 8$ classes, so $H(X) = \log_2 8 = 3$ bits, and you know the features Y carry at most $I(X;Y) \le 1$ bit about it. Then $H(X \mid Y) = 3 - I(X;Y) \ge 2$ bits. Every classifier, however it is trained, therefore has error at least the Fano bound at $H(X \mid Y) = 2$, the P_e that solves $h(P_e) + P_e \log_2 7 = 2$: 0.3730. The weak form gives $(2-1)/3 = 0.3333$.

Fano's method for estimation. The same idea shows that estimating a parameter needs many samples. Turn estimation into identification: pick k candidate parameter values $\theta_1, \dots, \theta_k$ that are far apart, so that estimating the parameter well would identify which candidate it is. Let X be a uniformly random index, and draw n independent samples $Y_1, \dots, Y_n$ (together written Y^n) from P_{θ_X}. If the samples carry little information about the index, Fano says no estimator can identify it, so none can estimate the parameter well. The argument has three steps.

1. **Information adds over independent samples.** Given X the samples are independent, so the chain rule gives $H(Y^n \mid X) = \sum_i H(Y_i \mid X)$ exactly. Without conditioning on X, the chain rule plus "conditioning reduces entropy" gives only $H(Y^n) \le \sum_i H(Y_i)$. Subtracting the first from the second, $I(X;Y^n) \le \sum_i I(X;Y_i) = n\, I(X;Y_1)$, since all samples have the same distribution.
2. **Each sample carries at most the largest pairwise KL divergence.** Let $\bar{P} = \frac{1}{k}\sum_x P_{\theta_x}$ be the average of the candidate distributions, which is the distribution of Y_1 when the index is random. By the KL form of Equation 5.11, $I(X;Y_1)$ is the average KL divergence from each candidate to this average, $\frac{1}{k}\sum_x D_{\mathrm{KL}}(P_{\theta_x} \,\|\, \bar{P})$. Expanding the logs shows that for any distribution Q, $\frac{1}{k}\sum_x D_{\mathrm{KL}}(P_{\theta_x} \,\|\, Q) = \frac{1}{k}\sum_x D_{\mathrm{KL}}(P_{\theta_x} \,\|\, \bar{P}) + D_{\mathrm{KL}}(\bar{P} \,\|\, Q)$, so the average divergence to $\bar{P}$ is the smallest average divergence to any Q. Taking $Q = P_{\theta_{x'}}$ gives $I(X;Y_1) \le \frac{1}{k}\sum_x D_{\mathrm{KL}}(P_{\theta_x} \,\|\, P_{\theta_{x'}})$ for each x', and hence $I(X;Y_1) \le \kappa = \max_{x,x'} D_{\mathrm{KL}}(P_{\theta_x} \,\|\, P_{\theta_{x'}})$.

3. **Apply Fano.** The index is uniform, so $H(X) = \log_2 k$ and $H(X \mid Y^n) = \log_2 k - I(X;Y^n) \geq \log_2 k - n\kappa$. Putting this into Equation 5.26 gives

$$P_e \geq 1 - \frac{n\kappa + 1}{\log_2 k}. \tag{5.27}$$

With $k = 1024$ candidates ($\log_2 k = 10$ bits) whose sample distributions are within $\kappa = 0.01$ bits of each other, $n = 100$ samples leave $P_e \geq 1 - (100 \times 0.01 + 1)/10 = 0.8000$, and even $n = 400$ samples leave $P_e \geq 1 - (4 + 1)/10 = 0.5000$. Choosing the candidates well, so that they are many and far apart yet hard to tell apart, is the art of the method; Wainwright (2019) works through many cases.

5.9.6. Check yourself

- If X is a deterministic function of Y, what does Fano's inequality say? *($H(X \mid Y) = 0$, so it allows $P_e = 0$, as it should.)*
- Why does step 6 of the derivation need the data-processing inequality? *(Steps 1–5 only bound $H(X \mid \hat{X})$. The bound must be stated in terms of what the estimator sees, Y, and the data-processing inequality says $\hat{X}$ knows no more about X than Y does.)*

5.10. Code: check every formula numerically

The script code/information_theory.py computes every number quoted in this chapter and draws its figures. Entropy, mutual information, vulnerability, leakage, capacity and the Fano bound are small typed functions of a joint table or a channel matrix; the script calls them once for the numbers and loops them over parameters for the figures. From the repository root:

```
uv run python code/part01-prerequisites/information_theory.py
```

Table 5.6 summarizes the output (seed 0; only the guessing simulation uses the seed).

Table 5.6.: Output of the chapter's script with seed 0. All quantities are in bits except probabilities.

Experiment	Result
Spam keyword	$H(X) = 0.5436$, $H(X \mid Y = 1) = 1.0000$, $H(X \mid Y) = 0.2500$, $I(X;Y) = 0.2936$ (from $H(X) - H(X \mid Y)$ and from the KL form); $I(X;Z) = 0.1668$ through a BSC(0.1)
PIN, 10% choose 1234	$H = 12.4278$, $H_\infty = 3.3219$ (uniform: 13.2877)
BSC(0.11)	$1 - h(p) = 0.5001$; Blahut–Arimoto 0.5001 at $\Pr[X = 1] = 0.5000$; min-capacity 0.8319
Guessing walk-through	$V(X) = 0.4000$, $V(X \mid Y) = 0.6600$, simulated 0.6594; $\mathcal{L} = 0.7225$; $\mathcal{ML} = 1.2630$; Shannon capacity 0.8269

Experiment	Result
Reveal-if-zero(3) vs reveal-low(9), $n = 64$	Shannon 8.1686 vs 9.0000; min-entropy 61.0000 vs 9.0000
Fano, $k = 8$, $p = 0.2$	Symmetric: bound 0.2000, MAP 0.2000. Shift: bound 0.0954, MAP 0.2000

tests/test_information_theory.py checks that the output still matches.

Five lessons come out of these runs. The first is that two formulas give one number: mutual information computed as an entropy difference and as a KL divergence agree, which is a useful check on any implementation. The second is that the closed forms are right. Blahut–Arimoto, which knows nothing about the binary symmetric channel, finds $1 - h(p)$ and the uniform input, and the leakage closed forms match the explicit matrices. The third is that vulnerability is a real success rate: the simulated MAP guesser wins at the rate $V(X \mid Y)$ predicts. The fourth is that Shannon and min-entropy measure different things. They can rank channels in opposite orders, and neither sees a single exposed secret value. The last is that Fano's bound is tight only when errors are spread out over the wrong values; concentrated errors make it loose.

5.12. Cheat sheet

Table 5.7 collects the results.

Table 5.7.: Every result of the chapter.

Quantity	Formula	Key facts
Entropy	$H(X) = -\sum_x p(x) \log_2 p(x)$	$0 \le H \le \log_2 \lvert\mathcal{X}\rvert$; uniform attains the maximum
Binary entropy	$h(p) = -p \log_2 p - (1-p) \log_2 (1-p)$	$h(\frac{1}{2}) = 1$; $h(0.11) \approx \frac{1}{2}$
Conditional entropy	$H(X \mid Y) = \sum_y p(y) H(X \mid Y = y)$	$\le H(X)$ on average; one y can raise it
Chain rule	$H(X,Y) = H(Y) + H(X \mid Y)$	Extends to n variables
Mutual information	$I(X;Y) = H(X) - H(X \mid Y) = D_{\mathrm{KL}}(P_{XY} \parallel P_X P_Y)$	Symmetric, ≥ 0, zero iff independent
Data processing	$X \to Y \to Z \Rightarrow I(X;Z) \le I(X;Y)$	From the chain rule for I
Capacity	$\mathcal{C} = \max_\pi I(X;Y)$	BSC(p): $1 - h(p)$ at the uniform input
Vulnerability, min-entropy	$V(X) = \max_x p(x)$, $H_\infty = -\log_2 V$	$H_\infty \le H$; one-guess success
Posterior vulnerability	$V(X \mid Y) = \sum_y \max_x p(x,y)$	Success of the MAP guesser
Min-entropy leakage	$\mathcal{L} = \log_2 V(X \mid Y)/V(X)$	Factor by which guessing success grows
Min-capacity	$\mathcal{ML}(K) = \log_2 \sum_y \max_x K[x,y]$	Attained at the uniform prior; $\le \log_2 \min(\lvert\mathcal{X}\rvert, \lvert\mathcal{Y}\rvert)$
Fano	$H(X \mid Y) \le h(P_e) + P_e \log_2 (k-1)$	Weak form $P_e \ge (H(X \mid Y) - 1)/\log_2 k$; tight when errors are spread evenly

Rules of thumb

- Shannon quantities average $\log_2$ over outcomes; min-entropy quantities take $\log_2$ of a best-case probability. When a rare outcome reveals a lot, the two disagree, by orders of magnitude.
- Both are averages over the secret. Neither tells you how exposed a single secret value is.
- To prove an estimator must fail, bound the mutual information between the unknown and the data, then apply Fano.
- Processing never adds information: compute the bound on the raw observation, and it holds for everything computed from it.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

6. Optimization

6.1. Why this matters

Training a model means minimizing an average loss over the training set. Two questions come up every time you do it. The first is **how fast the optimizer gets there.** Gradient descent and stochastic gradient descent (SGD) are the workhorses, and you want to know how many steps they need, how to pick the learning rate, and what it costs you that the gradients SGD uses are noisy. The second is **how much the answer depends on any one training record.** If you replace one record and train again, does the minimizer barely move, or can it jump somewhere else entirely? The first question is about the algorithm; the second is about the problem itself, and it is the bridge to the next chapter, where a model that does not depend much on any one record is shown to generalize.

Both questions have the same kind of answer. **A few constants of the loss decide everything.** The first is how steep the loss can be anywhere, which is the largest size of its gradient: the Lipschitz constant L. The second is how fast that slope can change as you move, which is a bound on the curvature from above: the smoothness β. The third is how much the loss curves upward at least, a bound on the curvature from below: the strong convexity λ. The last one belongs to the optimizer rather than the loss: how far the random gradients SGD uses scatter around the true gradient, their variance σ^2. Every rate and every bound in this chapter is a combination of these four constants, and once you know which constant each result uses, you can tell when it applies. Table 6.1 lists the results.

Table 6.1.: The results of this chapter and where they are used.

Result	What it controls	Typical use
Lipschitz, smooth, strongly convex	The constants every later result is stated in	Checking that a loss qualifies; picking learning rates
SGD, convex and Lipschitz: $RL/\sqrt{T}$	Error of the averaged iterate after T steps	Linear models with logistic or hinge loss
SGD, strongly convex: $O(G^2/(\lambda T))$, G the gradient bound	Error with a regularizer	Ridge and regularized logistic regression
SGD, smooth non-convex	How fast the gradient norm goes to zero	Neural networks
Gradient noise and minibatches	How variance slows SGD and shrinks the best step	Choosing learning rate and batch size

Result	What it controls	Typical use
Sensitivity of regularized empirical risk minimization (ERM): $2L/(\lambda n)$	How far the minimizer moves when one record changes	Stability and generalization; per-example influence

The distributions behind the noise (Probability distributions) and the way averages concentrate (Concentration inequalities) are used only lightly here. This chapter is about inequalities that hold for every input, and about expectations; it never needs a tail bound.

Notation. The training data are a dataset of n records $D = (z_1, \dots, z_n)$. The model is a parameter vector $\theta \in \mathbb{R}^d$, and its loss on a record z is $\ell(\theta; z)$. The **empirical risk** is the average loss over the training set, $\mathcal{L}(\theta; D) = \frac{1}{n}\sum_{i=1}^{n} \ell(\theta; z_i)$; until the last section the dataset is fixed, and this chapter writes it $\mathcal{L}(\theta)$ for short. A point where it is smallest is a **minimizer** θ^*, and $\mathcal{L}^* = \mathcal{L}(\theta^*)$ is the smallest value. $\nabla\mathcal{L}(\theta)$ is the gradient, the vector of partial derivatives, which points in the direction in which $\mathcal{L}$ increases fastest. $\langle a, b\rangle = \sum_j a_j b_j$ is the inner product of two vectors, and all norms are Euclidean, $\|a\| = \sqrt{\langle a, a\rangle}$.

6.2. Toolkit: five facts every derivation uses

Every proof in this chapter tracks the distance from the current parameters to the minimizer and asks how one step changes it. The five facts below are the pieces those proofs are built from, each stated and proved once.

6.2.1. Fact 1 — A convex function lies above its tangents

A function is **convex** when it curves upward everywhere, with no dents. The usual way to say this is that the straight segment (the chord) between any two points on its graph never dips below the graph: for all θ, θ' and every mixing weight $s \in [0, 1]$, the value at the mixed point is at most the same mix of the two values, $f(s\theta' + (1-s)\theta) \le sf(\theta') + (1-s)f(\theta)$.

For a differentiable f there is an equivalent picture, and it is the one the proofs use. The tangent at θ predicts the value at another point θ' by starting from $f(\theta)$ and adding the slope times the displacement, $\langle \nabla f(\theta), \theta' - \theta\rangle$. Convexity says this linear prediction never overshoots: the graph lies above every one of its tangents,

$$f(\theta') \ge f(\theta) + \langle \nabla f(\theta), \theta' - \theta\rangle \quad \text{for all } \theta, \theta'. \tag{6.1}$$

To see why the chord condition gives this, write the mixed point as $\theta + s(\theta' - \theta)$, a step of size s from θ towards θ'. Subtract $f(\theta)$ from both sides of the chord condition and divide by $s > 0$: $\frac{f(\theta + s(\theta' - \theta)) - f(\theta)}{s} \le f(\theta') - f(\theta)$. The left side is the average slope over a short step towards θ', and as $s \to 0$ it becomes the slope in that direction, the directional derivative $\langle \nabla f(\theta), \theta' - \theta\rangle$. That is Equation 6.1. (The other direction, from tangents to chords, is in the references, and Section G.1 in the appendices derives it step by step.) For a concrete case take $f(\theta) = \theta^2$ at $\theta = 1$. The slope

there is 2, so the tangent is $1 + 2(\theta' - 1)$. At $\theta' = 3$ the tangent predicts 5, and the function is 9, above it.

Here is why this matters. The fact turns a gradient, which you can compute, into a lower bound on how much higher the function is somewhere else. Every convex convergence proof uses it with θ' set to the minimizer θ^* and the inequality rearranged: $\langle \nabla f(\theta), \theta - \theta^* \rangle \geq f(\theta) - f(\theta^*)$. In words, the gradient at θ points away from the minimizer, and its component along the direction from θ^* to θ is at least the current error $f(\theta) - f(\theta^*)$. So a step against the gradient makes progress towards θ^* in proportion to how far from optimal you are.

6.2.2. Fact 2 — Expanding a square, and Cauchy–Schwarz

The squared length of a sum of two vectors is the two squared lengths plus a cross term, exactly as $(a+b)^2 = a^2 + 2ab + b^2$ for numbers. And the cross term can never be larger than the product of the lengths, because the inner product is the product of the lengths times the cosine of the angle between the vectors, and a cosine is at most 1 in size (the **Cauchy–Schwarz inequality**):

$$\|a + b\|^2 = \|a\|^2 + 2\langle a, b \rangle + \|b\|^2, \qquad |\langle a, b \rangle| \leq \|a\| \, \|b\|. \tag{6.2}$$

The first identity is what makes the SGD proofs work. One step moves θ to $\theta - \eta g$, where g is the gradient used and η the **learning rate**, also called the step size. The new squared distance to the minimizer, $\|\theta - \eta g - \theta^*\|^2$, splits by the identity (with $a = \theta - \theta^*$ and $b = -\eta g$) into the old squared distance, a cross term with the gradient that measures progress, and a step-length term $\eta^2 \|g\|^2$ that measures overshoot. That split is the whole SGD proof.

6.2.3. Fact 3 — Projection onto a convex set never increases distances to its points

Sometimes the parameters are kept inside a set $\mathcal{W}$, such as a ball, and any step that leaves it is pulled back to the closest point of the set. This **projection** is $\Pi(u) = \arg\min_{p \in \mathcal{W}} \|u - p\|$, the point p of $\mathcal{W}$ nearest to u. The fact is that pulling back can only bring you closer to every point of the set, so it never undoes progress towards a minimizer that lies in the set. This needs $\mathcal{W}$ to be closed (so that a nearest point exists) and convex (so that the segment between two of its points stays inside). For every $\theta \in \mathcal{W}$,

$$\|\Pi(u) - \theta\| \leq \|u - \theta\|. \tag{6.3}$$

The picture behind the proof: if u is outside the set and p is its nearest point, then any point θ of the set lies "behind" p as seen from u, at an angle of at least 90° at p. Pythagoras then makes u farther from θ than p is. To make this precise, let $p = \Pi(u)$ and $\theta \in \mathcal{W}$. Points of the segment from p to θ have the form $p + s(\theta - p)$ with $s \in [0, 1]$, and they are all in $\mathcal{W}$ because it is convex. Their squared distance to u is $h(s) = \|u - p - s(\theta - p)\|^2$. Since p is the closest point of the whole set, h is smallest at $s = 0$, so it cannot start decreasing as s grows from 0: $h'(0) = -2\langle u - p, \theta - p \rangle \geq 0$, which says $\langle u - p, p - \theta \rangle \geq 0$. That is the obtuse angle. Now expand $u - \theta = (u - p) + (p - \theta)$ with Fact 2: $\|u - \theta\|^2 = \|u - p\|^2 + \|p - \theta\|^2 + 2\langle u - p, p - \theta \rangle$. The cross term is non-negative and so is $\|u - p\|^2$, so $\|u - \theta\|^2 \geq \|p - \theta\|^2$.

For the ball $\{\|\theta\| \leq R\}$ the projection is simple: $\Pi(u) = u \min(1, R/\|u\|)$, which leaves u alone if it is inside and shrinks it back to the sphere of radius R if it left. Projected SGD uses this to

keep its iterates in a bounded set, and Fact 3 says this costs nothing in the analysis, as long as the minimizer θ^* is in $\mathcal{W}$.

6.2.4. Fact 4 — Jensen: averaging inside a convex function helps

The chord condition of Fact 1 says that the value at a mix of two points is at most the mix of the values. Applying it repeatedly extends it to a mix of any number of points, which is **Jensen's inequality**: for a convex f and weights $\alpha_t \geq 0$ that add up to 1,

$$f\Big(\sum_t \alpha_t \theta_t\Big) \leq \sum_t \alpha_t f(\theta_t). \tag{6.4}$$

(Mix the first two points, then mix the result with the third, and so on.)

The proofs need it for the following reason. They can only bound the *average* error over the run, $\frac{1}{T}\sum_t (\mathcal{L}(\theta_t) - \mathcal{L}^*)$, which is not the error of any model you could hand to someone. Jensen with equal weights $1/T$ turns it into a bound for one model, the **averaged iterate** $\bar{\theta}_T = \frac{1}{T}\sum_t \theta_t$: its error is at most the average error.

6.2.5. Fact 5 — Unbiased gradients: the cross term averages out, the square does not

SGD does not use the true gradient $\nabla\mathcal{L}(\theta_t)$, which needs a pass over the whole training set. It uses a cheap random estimate g_t, for example the gradient of one record picked at random. The estimate is **unbiased**: averaged over the random pick, it equals the true gradient, $\mathbb{E}[g_t \mid \text{past}] = \nabla\mathcal{L}(\theta_t)$. Here "past" means all the random choices made before step t. Those choices determine θ_t, so once you condition on them θ_t is a fixed vector and only the new pick at step t is random. Two consequences follow, and they explain the title of this fact.

First, an inner product of g_t with any vector v_t fixed by the past (such as $\theta_t - \theta^*$) behaves as if g_t were the true gradient: $\mathbb{E}\langle g_t, v_t\rangle = \mathbb{E}\langle \nabla\mathcal{L}(\theta_t), v_t\rangle$. The reason is that an inner product with a fixed vector is linear, so the conditional expectation passes inside it, $\mathbb{E}[\langle g_t, v_t\rangle \mid \text{past}] = \langle \mathbb{E}[g_t \mid \text{past}], v_t\rangle = \langle \nabla\mathcal{L}(\theta_t), v_t\rangle$; then average over the past.

Second, the squared length of g_t does not average to the squared length of the true gradient. It is larger, by the **variance**, the mean squared error of the estimate. This is the **bias–variance split**:

$$\mathbb{E}[\|g_t\|^2 \mid \text{past}] = \|\nabla\mathcal{L}(\theta_t)\|^2 + \mathbb{E}[\|g_t - \nabla\mathcal{L}(\theta_t)\|^2 \mid \text{past}]. \tag{6.5}$$

To prove it, write g_t as the true gradient plus an error, $\nabla\mathcal{L} + (g_t - \nabla\mathcal{L})$, and expand the square with Fact 2. The cross term is $2\langle \nabla\mathcal{L}(\theta_t), g_t - \nabla\mathcal{L}(\theta_t)\rangle$. The first vector is fixed by the past, and the error has conditional mean zero, so by the first consequence the cross term averages to zero. The two squares remain.

A concrete case makes both consequences visible. Take three one-dimensional records $z = (1, 2, 6)$ and the loss $\ell(\theta; z) = \frac{1}{2}(\theta - z)^2$. The risk is $\mathcal{L}(\theta) = \frac{1}{3}\sum_i \frac{1}{2}(\theta - z_i)^2$, whose gradient is the average of the $\theta - z_i$, that is $\nabla\mathcal{L}(\theta) = \theta - 3$, since the mean of the data is 3. At $\theta = 4$, SGD picks one record uniformly at random and uses its gradient $\theta - z_i$. Table 6.2 lists the three equally likely outcomes.

Table 6.2.: SGD gradients for $\mathcal{L}(\theta) = \frac{1}{3}\sum_i \frac{1}{2}(\theta - z_i)^2$ at $\theta = 4$, where $\nabla\mathcal{L}(4) = 1$.

Example picked	$z_1 = 1$	$z_2 = 2$	$z_3 = 6$	Average
$g = \theta - z_i$	3	2	-2	1
g^2	9	4	4	17/3
$(g - \nabla\mathcal{L})^2$	4	1	9	14/3

The gradient is right on average: $(3 + 2 - 2)/3 = 1 = \nabla\mathcal{L}(4)$. Its second moment is $(9 + 4 + 4)/3 = 17/3$, and it splits as $17/3 = 1^2 + 14/3$, the squared true gradient plus the variance $(4 + 1 + 9)/3 = 14/3$. Averaging removed the error from the gradient itself but not from its square. The variance never averages out, and every SGD rate in this chapter pays for it.

6.3. Convexity, Lipschitz continuity and smoothness

6.3.1. Context

To say anything about an optimizer, you need assumptions on the loss. Four properties are enough for this whole chapter. Two of them bound a derivative from above: Lipschitz continuity bounds the slope, and smoothness bounds the curvature. The other two bound the curvature from below: convexity says it is never negative, and strong convexity says it is at least some $\lambda > 0$. Mixing them up is the most common mistake in reading optimization results, so this section says exactly what each one means, how they are related, and how to check them on two common losses.

6.3.2. Statement

Each property below is about a function $f : \mathbb{R}^d \to \mathbb{R}$.

Lipschitz. f is **L-Lipschitz** when it can never change faster than L per unit of distance: $|f(\theta) - f(\theta')| \le L\|\theta - \theta'\|$. For differentiable f this is the same as saying the slope is at most L everywhere, $\|\nabla f(\theta)\| \le L$ for all θ.

Smooth. f is **β-smooth** when its *gradient* is β-Lipschitz, that is, the slope changes by at most β per unit of distance: $\|\nabla f(\theta) - \nabla f(\theta')\| \le \beta\|\theta - \theta'\|$. Because the slope cannot change quickly, the tangent at θ stays a good prediction of f nearby, and its error grows at most like a parabola with curvature β. This is the **descent lemma**, the upper-bound counterpart of Equation 6.1:

$$f(\theta') \le f(\theta) + \langle \nabla f(\theta), \theta' - \theta \rangle + \frac{\beta}{2}\|\theta' - \theta\|^2. \tag{6.6}$$

Convex. As in Fact 1, f lies above its tangents, Equation 6.1.

Strongly convex. f is **λ-strongly convex** when it lies above each tangent by at least a bowl of curvature λ: $f(\theta') \ge f(\theta) + \langle \nabla f(\theta), \theta' - \theta \rangle + \frac{\lambda}{2}\|\theta' - \theta\|^2$. It is convexity with a margin that grows with distance. An equivalent form compares gradients at two points: going from θ' to θ,

the slope in the direction of travel increases by at least λ per unit of distance. Multiplying by the distance, this says the gradient is **strongly monotone**:

$$\langle \nabla f(\theta) - \nabla f(\theta'), \theta - \theta' \rangle \geq \lambda \|\theta - \theta'\|^2. \tag{6.7}$$

For a twice-differentiable f, all four properties can be read off the Hessian $\nabla^2 f$, the matrix of second derivatives, whose eigenvalues are the curvatures of f along its principal directions. Write $A \succeq B$ when $A - B$ has no negative eigenvalue, so that the curvature of A in every direction is at least that of B. Then convex means $\nabla^2 f \succeq 0$ (no direction curves down), λ-strongly convex means $\nabla^2 f \succeq \lambda I$ (every direction curves up by at least λ), and β-smooth means every eigenvalue of $\nabla^2 f$ lies in $[-\beta, \beta]$ (no direction curves by more than β either way). Smoothness and strong convexity together sandwich the curvature, $\lambda I \preceq \nabla^2 f \preceq \beta I$. The ratio of the largest to the smallest curvature, $\kappa = \beta/\lambda$, is the **condition number**, and it measures how much more steeply the function rises in its steepest direction than in its flattest one.

6.3.3. Derivation

Steps 1 to 4 all use one move: to compare f (or ∇f) at two points, walk along the straight segment $\theta_s = \theta + s(\theta' - \theta)$, $s \in [0, 1]$, between them and add up the changes, using the fundamental theorem of calculus.

1. **Bounded gradient implies Lipschitz.** The change in f along the segment is the integral of the slope in the direction of travel, $f(\theta') - f(\theta) = \int_0^1 \langle \nabla f(\theta_s), \theta' - \theta \rangle \, \mathrm{d}s$. By Cauchy–Schwarz (Fact 2) each inner product is at most $\|\nabla f(\theta_s)\| \, \|\theta' - \theta\| \leq L\|\theta' - \theta\|$, and integrating over an interval of length 1 gives $f(\theta') - f(\theta) \leq L\|\theta' - \theta\|$. Swapping θ and θ' bounds the change in the other direction, which gives the absolute value.

2. **Lipschitz implies bounded gradient.** Step a short distance h from θ in the direction of the gradient, $u = \nabla f(\theta)/\|\nabla f(\theta)\|$. The Lipschitz condition says the change per unit distance is at most L: $\frac{f(\theta + hu) - f(\theta)}{h} \leq L$. As $h \to 0$ the left side becomes the slope in direction u, $\langle \nabla f(\theta), u \rangle = \|\nabla f(\theta)\|$, so $\|\nabla f(\theta)\| \leq L$.

3. **Smoothness implies the descent lemma.** The error of the tangent prediction is the integral of how much the slope has changed since the start of the segment: $f(\theta') - f(\theta) - \langle \nabla f(\theta), \theta' - \theta \rangle = \int_0^1 \langle \nabla f(\theta_s) - \nabla f(\theta), \theta' - \theta \rangle \, \mathrm{d}s$. At position s you are a distance $s\|\theta' - \theta\|$ from θ, so smoothness bounds the gradient change by $\beta s\|\theta' - \theta\|$, and Cauchy–Schwarz bounds the integrand by $\beta s\|\theta' - \theta\|^2$. Since $\int_0^1 \beta s \, \mathrm{d}s = \beta/2$, the error is at most $\frac{\beta}{2}\|\theta' - \theta\|^2$.

4. **Hessian bound implies smoothness.** The gradient change along the segment is the integral of the Hessian applied to the direction of travel, $\nabla f(\theta') - \nabla f(\theta) = \int_0^1 \nabla^2 f(\theta_s)(\theta' - \theta) \, \mathrm{d}s$. A symmetric matrix with eigenvalues in $[-\beta, \beta]$ stretches no vector by more than a factor β, so the integrand has length at most $\beta\|\theta' - \theta\|$, and so does the integral.

5. **Strong convexity implies strong monotonicity.** Write the strong convexity inequality twice, once from θ to θ' and once from θ' to θ, and add the two. The function values appear on both sides and cancel, which leaves $0 \geq \langle \nabla f(\theta) - \nabla f(\theta'), \theta' - \theta \rangle + \lambda\|\theta - \theta'\|^2$. Moving the inner product to the left (and flipping $\theta' - \theta$ to $\theta - \theta'$) gives Equation 6.7. The converse, and the Hessian forms of convexity, are proved in Nesterov's *Lectures on Convex Optimization*, §2.1, and step by step in Section G.1 in the appendices.

6. **Two consequences of strong convexity.** Both are used later in the chapter.

   (a) *A small gradient means you are close to the minimizer.* At the minimizer the gradient is zero, $\nabla f(\theta^*) = 0$. Put $\theta' = \theta^*$ in Equation 6.7, so that the left side is $\langle \nabla f(\theta), \theta - \theta^* \rangle$, and bound it with Cauchy–Schwarz: $\lambda \|\theta - \theta^*\|^2 \le \|\nabla f(\theta)\| \, \|\theta - \theta^*\|$. Dividing by $\lambda \|\theta - \theta^*\|$ gives $\|\theta - \theta^*\| \le \|\nabla f(\theta)\|/\lambda$. In particular a second point with zero gradient would be at distance 0 from θ^*, so the minimizer is unique.

   (b) *Adding $\frac{\lambda}{2}\|\theta\|^2$ to a convex function makes it λ-strongly convex.* The term $\frac{\lambda}{2}\|\theta\|^2$ meets its own strong convexity inequality with equality, because by Fact 2 (with $a = \theta$, $b = \theta' - \theta$) $\frac{\lambda}{2}\|\theta'\|^2 = \frac{\lambda}{2}\|\theta\|^2 + \lambda\langle \theta, \theta' - \theta \rangle + \frac{\lambda}{2}\|\theta' - \theta\|^2$, and $\lambda\theta$ is its gradient. Adding this equality to the tangent inequality Equation 6.1 of the convex function gives the strong convexity inequality for the sum.

6.3.4. Interpretation: Lipschitz is not smooth

The two conditions bound different derivatives, so neither implies the other, and two one-dimensional functions show it (Figure 6.1). The absolute value $f(\theta) = |\theta|$ is 1-Lipschitz, because its slope is always -1 or $+1$. But it is not smooth for any β, because the slope jumps from -1 to 1 at 0, an infinite rate of change. The parabola $f(\theta) = \theta^2/2$ is the opposite. Its slope is θ, which changes at rate 1, so it is 1-smooth. But it is not Lipschitz on all of $\mathbb{R}$, because its slope grows without bound as $|\theta|$ grows.

The parabola is a special case of something general: **a strongly convex function is never Lipschitz on all of $\mathbb{R}^d$.** Consequence (a) rearranged says $\|\nabla f(\theta)\| \ge \lambda \|\theta - \theta^*\|$, so the slope grows at least linearly with the distance from the minimizer. That is why every strongly convex result below works on a bounded set $\mathcal{W}$, where the slope stays bounded, and projects onto it.

The two constants also do different jobs. L bounds how large one step's gradient can be. That governs SGD on losses that are not smooth, and, at the end of this chapter, how far one record can move the minimizer. β bounds how far you can trust the linear approximation of the tangent. That governs the largest safe learning rate, $1/\beta$, and the analysis of non-convex losses.

6.3.5. Example: logistic regression is 1-Lipschitz and 1/4-smooth

Logistic regression is the loss that has both properties, and checking them shows how the constants are found in practice: compute the gradient and bound its size, then compute the Hessian and bound its eigenvalues. Take a label $y \in \{-1, +1\}$, features x with $\|x\| \le 1$, and the **margin** $m = y\langle \theta, x \rangle$, which is positive when the model classifies the record correctly and large when it does so confidently. The logistic loss is $\ell(\theta) = \ln(1 + e^{-m})$: close to 0 for a large positive margin, and growing linearly for a large negative one. Write $\sigma(s) = 1/(1 + e^{-s})$ for the logistic (sigmoid) function, which rises from 0 to 1.

1. **Gradient.** Differentiate in m first: $\frac{\mathrm{d}}{\mathrm{d}m} \ln(1 + e^{-m}) = -\frac{e^{-m}}{1+e^{-m}} = -\sigma(-m)$. The margin's gradient in θ is $\nabla_\theta m = yx$, so by the chain rule $\nabla \ell(\theta) = -\sigma(-m)\, y\, x$.
2. **Lipschitz.** The gradient's length is $\|\nabla \ell(\theta)\| = \sigma(-m)\|x\| \le 1$, because $\sigma < 1$, $|y| = 1$ and $\|x\| \le 1$. A gradient bounded by 1 means the loss is 1-Lipschitz (step 2 of the derivation).

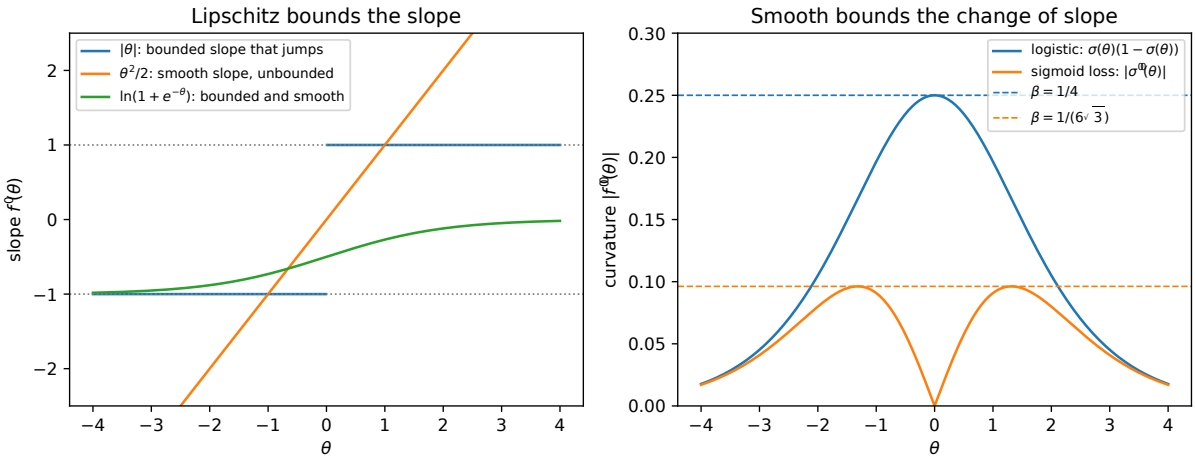

Figure 6.1.: Left: the slopes of $|\theta|$ (bounded, but jumps), $\theta^2/2$ (continuous, unbounded) and the logistic loss $\ln(1+e^{-\theta})$ (bounded and continuous). Right: the curvature of the logistic loss never exceeds $1/4$, and that of the non-convex sigmoid loss never exceeds $1/(6\sqrt{3})$.

3. **Hessian.** Differentiate the factor $-\sigma(-m)$ once more in m: $\frac{\mathrm{d}}{\mathrm{d}m}[-\sigma(-m)] = \sigma'(-m) = \sigma(m)(1-\sigma(m))$, using that the sigmoid's derivative is $\sigma' = \sigma(1-\sigma)$ and that this expression is the same at m and $-m$. The chain rule brings in yx twice, so $\nabla^2\ell(\theta) = \sigma(m)(1-\sigma(m))\,y^2\,xx^\top = \sigma(m)(1-\sigma(m))\,xx^\top$.
4. **Smooth and convex.** The matrix $xx^\top$ curves only along x: it has eigenvalue $\|x\|^2 \le 1$ in that direction and 0 in every direction perpendicular to it. The factor in front is $u(1-u)$ with $u = \sigma(m) \in [0,1]$, and $u(1-u) \le \frac{1}{4}$, with equality at $u = \frac{1}{2}$ (a parabola peaking at its middle). So every eigenvalue of the Hessian lies between 0 and $\frac{1}{4}$, $0 \preceq \nabla^2\ell \preceq \frac{1}{4}I$: the loss is convex and $\frac{1}{4}$-smooth.
5. **Not strongly convex.** The Hessian has rank one, so it has no curvature at all in directions perpendicular to x, and even along x its curvature $u(1-u)$ vanishes as $|m| \to \infty$. No $\lambda > 0$ bounds it from below.

With numbers: for $x = (0.6, 0.8)$ (length 1) and $y = +1$, at $\theta = 0$ the margin is 0, the loss is $\ln 2 = 0.6931$, the gradient norm is $\sigma(0) = 0.5000$ and the curvature is the maximum, $\frac{1}{2}\cdot\frac{1}{2} = 0.2500$. At $\theta = (3,4)$ the margin is $0.6\cdot 3 + 0.8\cdot 4 = 5$, and loss, gradient norm and curvature are all tiny: 0.0067, 0.0067 and 0.0066. Confidently classified records contribute almost no curvature, so the empirical risk $\mathcal{L}$ is only weakly curved at a good solution, where most records are confidently classified. On the logistic dataset used in the experiments below ($n = 1{,}000$, $d = 5$), the smallest eigenvalue of $\nabla^2\mathcal{L}(\theta^*)$ is 0.0233.

Adding a ridge term gives $\ell + \frac{\lambda}{2}\|\theta\|^2$. By consequence (b) it is λ-strongly convex, and since the ridge term adds λ to every eigenvalue of the Hessian it is $(\frac{1}{4}+\lambda)$-smooth. But its gradient $\nabla\ell + \lambda\theta$ grows with $\|\theta\|$, so it is no longer Lipschitz on $\mathbb{R}^d$. On the ball $\|\theta\| \le R$ its gradient is at most $1 + \lambda R$: at most 1 from the loss and at most λR from the ridge term.

6.3.6. Example: least squares and ridge

For the squared loss $\ell(\theta;(x,y)) = \frac{1}{2}(\langle\theta,x\rangle - y)^2$, the chain rule gives the gradient $(\langle\theta,x\rangle - y)x$, the prediction error times the features, and differentiating again gives the Hessian $xx^\top$. As in the logistic case, $xx^\top$ has eigenvalues $\|x\|^2$ and 0, so the loss is convex and $\|x\|^2$-smooth. It is not Lipschitz, because the prediction error, and with it the gradient, grows linearly in θ. On the ball $\|\theta\| \le R$ with $|y| \le Y$ and $\|x\| \le 1$, the prediction error is at most $|\langle\theta,x\rangle| + |y| \le R + Y$, so the loss is $(R+Y)$-Lipschitz there.

Stack the n feature vectors as the rows of a matrix X and the labels into a vector y. The empirical risk then has the same Hessian everywhere, $H = \frac{1}{n}X^\top X$, the average of the $x_i x_i^\top$, called the sample second-moment matrix. It is strongly convex exactly when H is invertible (no direction with zero curvature), with $\lambda = \lambda_{\min}(H)$ and $\beta = \lambda_{\max}(H)$, its smallest and largest eigenvalues. When $d > n$, the n records cannot span all d directions, H is singular, and $\mathcal{L}$ is flat along the missing directions, so it has a whole affine space of minimizers. **Ridge** regression adds $\frac{\lambda}{2}\|\theta\|^2$, which adds λ to every curvature. The Hessian becomes $H + \lambda I$, which is λ-strongly convex for any data. Setting the gradient $\frac{1}{n}X^\top(X\theta - y) + \lambda\theta$ to zero and multiplying by n gives $(X^\top X + n\lambda I)\theta = X^\top y$, so the unique minimizer is $\theta^* = (X^\top X + n\lambda I)^{-1}X^\top y$.

6.3.7. Check yourself

- Is the hinge loss $\max(0, 1 - y\langle\theta,x\rangle)$ with $\|x\| \le 1$ Lipschitz? Smooth? *(It is 1-Lipschitz: where it is not flat its gradient is $-yx$, and in general its subgradients have norm at most $\|x\| \le 1$. It is not smooth: the gradient jumps from $-yx$ to 0 at margin 1.)*
- Why can a λ-strongly convex, β-smooth function never have $\lambda > \beta$? *(Both bound the same quantity, the error of the tangent prediction $f(\theta') - f(\theta) - \langle\nabla f(\theta), \theta' - \theta\rangle$. Strong convexity says it is at least $\frac{\lambda}{2}\|\theta' - \theta\|^2$ and the descent lemma says it is at most $\frac{\beta}{2}\|\theta' - \theta\|^2$, so $\lambda \le \beta$.)*

6.4. Gradient descent and SGD

6.4.1. Context

Gradient descent (GD) steps against the full gradient of the empirical risk. On a training set of a million records, one step costs a million gradient evaluations. SGD replaces the full gradient with the gradient of one record, or of a small batch, chosen at random. Each step is cheap and right on average, but noisy. This section defines both algorithms and shows, on a quadratic, what a fast rate looks like when there is no noise, so that you can see later what the noise costs.

6.4.2. Statement

Gradient descent takes a step of size η against the full gradient: $\theta_{t+1} = \theta_t - \eta\nabla\mathcal{L}(\theta_t)$.

Projected SGD does the same with a random estimate of the gradient, and then pulls the result back into the set $\mathcal{W}$ with the projection $\Pi_{\mathcal{W}}$ of Fact 3. At step t it draws an index i_t uniformly from $\{1, \dots, n\}$, takes that record's gradient $g_t = \nabla \ell(\theta_t; z_{i_t})$, and updates

$$\theta_{t+1} = \Pi_{\mathcal{W}}(\theta_t - \eta_t g_t), \tag{6.8}$$

where the learning rate η_t may change with t. With a **minibatch** $\mathcal{B}_t$ of B indices, $g_t = \frac{1}{B}\sum_{i \in \mathcal{B}_t} \nabla \ell(\theta_t; z_i)$ is the average gradient over the batch. Either way the estimate is unbiased, $\mathbb{E}[g_t \mid \text{past}] = \nabla \mathcal{L}(\theta_t)$, because averaging $\nabla \ell(\theta_t; z_i)$ over a uniformly chosen i gives exactly $\frac{1}{n}\sum_i \nabla \ell(\theta_t; z_i)$, which is the true gradient (Fact 5).

GD on a strongly convex quadratic. Take a quadratic risk $\mathcal{L}(\theta) = \mathcal{L}^* + \frac{1}{2}(\theta - \theta^*)^\top H(\theta - \theta^*)$ whose curvatures (the eigenvalues of H) lie between λ and β, $\lambda I \preceq H \preceq \beta I$. The idea is that on a quadratic the gradient is a linear function of the error $\theta - \theta^*$, so each GD step multiplies the error by a fixed matrix. With the step $\eta = 1/\beta$, the error along each principal direction shrinks by the factor $1 - h/\beta$, where h is the curvature in that direction. The steepest direction ($h = \beta$) is fixed in one step, and the flattest one ($h = \lambda$) shrinks slowest, by $1 - \lambda/\beta = 1 - 1/\kappa$ per step. So the distance to the minimizer shrinks at least geometrically:

$$\|\theta_t - \theta^*\| \le \left(1 - \frac{1}{\kappa}\right)^t \|\theta_0 - \theta^*\|. \tag{6.9}$$

6.4.3. Derivation

1. **One step multiplies the error by a matrix.** The gradient of the quadratic is $\nabla \mathcal{L}(\theta) = H(\theta - \theta^*)$. Subtract θ^* from both sides of the GD update: $\theta_{t+1} - \theta^* = (\theta_t - \theta^*) - \eta H(\theta_t - \theta^*) = (I - \eta H)(\theta_t - \theta^*)$.
2. **Find the factor in each direction.** $I - \eta H$ has the same principal directions as H. With $\eta = 1/\beta$, a curvature h of H becomes the factor $1 - h/\beta$ of $I - H/\beta$. Since $h \in [\lambda, \beta]$, these factors lie in $[0, 1 - \lambda/\beta] = [0, 1 - 1/\kappa]$.
3. **Bound the shrinkage, then repeat.** Write the error in the orthonormal basis of principal directions. Each coordinate is multiplied by its own factor, all of them between 0 and $1 - 1/\kappa$, so the length of the error shrinks by at least $1 - 1/\kappa$. Applying this at each of the t steps gives Equation 6.9.

The quadratic makes the factors exact, but a weaker statement holds for every β-smooth $\mathcal{L}$, and the non-convex analysis later in this chapter starts from it: each GD step with $\eta = 1/\beta$ lowers $\mathcal{L}$ by at least $\|\nabla \mathcal{L}\|^2/(2\beta)$. The reason is the descent lemma Equation 6.6. It says that around the current point, $\mathcal{L}$ lies below a parabola: the tangent plus $\frac{\beta}{2}\|\theta' - \theta\|^2$. Put in the GD step, $\theta' - \theta = -\nabla \mathcal{L}(\theta)/\beta$. The tangent term $\langle \nabla \mathcal{L}, \theta' - \theta \rangle$ becomes $-\frac{1}{\beta}\|\nabla \mathcal{L}\|^2$, the progress, and the parabola term becomes $\frac{\beta}{2} \cdot \frac{1}{\beta^2}\|\nabla \mathcal{L}\|^2$, the price of overshooting. Together,

$$\mathcal{L}(\theta_{t+1}) \le \mathcal{L}(\theta_t) - \frac{1}{\beta}\|\nabla \mathcal{L}(\theta_t)\|^2 + \frac{\beta}{2} \cdot \frac{1}{\beta^2}\|\nabla \mathcal{L}(\theta_t)\|^2 = \mathcal{L}(\theta_t) - \frac{1}{2\beta}\|\nabla \mathcal{L}(\theta_t)\|^2. \tag{6.10}$$

The overshoot eats half of the progress, and half is left.

6.4.4. Interpretation

GD on a strongly convex smooth function converges **linearly**: the error shrinks by a constant factor per step. Section G.1 in the appendices proves this for every such function: the gap $\mathcal{L} - \mathcal{L}^*$ shrinks by the factor $1 - 1/\kappa$ per step, and Equation 6.9 holds as stated whenever $\mathcal{L}$ is twice differentiable. To see how many steps that takes, use $1 - x \leq e^{-x}$: after t steps the factor is at most $e^{-t/\kappa}$, which reaches a target accuracy τ once $t \geq \kappa \ln(1/\tau)$. So reaching τ takes about $\kappa \ln(1/\tau)$ steps. Ill-conditioning, a large κ, is what makes GD slow. The step has to be small enough for the steepest direction, $\eta \leq 1/\beta$, or it overshoots there; and with that small step, the flattest direction, with curvature λ, moves only a fraction λ/β of the way per step.

SGD cannot do this with a constant step. Near θ^* the true gradient vanishes, but the per-example gradients do not: in Table 6.2, even at the minimizer $\theta = 3$ the three records would give gradients 2, 1 and -3. So the iterates keep jumping around θ^*, at a distance set by η and the gradient variance. What makes SGD converge is averaging the iterates, which cancels the jumps, or shrinking η_t over time, which shrinks them. Both give slower rates than GD's, and the next sections derive them.

6.4.5. Example: GD and SGD on a two-dimensional least-squares problem

The script draws 200 records with $x \sim \mathcal{N}(0, \mathrm{diag}(1, 0.1))$, so that the second feature varies much less than the first, and \$y = x_1 + x_2 + \$ noise. The empirical Hessian has $\lambda = 0.101$ and $\beta = 0.969$, so $\kappa = 9.58$. Starting at $\theta_0 = (-1, 3)$, Equation 6.9 predicts that GD with $\eta = 1/\beta$ needs at most 126 steps to shrink $\|\theta - \theta^*\|$ by a factor 10^6. That is the smallest t with $(1 - 1/9.58)^t \leq 10^{-6}$: taking logarithms, $t \geq \ln(10^6)/(-\ln(1 - 1/9.58)) = 13.8155/0.11024 = 125.3$, so $t = 126$. GD actually takes 122. The bound is nearly exact because the starting error has a large component along the flat direction, and that component contracts at exactly the worst-case rate $1 - 1/\kappa$.

Figure 6.2 shows the two algorithms on such a problem. GD first kills the error along the steep direction, then crawls along the flat valley. SGD with a constant step follows roughly the same route but keeps jittering around θ^*.

6.4.6. Check yourself

- Why is $\eta = 2/\beta$ the largest constant step for which GD on a quadratic does not diverge? *(Along the steepest direction the error is multiplied by $1 - \eta\beta$ at each step. It stays bounded only if $|1 - \eta\beta| < 1$, that is $\eta < 2/\beta$; beyond that, each step overshoots by more than it corrects.)*
- In SGD, why does drawing i_t uniformly matter? *(It makes $\mathbb{E}[g_t \mid \textit{past}] = \nabla\mathcal{L}(\theta_t)$. A biased draw would give each record a different weight, so SGD would minimize a reweighted risk instead.)*

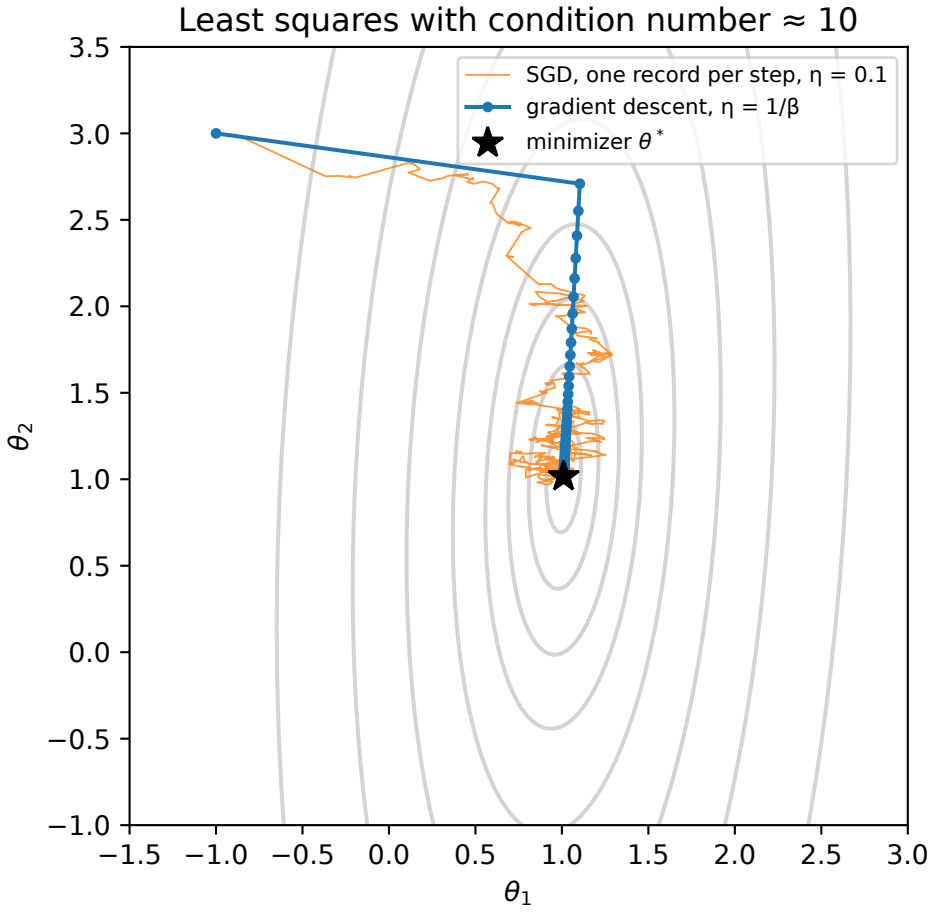

Figure 6.2.: Gradient descent (step $1/\beta$) and single-record SGD (constant step 0.1) on a two-dimensional least-squares risk with condition number about 10. The grey curves are contours of the risk.

6.5. SGD for convex Lipschitz objectives

6.5.1. Context

The cleanest guarantee for SGD needs only convexity and bounded gradients, with no smoothness at all, so it covers the hinge loss and the absolute loss as well as the logistic loss. Its proof is the template for every other proof in this chapter, so it is worth following line by line.

6.5.2. Statement

The guarantee says that SGD's error after T steps comes from two costs that pull the learning rate in opposite directions. The first is the cost of *travel*: you start at distance R from the minimizer, and with small steps it takes a long time to get there, so this cost falls as η grows. The second is the cost of *noise*: each step overshoots by an amount that grows with the learning rate and with the size of the random gradients, so this cost rises with η. The right step balances the two.

The setting is this. $\mathcal{L}$ is convex, and projected SGD runs inside a closed convex set $\mathcal{W}$ that contains the minimizer θ^*. It starts at $\theta_1 \in \mathcal{W}$, at distance $\|\theta_1 - \theta^*\| \le R$ from the minimizer. The random gradients have a bounded second moment, $\mathbb{E}\|g_t\|^2 \le G^2$, so G is the typical size of a gradient used. Run projected SGD with a constant step η for T steps and return the averaged iterate $\bar{\theta}_T = \frac{1}{T}\sum_{t=1}^{T} \theta_t$. Then

$$\mathbb{E}[\mathcal{L}(\bar{\theta}_T)] - \mathcal{L}^* \le \frac{R^2}{2\eta T} + \frac{\eta G^2}{2}. \tag{6.11}$$

The first term is the travel cost and the second the noise cost. The step $\eta = R/(G\sqrt{T})$ minimizes the right side, which then becomes $RG/\sqrt{T}$. For an L-Lipschitz loss with per-example gradients, every gradient has $\|g_t\| \le L$, so $G = L$ and the bound is $RL/\sqrt{T}$.

6.5.3. Derivation

The idea is to follow the squared distance to the minimizer, $a_t = \|\theta_t - \theta^*\|^2$. One step changes it by two terms (Fact 2): a cross term that shrinks it, which convexity ties to the current error $\mathcal{L}(\theta_t) - \mathcal{L}^*$, and a step-length term that grows it, which is at most $\eta^2 G^2$ on average. Rearranging bounds the error at each step by the decrease in distance plus the noise term, and summing over the steps makes the decreases cancel in a chain.

1. **Projection can only help.** The new point is the projection of $\theta_t - \eta g_t$, and θ^* is in $\mathcal{W}$, so by Fact 3 (projection never increases the distance to a point of the set) $a_{t+1} \le \|\theta_t - \eta g_t - \theta^*\|^2$.
2. **Expand the square** (Fact 2, with $a = \theta_t - \theta^*$ and $b = -\eta g_t$): $\|\theta_t - \eta g_t - \theta^*\|^2 = a_t - 2\eta\langle g_t, \theta_t - \theta^*\rangle + \eta^2\|g_t\|^2$.
3. **Rearrange** steps 1 and 2 to isolate the cross term, which is the progress the step makes: $\langle g_t, \theta_t - \theta^*\rangle \le \frac{a_t - a_{t+1}}{2\eta} + \frac{\eta}{2}\|g_t\|^2$.
4. **Take expectations.** The vector $\theta_t - \theta^*$ is fixed by the past, so by Fact 5 the inner product with g_t averages to the inner product with the true gradient $\nabla\mathcal{L}(\theta_t)$. On the right, $\mathbb{E}\|g_t\|^2 \le G^2$. This gives $\mathbb{E}\langle \nabla\mathcal{L}(\theta_t), \theta_t - \theta^*\rangle \le \frac{\mathbb{E}a_t - \mathbb{E}a_{t+1}}{2\eta} + \frac{\eta G^2}{2}$.

5. **Convexity turns progress into error.** Fact 1 with $\theta = \theta_t$ and $\theta' = \theta^*$ says the gradient's component towards θ_t from θ^* is at least the current error: $\mathcal{L}(\theta_t) - \mathcal{L}^* \le \langle \nabla\mathcal{L}(\theta_t), \theta_t - \theta^* \rangle$. So $\mathbb{E}[\mathcal{L}(\theta_t) - \mathcal{L}^*] \le \frac{\mathbb{E}a_t - \mathbb{E}a_{t+1}}{2\eta} + \frac{\eta G^2}{2}$.
6. **Sum over $t = 1, \dots, T$.** The distance terms cancel in a chain (they **telescope**): $(a_1 - a_2) + (a_2 - a_3) + \cdots + (a_T - a_{T+1}) = a_1 - a_{T+1}$. Since $a_{T+1} \ge 0$ and $a_1 \le R^2$, the total is at most R^2. The noise term is added T times. Hence $\sum_t \mathbb{E}[\mathcal{L}(\theta_t) - \mathcal{L}^*] \le \frac{R^2}{2\eta} + \frac{\eta T G^2}{2}$.
7. **Average and apply Jensen.** Dividing by T bounds the average error over the run, and Fact 4 (Jensen: for convex $\mathcal{L}$ the error of the averaged iterate is at most the average error, $\mathcal{L}(\bar{\theta}_T) \le \frac{1}{T}\sum_t \mathcal{L}(\theta_t)$) passes the bound to $\bar{\theta}_T$. That is Equation 6.11.
8. **Optimize η.** The right side $\frac{R^2}{2\eta T} + \frac{\eta G^2}{2}$ has derivative $-\frac{R^2}{2\eta^2 T} + \frac{G^2}{2}$ in η, which vanishes at $\eta = R/(G\sqrt{T})$. At that step both terms equal $RG/(2\sqrt{T})$, and their sum is $RG/\sqrt{T}$.

Nothing in the proof needed $\mathcal{L}$ to be differentiable. For a function with kinks, such as the hinge loss, replace the gradient by a **subgradient**: any vector g whose "tangent" $\mathcal{L}(\theta) + \langle g, \theta' - \theta \rangle$ stays below the graph everywhere (at the kink of $|\theta|$ at 0, any slope between -1 and 1). Then step 5 holds by the definition of a subgradient, and the rest of the proof is unchanged.

6.5.4. Interpretation

The two terms of Equation 6.11 are a trade-off. $R^2/(2\eta T)$ is the cost of travelling the distance R with steps of size η, and $\eta G^2/2$ is the cost of the jitter each step adds. A longer run, larger T, makes travel cheaper, so it allows smaller steps and less jitter, which is why the best step shrinks like $1/\sqrt{T}$.

The rate $1/\sqrt{T}$ cannot be improved for this class of functions. There are convex L-Lipschitz functions on which every method that only queries gradients has error at least of order $RL/\sqrt{T}$ after T queries (Bubeck 2015, §3.5; Section G.3 in the appendices derives the bound $RL/(2(1+\sqrt{T+1}))$ for gradient methods that stay in the span of their gradients). Smoothness alone does not help SGD either, because smoothness reduces the overshoot of the true gradient but not the noise term, which comes from the randomness of g_t.

The guarantee is for the averaged model, not the last one. The proof bounds the average of $\mathcal{L}(\theta_t)$ over the run, and Jensen passes that bound only to the average of the θ_t. So average the iterates, and do not just take the last one.

Finally, it is a worst case. Real objectives often have curvature near the optimum, which the bound does not use, and then SGD does much better than the bound, as the example shows.

6.5.5. Example: logistic regression

The script draws $n = 1{,}000$ records in $d = 5$ with x uniform on the unit sphere and labels from a logistic model. It finds the minimizer with Newton's method ($\|\theta^*\| = 3.152$, $\mathcal{L}^* = 0.5198$), and runs projected SGD on the ball of radius $R = 5$ from $\theta_1 = 0$. The minimizer is inside the ball, and the start is at distance $3.152 \le R$ from it, so the statement applies. The loss is 1-Lipschitz, $L = 1$, and the step is $\eta = R/(L\sqrt{T})$, which is $5/\sqrt{100} = 0.5$ at $T = 100$. Table 6.3 shows the results averaged over 20 runs.

Table 6.3.: Projected SGD on logistic regression against the convex Lipschitz bound Equation 6.11.

Steps T	Step η	Observed $\mathcal{L}(\bar{\theta}_T) - \mathcal{L}^*$	Bound $RL/\sqrt{T}$
100	0.5000	4.44×10^{-2}	0.500
1,000	0.1581	6.46×10^{-3}	0.158
10,000	0.0500	7.71×10^{-4}	0.050

The bound holds in every row. It is loose by a factor of 11 at $T = 100$ ($0.500/0.0444 = 11.3$) and 65 at $T = 10{,}000$ ($0.050/0.000771 = 64.9$). The gap grows because the observed error falls faster than the bound's $1/\sqrt{T}$. From $T = 100$ to $T = 10{,}000$, a hundredfold increase, the error falls by $0.0444/0.000771 = 57.6$, much closer to the factor 100 of a $1/T$ rate than to the factor 10 of $1/\sqrt{T}$. The reason is that this $\mathcal{L}$ is strongly convex near θ^* (its smallest curvature there is 0.0233), which the bound does not know. The next section shows what a bound that uses curvature gives. The left panel of Figure 6.3 shows the same comparison over a range of T.

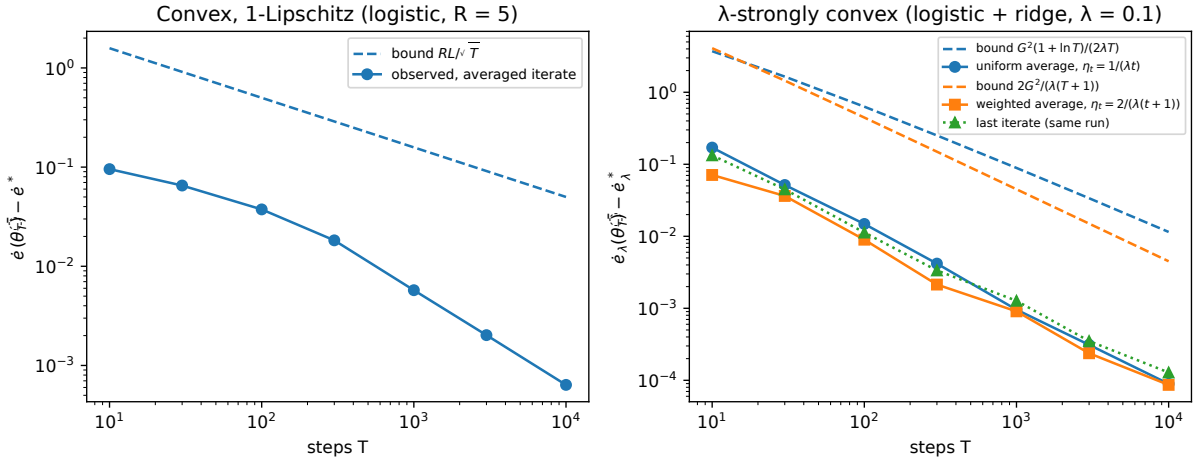

Figure 6.3.: Left: projected SGD on unregularized logistic regression, averaged iterate, against $RL/\sqrt{T}$. Right: the same data with a ridge term $\lambda = 0.1$: the uniformly averaged iterate with steps $1/(\lambda t)$, the t-weighted average with steps $2/(\lambda(t+1))$, and its last iterate, against the two strongly convex bounds.

6.5.6. Check yourself

- Where did the proof use that $\theta^* \in \mathcal{W}$? *(In step 1: Fact 3 only promises that projection does not increase the distance to points of $\mathcal{W}$.)*
- If you doubled the radius R used to set η but θ^* stayed put, what would happen to the guarantee? *(The bound doubles, since it is $RL/\sqrt{T}$; in practice the step is just twice as large.)*

6.6. Strongly convex objectives

6.6.1. Context

Regularized models are strongly convex, and strong convexity pulls the iterates towards θ^* at every step: the farther you are, the larger the gradient pointing back. That turns the $1/\sqrt{T}$ rate into $1/T$, provided you choose the learning rates and the average to match. This section shows two choices that work, and why the plain uniform average loses a factor $\ln T$.

6.6.2. Statement

The two schedules below differ only in how they weight the run. Both let the step shrink like $1/(\lambda t)$, which is the right size once strong convexity is pulling the iterates in. The first averages all iterates equally; the second gives later, better iterates more weight. Let $\mathcal{L}$ be λ-strongly convex on the closed convex set $\mathcal{W}$, which contains θ^*, and let $\mathbb{E}\|g_t\|^2 \le G^2$ as before.

With steps $\eta_t = \frac{1}{\lambda t}$ and the uniform average $\bar{\theta}_T = \frac{1}{T}\sum_t \theta_t$, the error after T steps is

$$\mathbb{E}[\mathcal{L}(\bar{\theta}_T)] - \mathcal{L}^* \le \frac{G^2(1+\ln T)}{2\lambda T}. \tag{6.12}$$

With steps $\eta_t = \frac{2}{\lambda(t+1)}$ and the weighted average $\tilde{\theta}_T = \sum_t \frac{2t}{T(T+1)}\theta_t$, in which iterate t has weight proportional to t, the $\ln T$ disappears:

$$\mathbb{E}[\mathcal{L}(\tilde{\theta}_T)] - \mathcal{L}^* \le \frac{2G^2}{\lambda(T+1)}. \tag{6.13}$$

6.6.3. Derivation

The proof is the convex one with a better step 5. Strong convexity adds a term $\frac{\lambda}{2}\|\theta_t - \theta^*\|^2$ to the progress each step makes, and with the right steps that term makes the distance terms telescope away without leaving the R^2 of the convex case behind.

1. **The per-step inequality.** Steps 1 to 4 of the convex proof hold with a step η_t that changes over time: $\mathbb{E}\langle \nabla\mathcal{L}(\theta_t), \theta_t - \theta^*\rangle \le \frac{\mathbb{E}a_t - \mathbb{E}a_{t+1}}{2\eta_t} + \frac{\eta_t G^2}{2}$, where $a_t = \|\theta_t - \theta^*\|^2$ is again the squared distance to the minimizer.
2. **Strong convexity improves step 5 by a distance term.** The strong convexity inequality at $\theta = \theta_t$, $\theta' = \theta^*$, rearranged, says $\langle \nabla\mathcal{L}(\theta_t), \theta_t - \theta^*\rangle \ge \mathcal{L}(\theta_t) - \mathcal{L}^* + \frac{\lambda}{2}\|\theta_t - \theta^*\|^2$. Using this on the left of step 1 and moving the distance term to the right,
$$\mathbb{E}[\mathcal{L}(\theta_t) - \mathcal{L}^*] \le \Big(\frac{1}{2\eta_t} - \frac{\lambda}{2}\Big)\mathbb{E}a_t - \frac{1}{2\eta_t}\mathbb{E}a_{t+1} + \frac{\eta_t G^2}{2}. \tag{6.14}$$
3. **Uniform schedule.** With $\eta_t = 1/(\lambda t)$, the coefficients are $\frac{1}{2\eta_t} - \frac{\lambda}{2} = \frac{\lambda t}{2} - \frac{\lambda}{2} = \frac{\lambda(t-1)}{2}$ and $\frac{1}{2\eta_t} = \frac{\lambda t}{2}$, so the distance terms are $\frac{\lambda}{2}[(t-1)\mathbb{E}a_t - t\,\mathbb{E}a_{t+1}]$. Summed over t, each $t\,\mathbb{E}a_{t+1}$ subtracted at step t is added back at step $t+1$, and the chain telescopes to $\frac{\lambda}{2}[0 \cdot a_1 - T\,\mathbb{E}a_{T+1}] \le 0$. The starting distance has disappeared, multiplied by 0. The

noise terms are $\frac{\eta_t G^2}{2} = \frac{G^2}{2\lambda t}$, and they sum to $\frac{G^2}{2\lambda}\sum_{t\le T}\frac{1}{t} \le \frac{G^2(1+\ln T)}{2\lambda}$, because the harmonic sum $\sum_{t\le T} 1/t$ is 1 plus terms that are each below the area under $1/s$, and $\int_1^T \mathrm{d}s/s = \ln T$. Divide by T and apply Jensen (Fact 4). The harmonic sum is where the $\ln T$ comes from: the early iterates, taken with huge steps, are bad, and the uniform average gives them full weight.

4. **Weighted schedule.** With $\eta_t = 2/(\lambda(t+1))$, the coefficients are $\frac{1}{2\eta_t} - \frac{\lambda}{2} = \frac{\lambda(t+1)}{4} - \frac{\lambda}{2} = \frac{\lambda(t-1)}{4}$ and $\frac{1}{2\eta_t} = \frac{\lambda(t+1)}{4}$. Multiply the step-2 inequality by t, which is the weight this average gives to iterate t. The distance terms become $\frac{\lambda}{4}[(t-1)t\,\mathbb{E}a_t - t(t+1)\mathbb{E}a_{t+1}]$, which telescope in the same way to at most 0. The noise term becomes $t\cdot\frac{\eta_t G^2}{2} = \frac{t}{t+1}\cdot\frac{G^2}{\lambda} \le \frac{G^2}{\lambda}$, the same for every t, so no harmonic sum appears. Summing, $\sum_t t\,\mathbb{E}[\mathcal{L}(\theta_t) - \mathcal{L}^*] \le \frac{TG^2}{\lambda}$. Divide by $\sum_t t = T(T+1)/2$ and apply Jensen with weights $2t/(T(T+1))$.

Shalev-Shwartz and Ben-David prove the uniform case (*Understanding Machine Learning*, Theorem 14.11). The weighted scheme is from Lacoste-Julien, Schmidt and Bach (2012). Rakhlin, Shamir and Sridharan (2012) get the same $O(G^2/(\lambda T))$ by averaging only the last half of the iterates, which drops the bad early ones in another way.

6.6.4. Interpretation

The rate is now $1/T$ instead of $1/\sqrt{T}$, so to halve the error you need twice the steps, not four times. Strong convexity is what buys this, and it costs a $1/\lambda$ in the constant: a weak regularizer gives a fast rate only after many steps.

The constant G depends on the domain. For a regularized loss $\ell + \frac{\lambda}{2}\|\theta\|^2$ with ℓ L-Lipschitz, the gradient is $\nabla\ell + \lambda\theta$, which on the ball $\|\theta\| \le R$ has length at most $L + \lambda R$. As in Section 6.3, a strongly convex function has no bound on its gradient over all of $\mathbb{R}^d$, so the bound needs a bounded set, and that is the reason for the projection.

The $1/(\lambda T)$ is not an artefact of the proof. Exercise 3 in the exercise book gives a one-dimensional noisy quadratic on which SGD's error is exactly $\sigma^2/(2\lambda T)$, where σ^2 is the gradient variance.

6.6.5. Example: regularized logistic regression

On the same data with $\lambda = 0.1$, the minimizer has $\|\theta^*\| = 0.839$, inside the ball of radius 5, and the gradient bound is $G = L + \lambda R = 1 + 0.1\times 5 = 1.5$. After $T = 10{,}000$ steps, averaged over 20 runs, the uniform average has error 9.09×10^{-5} against the bound 1.15×10^{-2}, and the weighted average 7.85×10^{-5} against 4.50×10^{-3} from Equation 6.13. Those bounds are the formulas with these numbers: $G^2 = 2.25$, so the uniform bound is $2.25\,(1+\ln 10^4)/(2\times0.1\times10^4) = 2.25\times10.21/2000$ and the weighted bound is $2\times2.25/(0.1\times10{,}001)$. The bounds hold but are loose by factors of about 130 and 60 ($0.0115/0.0000909 = 127$ and $0.0045/0.0000785 = 57$). The main reason is that $G = 1.5$ is the worst case over the whole ball, while the actual gradients near θ^* are much smaller. In the right panel of Figure 6.3, all three iterates (uniform, weighted, and the last one) fall like $1/T$, and the weighted average is slightly ahead.

6.6.6. Check yourself

- Why do the first steps of the $1/(\lambda t)$ schedule, which can be huge, not wreck the result? *(The projection keeps every iterate in $\mathcal{W}$, and the telescoping in step 3 cancels their distance terms exactly: the first one is multiplied by $t-1=0$.)*
- What goes wrong if you use $\eta_t = 1/(\lambda t)$ with a λ larger than the true strong convexity? *(Step 2 claims more pull towards θ^* than there is, so the telescoping fails, and the steps shrink too fast: the iterates can stall far from θ^*.)*

6.7. Gradient noise and minibatches

6.7.1. Context

Every SGD bound so far paid for the second moment $\mathbb{E}\|g_t\|^2$, which by the bias–variance split of Fact 5 is the squared true gradient plus the variance of the estimate. Variance comes from sampling records, and also from computing gradients in low precision or compressing them to send between machines. In later parts noise is sometimes added to gradients deliberately. This section answers two practical questions: how does the batch size change the variance, and how should the learning rate change when the gradients get noisier?

6.7.2. Statement

Minibatch variance. Averaging B independent random gradients divides their variance by B, just as the variance of a sample mean is the variance of one sample divided by the sample size. If the B records are drawn without replacement, the average does a little better still, because no record can be drawn twice and the batch covers more of the dataset. To state this, let $\sigma_1^2 = \frac{1}{n}\sum_i \|\nabla\ell(\theta; z_i) - \nabla\mathcal{L}(\theta)\|^2$ be the variance of a per-example gradient at θ: the average squared distance of the n per-example gradients from their mean. For the average gradient g_B of a batch of B indices drawn uniformly,

$$\mathbb{E}\|g_B - \nabla\mathcal{L}(\theta)\|^2 = \begin{cases} \dfrac{\sigma_1^2}{B} & \text{with replacement,} \\ \dfrac{\sigma_1^2}{B}\cdot\dfrac{n-B}{n-1} & \text{without replacement.} \end{cases} \tag{6.15}$$

The extra factor $\frac{n-B}{n-1}$ is 1 for $B=1$ and 0 for $B=n$, when the batch is the whole dataset and its gradient is exact.

Noisy SGD. Suppose each stochastic gradient is perturbed by extra noise ξ_t, independent of everything else, with mean zero and mean squared size $\mathbb{E}\|\xi_t\|^2 = \sigma^2$. Independent noise with mean zero adds its squared size to the second moment without changing anything else, so the convex Lipschitz bound Equation 6.11 holds with $G^2 = L^2 + \sigma^2$. Its best step and its value at that step follow as before:

$$\mathbb{E}[\mathcal{L}(\bar{\theta}_T)] - \mathcal{L}^* \le \frac{R^2}{2\eta T} + \frac{\eta(L^2+\sigma^2)}{2}, \qquad \eta^* = \frac{R}{\sqrt{(L^2+\sigma^2)T}}, \qquad \text{bound at } \eta^* = \frac{R\sqrt{L^2+\sigma^2}}{\sqrt{T}}. \tag{6.16}$$

6.7.3. Derivation

With replacement. The B draws are independent, each with mean $\nabla\mathcal{L}(\theta)$ and variance σ_1^2. Variances of independent random vectors add, just as for numbers: expanding the squared length of the sum of their deviations gives the squared lengths plus cross terms, and each cross term has mean zero because the draws are independent and each deviation has mean zero. So the sum of the B gradients has variance $B\sigma_1^2$. Dividing the sum by B divides the variance by B^2, so the average has variance $B\sigma_1^2/B^2 = \sigma_1^2/B$.

Without replacement. Now the draws are not independent, and the cross terms no longer vanish. They turn out to be slightly negative, which is where the gain comes from. Write $u_i = \nabla\ell(\theta; z_i) - \nabla\mathcal{L}(\theta)$ for the deviation of record i's gradient from the mean, so that the deviations sum to zero, $\sum_i u_i = 0$, and $\frac{1}{n}\sum_i \|u_i\|^2 = \sigma_1^2$. Let $I_1, \dots, I_B$ be the indices drawn.

1. **Each single draw behaves as before.** Each draw I_j on its own is still uniform over the n records, so $\mathbb{E}\|u_{I_j}\|^2 = \sigma_1^2$.
2. **Two different draws are negatively related.** A pair of different draws $I_j \neq I_k$ is a uniformly random pair of distinct indices, so $\mathbb{E}\langle u_{I_j}, u_{I_k}\rangle = \frac{1}{n(n-1)}\sum_{i\neq i'}\langle u_i, u_{i'}\rangle$, the average over the $n(n-1)$ ordered pairs. That sum of cross terms is the squared length of the total minus the squares: $\sum_{i\neq i'}\langle u_i, u_{i'}\rangle = \|\sum_i u_i\|^2 - \sum_i \|u_i\|^2 = 0 - n\sigma_1^2$. So the expected cross term is $-n\sigma_1^2/(n(n-1)) = -\sigma_1^2/(n-1)$. In words: the deviations sum to zero, so once you have drawn an example that deviates one way, the ones left over deviate, on average, slightly the other way.
3. **Add up.** The squared length of the batch average $\frac{1}{B}\sum_j u_{I_j}$ is $\frac{1}{B^2}$ times B squares plus $B(B-1)$ ordered cross terms. Taking expectations with steps 1 and 2, $\frac{1}{B^2}[B\sigma_1^2 - B(B-1)\frac{\sigma_1^2}{n-1}] = \frac{\sigma_1^2}{B}(1 - \frac{B-1}{n-1}) = \frac{\sigma_1^2}{B}\cdot\frac{n-B}{n-1}$.

The toy data of Table 6.2 make this concrete. There $\sigma_1^2 = 14/3$, and the deviations $u_i = g - \nabla\mathcal{L}$ are $3-1=2$, $2-1=1$ and $-2-1=-3$, which sum to zero. Table 6.4 lists every batch of $B = 2$ drawn without replacement, with the mean deviation of the batch and its square.

Table 6.4.: All batches of size 2 drawn without replacement from the toy data of Table 6.2.

Batch	$\{1,2\}$	$\{1,3\}$	$\{2,3\}$	Average
Mean deviation $\bar{u}$	1.5	-0.5	-1	0
$\bar{u}^2$	2.25	0.25	1	7/6

The variance is the average of the last row, $(2.25 + 0.25 + 1)/3 = 7/6$. The formula gives $\frac{14/3}{2}\cdot\frac{3-2}{3-1} = \frac{7}{6}$, matching Table 6.4. With replacement the variance would be $\frac{14/3}{2} = \frac{7}{3}$, twice as large.

Noisy SGD. The noisy gradient is $\nabla\ell + \xi_t$. Expand its squared length with Fact 2: the cross term $2\langle\nabla\ell, \xi_t\rangle$ has mean zero, because ξ_t is independent of the gradient and has mean zero (the same argument as in Fact 5). So $\mathbb{E}\|\nabla\ell + \xi_t\|^2 = \mathbb{E}\|\nabla\ell\|^2 + \mathbb{E}\|\xi_t\|^2 \leq L^2 + \sigma^2$. Substitute $G^2 = L^2 + \sigma^2$ into Equation 6.11 and optimize η as in step 8 of that derivation, which gives $\eta^* = R/(G\sqrt{T})$ and the bound $RG/\sqrt{T}$.

6.7.4. Interpretation

A batch of B divides the variance by B, and sampling without replacement removes a further fraction $(B-1)/(n-1)$ of what is left. That correction only matters once B is a sizeable fraction of n, and at $B = n$ the gradient is exact.

Noise shrinks the best step. η^* scales like $1/\sqrt{L^2+\sigma^2}$, so noisier gradients call for smaller steps and longer runs. To see how much longer, set the bound $R\sqrt{L^2+\sigma^2}/\sqrt{T}$ equal to a target accuracy τ and solve for T: reaching τ takes $R^2(L^2+\sigma^2)/\tau^2$ steps. Noise of size $\sigma = 3L$ makes $L^2+\sigma^2 = L^2+9L^2 = 10L^2$, so it multiplies the number of steps by 10.

Larger batches are not free. A batch of B costs B gradient evaluations and divides the variance by B, so per gradient evaluation the variance reduction is exactly cancelled. Batches help mainly because the B evaluations can run in parallel. Exercise 6 in the exercise book makes this precise for the non-convex bound: beyond a critical batch size, larger batches waste computation.

6.7.5. Example

Minibatch variance. At the logistic minimizer θ^* of the experiments, $\sigma_1^2 = 0.1722$. The true gradient there is zero, so this is just the mean squared per-example gradient. The script draws 4,000 random batches of each size and measures the variance of their average gradient (Table 6.5).

Table 6.5.: Measured minibatch gradient variance at θ^* for the logistic data ($n = 1{,}000$), against Equation 6.15.

Batch size B	With replacement: measured / σ_1^2/B	Without replacement: measured / Equation 6.15
1	1.75×10^{-1} / 1.72×10^{-1}	1.75×10^{-1} / 1.72×10^{-1}
10	1.74×10^{-2} / 1.72×10^{-2}	1.68×10^{-2} / 1.71×10^{-2}
100	1.73×10^{-3} / 1.72×10^{-3}	1.57×10^{-3} / 1.55×10^{-3}
500	3.47×10^{-4} / 3.44×10^{-4}	1.74×10^{-4} / 1.72×10^{-4}

The formulas in Table 6.5 match the measurements to within the Monte Carlo error. At $B = 500 = n/2$ the correction factor is $\frac{1000-500}{999}$, about one half, so sampling without replacement halves the variance. Figure 6.4 shows the full range.

Noise and learning rate. The script adds Gaussian noise with $\mathbb{E}\|\xi_t\|^2 = \sigma^2$ to every per-example gradient and runs projected SGD on the logistic problem for $T = 10{,}000$ steps, 10 runs per setting, sweeping η over 17 values from 10^{-3} to 10. With $R = 5$ and $L = 1$, the bound's recommended step is $\eta^* = 5/\sqrt{(1+\sigma^2)\cdot 10^4}$, which is $5/100 = 0.05$ without noise, and the bound there is $5\sqrt{1+\sigma^2}/100$. Table 6.6 compares that step with the best one on the grid.

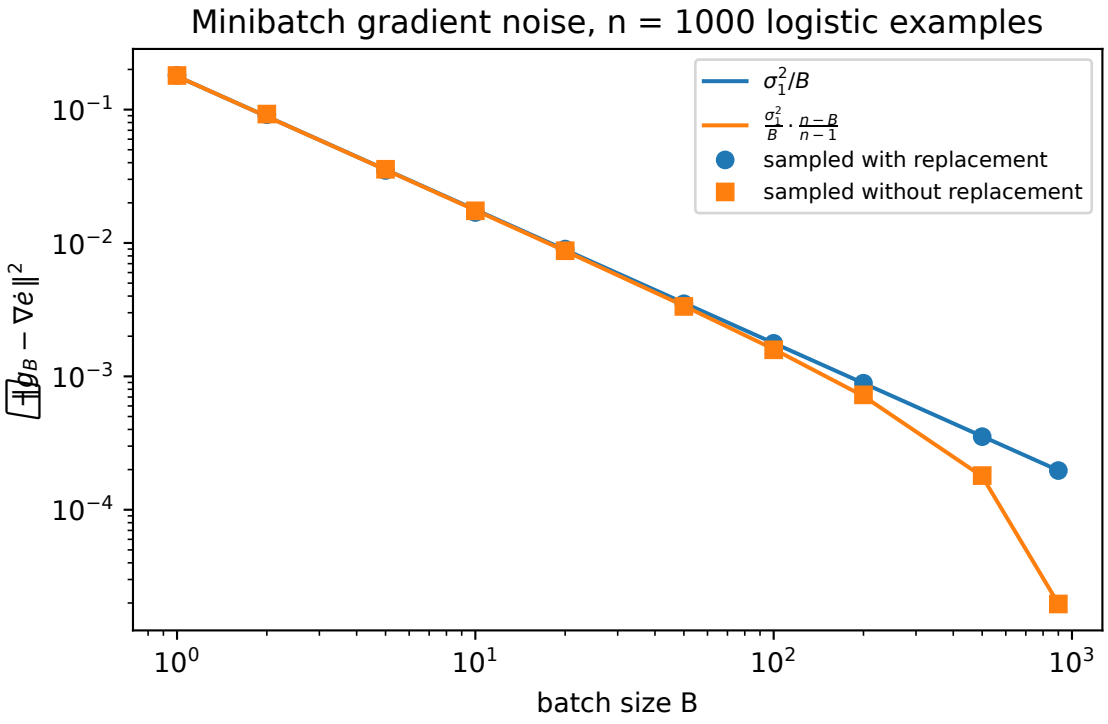

Figure 6.4.: Minibatch gradient variance at the logistic minimizer against batch size, measured and from Equation 6.15. Without replacement, the variance drops below σ_1^2/B as B approaches $n = 1000$.

Table 6.6.: Projected SGD with added gradient noise, $T = 10{,}000$: suboptimality $\mathcal{L}(\bar{\theta}_T) - \mathcal{L}^*$ at the learning rate the bound recommends and at the best learning rate on the grid.

Noise σ	η^* from the bound	Bound at η^*	Observed at η^*	Best η on the grid	Observed there
0	0.0500	0.050	4.99×10^{-4}	0.178	1.85×10^{-4}
1	0.0354	0.071	1.58×10^{-3}	0.056	1.38×10^{-3}
3	0.0158	0.158	9.58×10^{-3}	0.056	5.10×10^{-3}

Table 6.6 and Figure 6.5 show three things. First, noise costs accuracy: at the bound's step, the error grows about 20-fold from $\sigma = 0$ to $\sigma = 3$ ($9.58 \times 10^{-3} / 4.99 \times 10^{-4} = 19.2$). Second, noise pushes the best step down, from 0.178 to 0.056 on the grid, and the U-shaped curves in the figure move left. Third, the bound's η^* is conservative. It assumes the gradient is as large as L and the distance as large as R throughout, while the actual run has smaller gradients and starts closer, so the best observed step is larger: by a factor of 3.6 without noise ($0.178/0.05 = 3.56$).

6.7.6. Check yourself

- You quadruple the batch size. By how much should the variance term in a bound like $\eta\sigma^2$ drop, and what happens to the cost of a step? *(By a factor of 4, slightly more without replacement; each step costs 4 times as many gradient evaluations.)*
- Why does a very small η give the same error for every noise level in Figure 6.5? *(The iterates barely leave $\theta_1 = 0$, so the error is just $\mathcal{L}(0) - \mathcal{L}^*$, set by the travel term $R^2/(2\eta T)$, not by the noise.)*

6.8. Non-convex objectives: convergence to stationary points

6.8.1. Context

Neural network losses are not convex. There can be many local minima and saddle points, and no method that only uses gradients can promise to find the global minimum. What you can still guarantee is that SGD finds a point where the gradient is small, an **approximate stationary point**. The argument uses smoothness instead of convexity, and it shows directly how the gradient variance and the learning rate trade off.

6.8.2. Statement

The idea is that each step lowers $\mathcal{L}$ in proportion to the squared gradient, by the descent lemma (as for GD in the section on gradient descent), minus a penalty for the noise. $\mathcal{L}$ cannot fall forever, because it is bounded below, so the total of the squared gradients over the run is bounded, and they must be small on average.

To state it, let $\mathcal{L}$ be β-smooth and bounded below by $\mathcal{L}_{\text{inf}}$, and let $\Gamma = \mathcal{L}(\theta_1) - \mathcal{L}_{\text{inf}}$ be the most it can fall from the starting point. Let the stochastic gradients be unbiased, with variance at

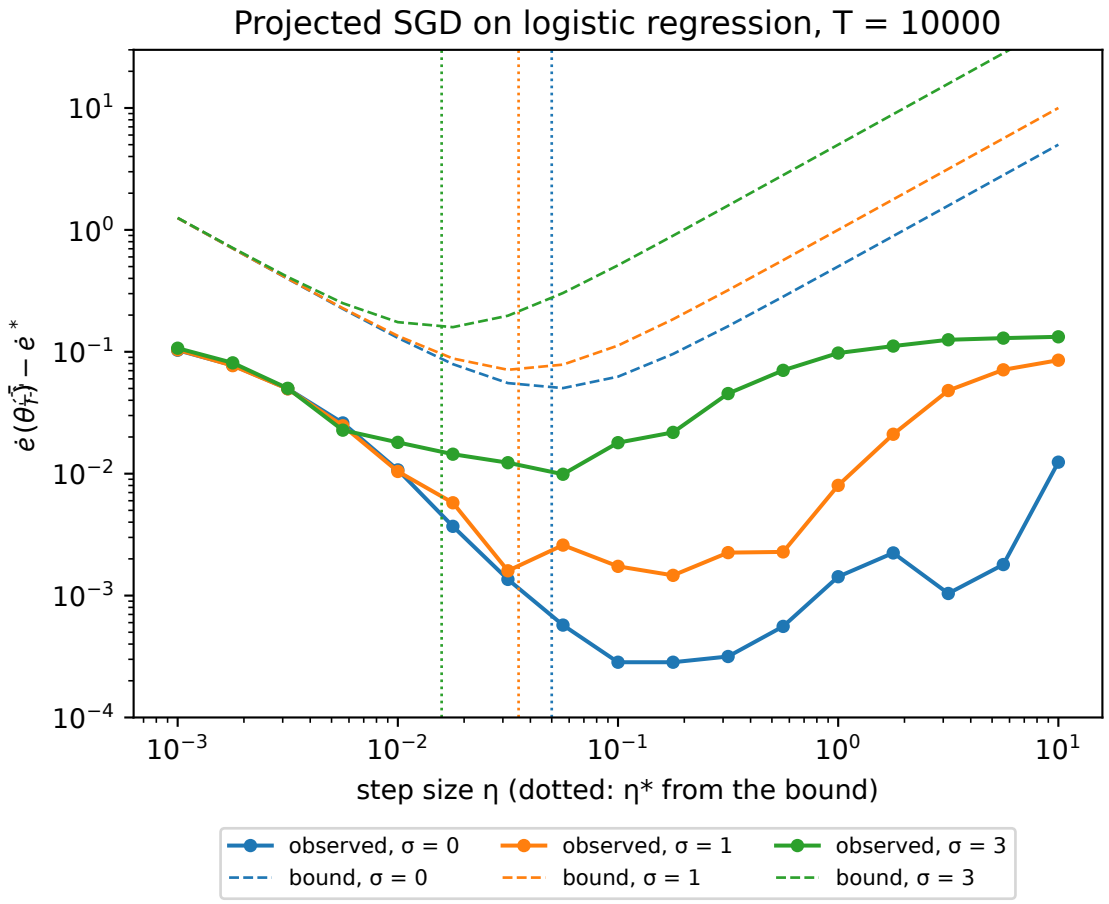

Figure 6.5.: Suboptimality of the averaged iterate after $T = 10{,}000$ steps of projected SGD on logistic regression, as a function of the learning rate, for three levels of added gradient noise. Dashed curves are the bound $R^2/(2\eta T) + \eta(L^2 + \sigma^2)/2$; dotted vertical lines mark its minimizer η^*.

most σ^2: $\mathbb{E}[\|g_t - \nabla\mathcal{L}(\theta_t)\|^2 \mid \text{past}] \le \sigma^2$. SGD (with no projection) with a constant step $\eta \le 1/\beta$ satisfies

$$\min_{t\le T} \mathbb{E}\|\nabla\mathcal{L}(\theta_t)\|^2 \le \frac{1}{T}\sum_{t=1}^{T} \mathbb{E}\|\nabla\mathcal{L}(\theta_t)\|^2 \le \frac{2\Gamma}{\eta T} + \beta\eta\sigma^2. \tag{6.17}$$

As in the convex case, the first term is the travel cost and the second the noise cost. With $\eta = \min\left(1/\beta,\ \sqrt{2\Gamma/(\beta\sigma^2 T)}\right)$, the step that balances them unless that would exceed $1/\beta$, the right side is at most $\frac{4\beta\Gamma}{T} + 2\sqrt{\frac{2\beta\Gamma\sigma^2}{T}}$.

6.8.3. Derivation

1. **Descent lemma for one step.** Apply Equation 6.6 with $\theta = \theta_t$ and $\theta' = \theta_{t+1} = \theta_t - \eta g_t$, so that $\theta' - \theta = -\eta g_t$: $\mathcal{L}(\theta_{t+1}) \le \mathcal{L}(\theta_t) - \eta\langle\nabla\mathcal{L}(\theta_t), g_t\rangle + \frac{\beta\eta^2}{2}\|g_t\|^2$.
2. **Average over the random gradient.** By Fact 5, conditioned on the past the inner product averages to $\|\nabla\mathcal{L}(\theta_t)\|^2$, and the bias–variance split gives $\mathbb{E}\|g_t\|^2 \le \|\nabla\mathcal{L}(\theta_t)\|^2 + \sigma^2$. Collecting the two $\|\nabla\mathcal{L}(\theta_t)\|^2$ terms and averaging over the past, $\mathbb{E}\mathcal{L}(\theta_{t+1}) \le \mathbb{E}\mathcal{L}(\theta_t) - \eta(1 - \frac{\beta\eta}{2})\mathbb{E}\|\nabla\mathcal{L}(\theta_t)\|^2 + \frac{\beta\eta^2\sigma^2}{2}$.
3. **Make sure the step makes progress.** The factor $1 - \beta\eta/2$ must be positive, or the step could increase $\mathcal{L}$. With $\eta \le 1/\beta$ it is at least $1/2$, so $\frac{\eta}{2}\mathbb{E}\|\nabla\mathcal{L}(\theta_t)\|^2 \le \mathbb{E}\mathcal{L}(\theta_t) - \mathbb{E}\mathcal{L}(\theta_{t+1}) + \frac{\beta\eta^2\sigma^2}{2}$.
4. **Sum and telescope.** Summing over $t = 1, \dots, T$, the differences of $\mathcal{L}$ cancel in a chain to $\mathcal{L}(\theta_1) - \mathbb{E}\mathcal{L}(\theta_{T+1})$, which is at most Γ because $\mathcal{L}$ never goes below $\mathcal{L}_{\text{inf}}$: $\frac{\eta}{2}\sum_{t=1}^{T}\mathbb{E}\|\nabla\mathcal{L}(\theta_t)\|^2 \le \mathcal{L}(\theta_1) - \mathbb{E}\mathcal{L}(\theta_{T+1}) + \frac{T\beta\eta^2\sigma^2}{2} \le \Gamma + \frac{T\beta\eta^2\sigma^2}{2}$.
5. **Divide by** $\eta T/2$ to get the average in Equation 6.17. The minimum over t is at most the average, which gives the left inequality.
6. **Choose** η**.** There are two cases. If $\sqrt{2\Gamma/(\beta\sigma^2 T)} \le 1/\beta$, that step makes both terms equal to $\sqrt{2\beta\Gamma\sigma^2/T}$, so their sum is twice that. Otherwise $\eta = 1/\beta$, the first term is $2\beta\Gamma/T$, and the condition $1/\beta < \sqrt{2\Gamma/(\beta\sigma^2 T)}$, squared and rearranged, says $\sigma^2 < 2\beta\Gamma/T$, so the second term σ^2 is below $2\beta\Gamma/T$ too, and the sum is below $4\beta\Gamma/T$. Either way the total is at most $\frac{4\beta\Gamma}{T} + 2\sqrt{\frac{2\beta\Gamma\sigma^2}{T}}$.

This is the argument of Ghadimi and Lan (2013, Theorem 2.1 and Corollary 2.2). They output an iterate chosen uniformly at random from the run, so that its expected squared gradient equals the average in Equation 6.17.

6.8.4. Interpretation

There are two regimes. Without noise ($\sigma = 0$) the second term vanishes, the step is $1/\beta$, and the rate is of order $\beta\Gamma/T$, the deterministic GD rate. With noise the $\sqrt{\sigma^2/T}$ term dominates for large T: the squared gradient falls like $1/\sqrt{T}$, so the gradient norm, its square root, falls only like $T^{-1/4}$.

A small gradient is all you get. A stationary point can be a local minimum, a saddle point, or a flat region far from anything good, and the guarantee says nothing about $\mathcal{L}(\theta_T) - \mathcal{L}^*$.

The learning rate again balances travel against noise, $2\Gamma/(\eta T)$ against $\beta\eta\sigma^2$, the same trade-off as in the convex case. With batches of size B, replace σ^2 by σ^2/B, by Equation 6.15.

6.8.5. Example: the sigmoid loss

The **sigmoid loss** $\ell(\theta) = \sigma(-y\langle\theta, x\rangle)$ is a smooth stand-in for the 0–1 loss: with margin $m = y\langle\theta, x\rangle$ it is $\sigma(-m)$, close to 1 for a badly misclassified record and close to 0 for a confidently correct one. Here σ is the sigmoid function of the logistic example, not a noise level. The loss is not convex, because σ curves up on one side of 0 and down on the other. To apply the statement you need its constants β, Γ and the noise σ^2, and each is found by bounding a derivative.

With $\|x\| \le 1$ its gradient $-y\,\sigma'(-m)\,x$ has norm at most $\max\sigma' = \frac{1}{4}$, since $\sigma' = \sigma(1-\sigma) \le \frac{1}{4}$. Its Hessian $\sigma''(-m)\,xx^\top$ has eigenvalues of size at most $\max|\sigma''|$, which is therefore the smoothness constant. Differentiating $\sigma' = \sigma(1-\sigma)$ once more gives $\sigma'' = \sigma(1-\sigma)(1-2\sigma)$. Writing $u = \sigma \in (0,1)$ and maximizing $u(1-u)(1-2u)$ by setting its derivative to zero gives $u = \frac{1}{2} - \frac{\sqrt{3}}{6}$, where $u(1-u) = \frac{1}{6}$ and $1-2u = \frac{1}{\sqrt{3}}$. So $\beta = \frac{1}{6\sqrt{3}} = 0.0962$ (Figure 6.1, right). The loss lies in $(0,1)$, so $\mathcal{L}_{\inf} \ge 0$, and starting at $\theta_1 = 0$, where every margin is 0 and $\mathcal{L} = \sigma(0) = \frac{1}{2}$, gives $\Gamma \le \frac{1}{2}$. Finally, the variance is at most the second moment, which is at most the squared largest gradient: $\sigma^2 \le \mathbb{E}\|g\|^2 \le \frac{1}{16}$.

On the logistic data, $\|\nabla\mathcal{L}(0)\|^2 = 4.06 \times 10^{-3}$. SGD runs with the step from the statement. At $T = 100$ that step is $\sqrt{2\Gamma/(\beta\sigma^2 T)} = \sqrt{1/(0.0962 \times 0.0625 \times 100)} = 1.289$, well below $1/\beta = 10.4$. Table 6.7 shows the results averaged over 5 runs.

Table 6.7.: SGD on the non-convex sigmoid loss against the stationarity bound.

Steps T	Step η	Observed $\frac{1}{T}\sum_t \|\nabla\mathcal{L}(\theta_t)\|^2$	Bound Equation 6.17
100	1.289	1.64×10^{-3}	1.55×10^{-2}
1,000	0.408	5.22×10^{-4}	4.90×10^{-3}
10,000	0.129	1.87×10^{-4}	1.55×10^{-3}

The bound in Table 6.7 is loose by a factor of 8 to 10 (from $0.00155/0.000187 = 8.3$ to $0.0155/0.00164 = 9.5$) and has the right slope, $1/\sqrt{T}$: each tenfold increase in T divides it by $\sqrt{10} = 3.16$. The slack comes from the worst-case constants: Γ, σ^2 and β are all upper bounds that the actual run does not reach. Figure 6.6 shows the comparison over more values of T.

6.8.6. Check yourself

- Which step of the derivation would fail with $\eta = 3/\beta$? *(Step 3: $1 - \beta\eta/2$ becomes negative, so the descent lemma no longer guarantees progress.)*
- Why can the convex proof bound $\mathcal{L}(\bar{\theta}_T) - \mathcal{L}^*$ while this one cannot? *(It used Fact 1 to turn the inner product $\langle\nabla\mathcal{L}, \theta_t - \theta^*\rangle$ into a function gap. Without convexity there is no such link.)*

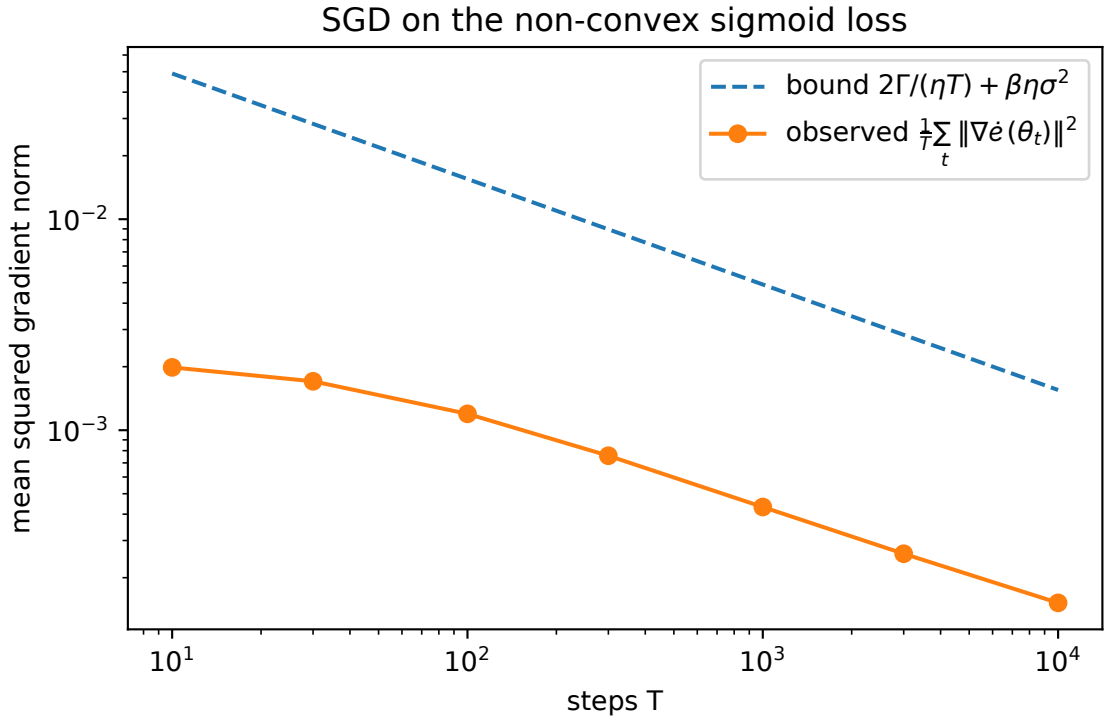

Figure 6.6.: Average squared gradient norm along SGD on the sigmoid loss, against the bound $2\Gamma/(\eta T) + \beta\eta\sigma^2$ with the step chosen for each horizon T.

6.9. Sensitivity of regularized ERM

6.9.1. Context

The previous sections asked how fast an optimizer reaches the minimizer. This one asks how much the minimizer itself depends on the data. Regularized ERM picks the parameters that minimize the average training loss plus a penalty $\frac{\lambda}{2}\|\theta\|^2$ on their size, the **regularized empirical risk**:

$$\mathcal{L}_\lambda(\theta; D) = \frac{1}{n}\sum_{i=1}^{n} \ell(\theta; z_i) + \frac{\lambda}{2}\|\theta\|^2, \tag{6.18}$$

and returns the minimizer $\theta^*(D) = \arg\min_\theta \mathcal{L}_\lambda(\theta; D)$. Suppose you replace one training record and retrain. How far can the minimizer move? This is a question about the problem, not about the optimizer: it asks how much any single record can influence the exact solution. The answer controls how stable the learned model is, and therefore how well it generalizes (Algorithmic stability and generalization). The quantity returns in later parts under the name *sensitivity*.

6.9.2. Statement

Changing one record changes only one of the n terms of the average, so the objective's gradient moves by at most $2L/n$: that record's gradient is removed and another added, each of length at most L. Strong convexity with curvature λ then converts a small change in the gradient into a small move of the minimizer, at most the gradient change divided by λ. Formally, let each $\ell(\cdot; z)$ be convex and L-Lipschitz, and let the datasets D and D' differ in one record, replaced by another. Then

$$\|\theta^*(D) - \theta^*(D')\| \le \frac{2L}{\lambda n}. \tag{6.19}$$

6.9.3. Derivation

Let D' replace z_i by z'. Write $\mathcal{L}_\lambda(\cdot; D)$ and $\mathcal{L}_\lambda(\cdot; D')$ for the two objectives, and $\theta = \theta^*(D)$ and $\theta' = \theta^*(D')$ for their minimizers.

1. **The two objectives differ by one term.** $\mathcal{L}_\lambda(\cdot; D') - \mathcal{L}_\lambda(\cdot; D) = h$ with $h(v) = \frac{1}{n}(\ell(v; z') - \ell(v; z_i))$: the new record's loss in, the old one's out, each with weight $1/n$. Each loss has gradient of length at most L, and the length of a difference is at most the sum of the lengths (the triangle inequality), so $\|\nabla h(v)\| \le \frac{2L}{n}$ for every v.
2. **At θ', the old objective has a small gradient.** Each minimizer has zero gradient for its own objective, $\nabla\mathcal{L}_\lambda(\theta; D) = 0$ and $\nabla\mathcal{L}_\lambda(\theta'; D') = 0$. So $\nabla\mathcal{L}_\lambda(\theta'; D) = \nabla\mathcal{L}_\lambda(\theta'; D') - \nabla h(\theta') = -\nabla h(\theta')$. The point θ' is not optimal for $\mathcal{L}_\lambda(\cdot; D)$, but the gradient of $\mathcal{L}_\lambda(\cdot; D)$ there has length at most $2L/n$.
3. **Strong convexity of $\mathcal{L}_\lambda(\cdot; D)$.** $\mathcal{L}_\lambda(\cdot; D)$ is an average of convex losses plus $\frac{\lambda}{2}\|\theta\|^2$, so it is λ-strongly convex (consequence (b) in Section 6.3: adding that term to a convex function adds curvature λ). Strong monotonicity Equation 6.7 then gives $\lambda\|\theta' - \theta\|^2 \le \langle \nabla\mathcal{L}_\lambda(\theta'; D) - \nabla\mathcal{L}_\lambda(\theta; D), \theta' - \theta\rangle$.
4. **Substitute step 2 and apply Cauchy–Schwarz.** With $\nabla\mathcal{L}_\lambda(\theta; D) = 0$ and $\nabla\mathcal{L}_\lambda(\theta'; D) = -\nabla h(\theta')$, $\lambda\|\theta' - \theta\|^2 \le \langle -\nabla h(\theta'), \theta' - \theta\rangle \le \frac{2L}{n}\|\theta' - \theta\|$.

5. **Divide** by $\lambda\|\theta' - \theta\|$ (if it is zero there is nothing to prove), which gives Equation 6.19.

In other words, this is consequence (a) of strong convexity, $\|\theta' - \theta\| \le \|\nabla\mathcal{L}_\lambda(\theta'; D)\|/\lambda$ (a small gradient means you are close to the minimizer), applied to $\mathcal{L}_\lambda(\cdot; D)$ at the point θ', where its gradient is at most $2L/n$. With subgradients in place of gradients, the same steps work for non-differentiable losses such as the hinge loss.

The bound is tight. A loss with no curvature of its own shows it, because then the regularizer is the only curvature and nothing is lost. Take $d = 1$, labels $z_i \in \{-1, +1\}$, and the linear loss $\ell(\theta; z) = z\theta$, which is convex and 1-Lipschitz. Then $\mathcal{L}_\lambda(\theta; D) = \bar{z}\theta + \frac{\lambda}{2}\theta^2$ with $\bar{z}$ the mean label, and setting the derivative $\bar{z} + \lambda\theta$ to zero gives $\theta^*(D) = -\bar{z}/\lambda$. Changing one label from $+1$ to -1 changes the sum of the labels by 2, so it lowers $\bar{z}$ by $2/n$ and moves θ^* by exactly $2/(\lambda n)$. For $n = 1{,}000$ and $\lambda = 0.1$ that is $2/100 = 0.02$.

6.9.4. Interpretation

Influence shrinks like $1/n$, because one record among n carries weight $1/n$ in the objective. Regularization buys stability: the curvature λ converts a small perturbation of the gradient into a small move of the minimizer, and halving λ can double the movement.

The bound also controls the loss. Because $\ell(\cdot; z)$ is L-Lipschitz, moving the parameters by at most $\frac{2L}{\lambda n}$ changes the loss on any point z by at most $L \cdot \frac{2L}{\lambda n} = \frac{2L^2}{\lambda n}$. A bound of this kind, on how much replacing one training record can change the loss at any point, is called **uniform stability**, and it is the input to the generalization bound in Algorithmic stability and generalization.

The bound is loose in two places. The proof used only the regularizer's curvature λ, while real data add curvature of their own. And it used the worst case $2L$ for the gradient difference, while two actual records rarely have gradients pointing in opposite directions at full length. If $\mathcal{L}_\lambda(\cdot; D)$ is λ'-strongly convex with $\lambda' > \lambda$, because the data contribute curvature too, the same proof gives $2L/(\lambda' n)$.

6.9.5. Example: logistic regression

The script draws logistic datasets of size n, solves regularized logistic regression exactly with Newton's method, replaces one random record with a fresh draw, solves again, and records the largest movement over 20 replacements. The logistic loss is 1-Lipschitz, so the bound is $2/(\lambda n)$: for example $2/(0.1 \times 1{,}000) = 0.02$. Table 6.8 compares the two.

Table 6.8.: Largest movement of the regularized logistic minimizer over 20 single-record replacements, against $2L/(\lambda n)$ with $L = 1$.

n	$\lambda = 0.01$: observed / bound	$\lambda = 0.1$: observed / bound	$\lambda = 1$: observed / bound
100	2.52×10^{-1} / 2.00	5.98×10^{-2} / 0.200	8.55×10^{-3} / 0.0200
1,000	2.13×10^{-2} / 0.200	6.66×10^{-3} / 0.0200	8.54×10^{-4} / 0.00200
10,000	2.06×10^{-3} / 0.0200	6.35×10^{-4} / 0.00200	7.80×10^{-5} / 0.000200

Read Table 6.8 in both directions. Down a column, n grows tenfold and the movement shrinks tenfold, exactly as $1/n$ predicts. Across a row, the ratio of observed to bound changes with λ: it is 0.39–0.43 at $\lambda = 1$ (for example $8.55 \times 10^{-3}/0.0200 = 0.43$), 0.30–0.33 at $\lambda = 0.1$ and 0.10–0.13 at $\lambda = 0.01$. The reason is the first source of slack above. At $\lambda = 1$ the regularizer supplies nearly all the curvature, and the remaining factor of about 2 is the gradient-difference slack. At $\lambda = 0.01$ the data supply more curvature than the regularizer (about 0.0233 at the unregularized minimizer, more for smaller θ), so the bound, which only knows λ, overestimates the movement tenfold.

Figure 6.7 shows both trends. On the right, as $\lambda \to 0$ the bound blows up while the observed movement levels off at the value set by the data's own curvature.

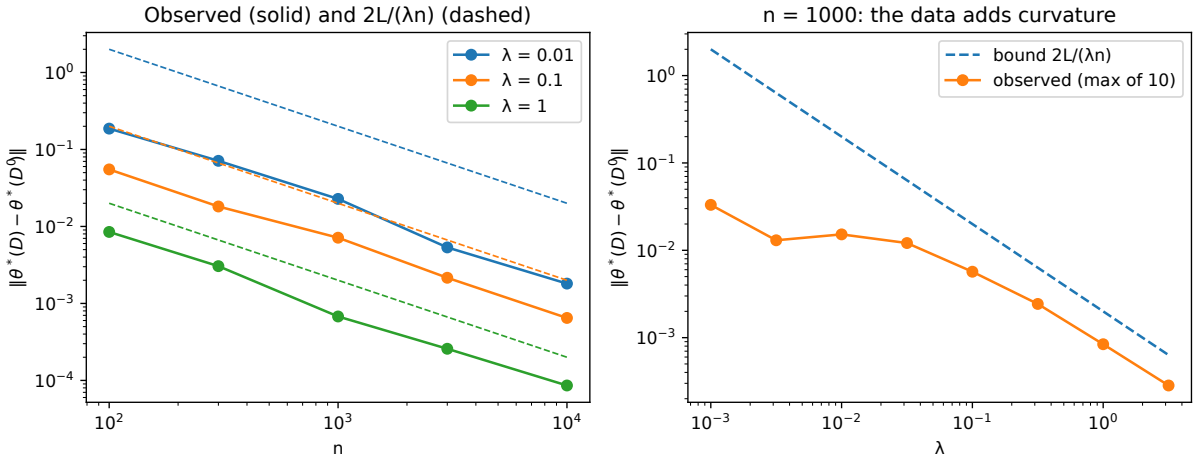

Figure 6.7.: Left: largest observed movement of the regularized logistic minimizer when one of n records is replaced (solid), against $2L/(\lambda n)$ (dashed), for three values of λ. Right: the same at $n = 1000$ as a function of λ.

6.9.6. Why strong convexity is needed

Without the regularizer, convexity alone does not stop the minimizer from jumping, because a convex function can be flat, and on a flat stretch a tiny change in the data can move the minimizer a long way. Take the absolute loss $\ell(\theta; z) = |\theta - z|$, which is convex and 1-Lipschitz. The minimizer of $\frac{1}{n}\sum_i |\theta - z_i|$ is the median: moving θ up by a little increases $|\theta - z_i|$ for each value below θ and decreases it for each value above, so the risk stops decreasing when half the values are on each side. With $n = 2k + 1$ values, $k + 1$ of them 0 and k of them 1, the median is 0. Replace one 0 by a 1 and the majority switches, so the median is 1. The minimizer moves by 1 for every n: no $1/n$ at all. With $\frac{\lambda}{2}\theta^2$ added, Equation 6.19 caps the move at $2/(\lambda n)$ (Exercise 8 in the exercise book finds the actual move).

6.9.7. Why no such bound exists for non-convex objectives

For a non-convex loss even strong curvature in places is not enough, because the risk can have two separate valleys of nearly equal depth, and one record can decide which is deeper. Take labels $z_i \in \{-1, +1\}$ and the double-well loss $\ell(\theta; z) = \frac{1}{4}(\theta^2 - 1)^2 - z\theta$. The first term has two valleys,

at $\theta = -1$ and $\theta = +1$, and the second tilts it towards the sign of z. On $[-2, 2]$ it is smooth and Lipschitz: its derivative $\theta^3 - \theta - z$ is at most $8 - 2 + 1 = 7$ in absolute value, and its second derivative $3\theta^2 - 1$ lies in $[-1, 11]$. The empirical risk is $\frac{1}{4}(\theta^2 - 1)^2 - \bar{z}\theta$: two wells near ± 1, tilted towards the sign of the mean label $\bar{z}$.

With $n = 11$ records, six labelled $+1$, the mean label is $\bar{z} = (6 - 5)/11 = 1/11$, the right well is lower, and the minimizer is $\theta = 1.0427$. Replace one $+1$ by -1: the mean label becomes $-1/11$, the tilt flips, and the minimizer jumps to -1.0427, a move of 2.0854 (Figure 6.8). With $n = 1{,}001$ (501 against 500) the move is still 2.0010. The minimizer jumps between wells regardless of n.

Adding $\frac{\lambda}{2}\theta^2$ does not fix this unless λ is large enough to make the whole objective convex. With $\lambda = 0.5$ and $\bar{z} = 0$ the derivative is $\theta^3 - \theta + 0.5\theta = \theta(\theta^2 - 0.5)$, so the wells sit at $\pm\sqrt{0.5} = \pm 0.71$, and a tilt still sends the minimizer across a gap of about 1.4. The proof of Equation 6.19 breaks at step 3, where it needs $\mathcal{L}_\lambda(\cdot; D)$ to be strongly convex. Without it, the empirical minimizer can be a discontinuous function of the data, or not unique at all, so no bound on its movement can hold. For non-convex models, statements about the influence of one record must therefore be about the *algorithm* (for example, a fixed number of SGD steps from a fixed start), not about the exact minimizer.

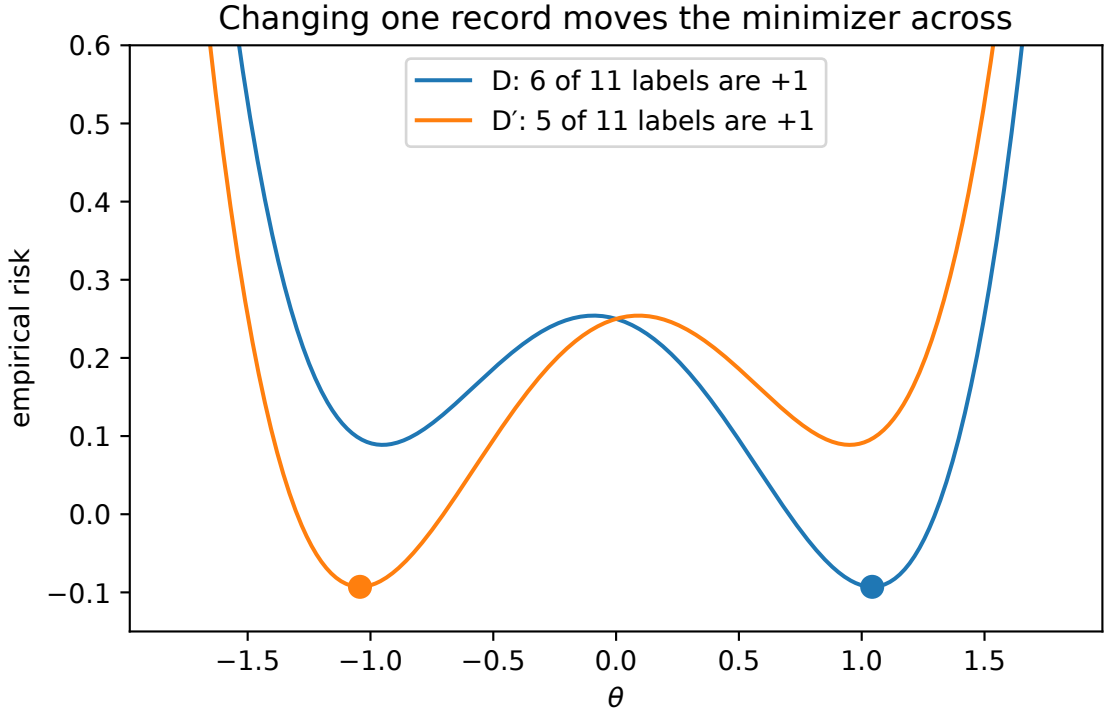

Figure 6.8.: A double-well empirical risk on 11 records before (D, six labels $+1$) and after (D', five labels $+1$) one label changes. The dots mark the global minimizers, which jump from one well to the other.

6.9.8. Check yourself

- In the derivation, where did the factor 2 in $2L$ come from? *(From the gradient of the removed record and that of the added one, each of norm at most L, in step 1.)*
- If the loss is L-Lipschitz but you regularize with $\frac{\lambda}{2}\|\theta - \theta_0\|^2$ for some fixed θ_0, does the bound change? *(No. The regularizer is still λ-strongly convex, and nothing else in the proof involved it.)*

6.10. Code: check every bound by simulation

The script code/optimization.py draws every figure in this chapter and computes every number quoted in it. Each loss, gradient, bound and simulation is a small typed function; the script calls them once for the table and loops them over parameters for the figures. From the repository root:

```
uv run python code/part01-prerequisites/optimization.py
```

Output (seed 0):

Table 6.9.: Summary of the script's output at seed 0.

Experiment	Result
Logistic example $x = (0.6, 0.8)$, $y = +1$	At $\theta = 0$: loss 0.6931, gradient norm 0.5000, curvature 0.2500. At $\theta = (3, 4)$: 0.0067, 0.0067, 0.0066
GD on least squares, $\kappa = 9.58$	122 steps to shrink the error by 10^6; Equation 6.9 predicts at most 126
Minibatch variance at θ^*, $\sigma_1^2 = 0.1722$	Matches Equation 6.15 for $B = 1$ to 500 (Table 6.5)
Projected SGD, convex, $T = 10^4$	7.71×10^{-4} against the bound 0.050 (Table 6.3)
Projected SGD, $\lambda = 0.1$, $T = 10^4$	Uniform average 9.09×10^{-5} (bound 1.15×10^{-2}); weighted 7.85×10^{-5} (bound 4.50×10^{-3}); last iterate 9.61×10^{-5}
Added gradient noise, $T = 10^4$	Best grid step 0.178, 0.056, 0.056 for $\sigma = 0, 1, 3$ (Table 6.6)
Non-convex sigmoid loss, $T = 10^4$	1.87×10^{-4} against the bound 1.55×10^{-3} (Table 6.7)
Regularized ERM, one record replaced	Observed/bound between 0.10 and 0.43 (Table 6.8)
Double well, $n = 11$ and 1,001	Minimizer moves by 2.0854 and 2.0010

tests/test_optimization.py checks that the output still matches Table 6.9 and the tables above.

What to take from it

The bounds hold, with room to spare. Every worst-case constant (R, L, G, Γ, σ^2) is an upper bound that the actual run does not reach, so the guarantees are loose by factors of about 10 to 130. Their *shape*, the way they depend on T, n, λ and σ, is what to trust.

The looseness has a common cause: real problems have more curvature than the assumptions grant. Unregularized logistic regression converged like $1/T$ rather than $1/\sqrt{T}$, and its regularized minimizer moved less than the λ-only bound predicts, both because the data themselves curve the risk.

Noise costs steps, and the right learning rate shrinks as the noise grows, so tune η again whenever the gradient noise changes.

Finally, strong convexity is what makes the minimizer stable. With it, one record moves the solution by $O(1/(\lambda n))$. Without it, even convexity is not enough, as the median shows, and non-convexity lets the minimizer jump between wells.

6.12. Cheat sheet

Table 6.10 collects every result in this chapter.

Table 6.10.: Every result in this chapter.

Result	Assumptions	Bound
Lipschitz	$\|\nabla f\| \le L$	$\|f(\theta) - f(\theta')\| \le L\|\theta - \theta'\|$

Result	Assumptions	Bound
Descent lemma	β-smooth	$f(\theta') \le f(\theta) + \langle \nabla f(\theta), \theta' - \theta \rangle + \frac{\beta}{2}\|\theta' - \theta\|^2$
Strong monotonicity	λ-strongly convex	$\langle \nabla f(\theta) - \nabla f(\theta'), \theta - \theta' \rangle \ge \lambda \|\theta - \theta'\|^2$; $\|\theta - \theta^*\| \le \|\nabla f(\theta)\|/\lambda$
Logistic loss	$\|x\| \le 1$	1-Lipschitz, $\frac{1}{4}$-smooth, convex, not strongly convex
GD, quadratic	$\lambda I \preceq H \preceq \beta I$, $\eta = 1/\beta$	$\|\theta_t - \theta^*\| \le (1 - 1/\kappa)^t \|\theta_0 - \theta^*\|$
SGD, convex	$\mathbb{E}\|g\|^2 \le G^2$, $\|\theta_1 - \theta^*\| \le R$, $\eta = R/(G\sqrt{T})$	$\mathbb{E}\mathcal{L}(\bar{\theta}_T) - \mathcal{L}^* \le RG/\sqrt{T}$
SGD, strongly convex	$\eta_t = 1/(\lambda t)$, uniform average	$G^2(1 + \ln T)/(2\lambda T)$
SGD, strongly convex	$\eta_t = 2/(\lambda(t+1))$, t-weighted average	$2G^2/(\lambda(T+1))$
SGD, non-convex	β-smooth, variance σ^2, $\eta \le 1/\beta$	$\frac{1}{T}\sum_t \mathbb{E}\|\nabla \mathcal{L}(\theta_t)\|^2 \le \frac{2\Gamma}{\eta T} + \beta\eta\sigma^2$
Minibatch variance	B of n, uniform	σ_1^2/B; times $\frac{n-B}{n-1}$ without replacement
Added gradient noise	$\mathbb{E}\|\xi\|^2 = \sigma^2$	$G^2 = L^2 + \sigma^2$; $\eta^* = R/\sqrt{(L^2 + \sigma^2)T}$
ERM sensitivity	Convex L-Lipschitz loss, $\frac{\lambda}{2}\|\theta\|^2$	$\|\theta^*(D) - \theta^*(D')\| \le 2L/(\lambda n)$; loss changes by $\le 2L^2/(\lambda n)$

Rules of thumb

- Lipschitz bounds the gradient; smooth bounds the change of the gradient. Convex Lipschitz SGD needs the first, learning rates and non-convex analysis need the second.
- Without curvature, SGD's error falls like $1/\sqrt{T}$; with λ-strong convexity, like $1/(\lambda T)$. Average the iterates either way.
- Noise multiplies the number of steps by $1 + \sigma^2/L^2$ in the convex bound. Lower the learning rate when the gradients get noisier.
- One record moves a λ-regularized minimizer by at most $2L/(\lambda n)$. Without strong convexity there is no such bound.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

7. Algorithmic stability and generalization

7.1. Why this matters

You train a model and its training loss is low. **Will its loss on new data be low too?** The difference between the loss on new data and the loss on the training data is the **generalization gap**, and controlling it is the central question of learning theory. The classical answer counts hypotheses: it measures how rich the class of models is that the algorithm could output, through the size of a finite class, a Vapnik–Chervonenkis dimension or a Rademacher complexity, and argues that a class that is not too rich cannot fit noise. This chapter takes a different route. It looks at the *algorithm* instead of the class of models it could output.

The organizing idea fits in one sentence: **a model generalizes when it does not depend much on any single training record.** Making it precise gives three results, and each one leads to the next.

The first is that **the gap is exactly an average per-example effect.** Take one training record out, put a fresh one from the same source in its place, retrain, and see how much worse the model now does on the record you took out. Average this over the records. The result is the expected gap, with no inequality involved: overfitting *is* dependence on individual records.

Once the gap is written that way, the second result follows: **a bounded per-example effect gives a bounded gap.** Call γ the largest amount by which replacing one record can move the loss of the trained model, at any test point. Each term of the average is then at most γ, so the expected gap is at most γ. McDiarmid's inequality, which says that a function of many independent inputs that no single input can move by much stays close to its mean, turns this average statement into one that holds with high probability for the one model you trained.

The third result makes this useful: **common algorithms have small γ.** Regularized empirical risk minimization (ERM), which minimizes the training loss plus a penalty $\frac{\lambda}{2}\|\theta\|^2$ on the weights, has $\gamma = 2L^2/(\lambda n)$, where n is the number of records and L bounds how fast the loss can change with the weights. Stochastic gradient descent (SGD) with learning rates η_t has $\gamma \le (2L^2/n)\sum_t \eta_t$, which grows with training time and gives a reason to stop early. Memorizing algorithms such as 1-nearest neighbour have $\gamma = 1$, the largest value for a loss between 0 and 1, and when labels are noisy their gap never closes.

Where each result is used (Table 7.1):

Table 7.1.: Results of this chapter and where they are used.

Result	Typical use
Expected gap = average replace-one effect	Reading overfitting as memorization of individual records

Result	Typical use
$\lvert\mathbb{E}[\text{gap}]\rvert \le \gamma$	Generalization guarantees that need no complexity measure of the model class
High-probability bound (McDiarmid)	A guarantee for the one model you actually trained
Regularized ERM, $\gamma = 2L^2/(\lambda n)$	Choosing λ; bounding how far one record moves a trained model
SGD, $\gamma \le (2L^2/n)\sum_t \eta_t$	Step sizes, number of epochs, early stopping
Unstable algorithms ($\gamma = 1$)	Recognizing models whose training error says nothing about test error
Questions fixed in advance cost $\ln k$; questions chosen after looking can be badly biased	Reusing a validation or test set; sample splitting

Notation. The training set is a dataset $D = (z_1, \dots, z_n)$ of n records drawn from a distribution $\mathcal{D}$, and a training algorithm $\mathcal{T}$ maps it to a model $\mathcal{T}(D)$. Datasets are compared through the replace-one relation: $D^{(i)}$ is D with record i replaced by another, which is how stability is defined in the learning-theory literature. The literature writes the stability parameter β; this book keeps β for a failure probability and writes the stability parameter γ.

Later parts return to how much a trained model depends on a single record, and they reuse the quantities defined here. Every fact this chapter borrows is restated where it is used. The full derivation of McDiarmid's inequality is in Concentration inequalities, and more on the convexity facts behind the ERM bound is in Optimization.

7.2. Toolkit: five facts every derivation uses

Each section below follows the same arc: the question, the statement, a derivation, an interpretation, an example and a self-check. The derivations reuse five facts. The first turns a change in the weights into a change in the loss; the second is the symmetry behind the main identity; the third and fourth say when an optimizer cannot let two nearby weight vectors drift apart; the fifth turns an average statement into a high-probability one.

7.2.1. Fact 1 — Lipschitz losses turn parameter changes into loss changes

A loss is L-**Lipschitz** in the weights when moving the weights by a distance d changes the loss by at most Ld, whatever the record. The constant L is a speed limit: the loss cannot change faster than L per unit of distance in weight space. Written out, if $\theta \mapsto \ell(\theta; z)$ is L-Lipschitz for every record z, then

$$|\ell(\theta; z) - \ell(\theta'; z)| \le L\,\|\theta - \theta'\| \quad \text{for all } z. \tag{7.1}$$

This is how every derivation below finishes. They first bound how far the trained weights move when one record changes, and this fact turns that into a bound on how far the loss moves, at every test point at once. For a differentiable loss, L can be taken as the largest norm of the gradient

$\nabla_\theta \ell(\theta; z)$, because the change along a straight path from θ' to θ is the integral of the gradient along it, and each bit of the path contributes at most (gradient norm) $\times$ (length).

The logistic loss is the example used throughout. For features x and a label $y = \pm 1$, it is $\ell(\theta; (x, y)) = \ln(1 + e^{-y\langle\theta, x\rangle})$, which is small when the **margin** $y\langle\theta, x\rangle$ is large and positive. Its gradient is $-y\,\sigma(-y\langle\theta, x\rangle)\,x$, where $\sigma(t) = 1/(1 + e^{-t})$ is the logistic function, which takes values between 0 and 1. Since $0 < \sigma < 1$ and $|y| = 1$, the gradient norm is at most $\|x\|$. With features scaled to $\|x\| \le 1$, the logistic loss is 1-Lipschitz.

7.2.2. Fact 2 — Swapping two i.i.d. variables does not change their joint law

If U and V are independent and identically distributed (i.i.d.), then nothing in their joint behaviour can tell which one is "first". So the pair (U, V) and the swapped pair (V, U) have the same joint distribution, and as a consequence $\mathbb{E}[f(U, V)] = \mathbb{E}[f(V, U)]$ for every function f.

The reason is the joint density (or probability mass function). Independence makes it the product $p(u)\,p(v)$ of the two individual densities, and identical distribution makes those two the same function p. The product $p(u)\,p(v)$ does not change when u and v are exchanged, so the two pairs have the same law, and expectations computed from that law agree.

This is the "renaming trick" in the expected-gap theorem. The theorem section walks through it with a table of every outcome.

7.2.3. Fact 3 — Strong convexity makes the gradient strongly monotone

A function G is **λ-strongly convex** when it lies above each of its tangent planes by at least a quadratic bowl of curvature λ: for all u and v,

$$G(v) \ge G(u) + \langle \nabla G(u), v - u\rangle + \frac{\lambda}{2}\|v - u\|^2. \tag{7.2}$$

Adding $\frac{\lambda}{2}\|\theta\|^2$ to any convex function produces such a G. The consequence used below is that the gradient changes at least as fast as the point does, in the direction of the change: if you move from v to u, the gradient moves by at least $\lambda\|u - v\|$ along that direction. In symbols,

$$\langle \nabla G(u) - \nabla G(v),\, u - v\rangle \ge \lambda\|u - v\|^2. \tag{7.3}$$

To see why, write the strong convexity inequality as given, and again with u and v exchanged: $G(u) \ge G(v) + \langle \nabla G(v), u - v\rangle + \frac{\lambda}{2}\|u - v\|^2$. Add the two inequalities. The values $G(u)$ and $G(v)$ appear on both sides and cancel, and what is left is $0 \ge -\langle \nabla G(u) - \nabla G(v), u - v\rangle + \lambda\|u - v\|^2$, which rearranges to the claim. The stability of regularized ERM rests on this fact: two different minimizers have gradients that must differ by a lot, so if the gradients differ by little, the minimizers are close.

7.2.4. Fact 4 — For convex smooth functions, a small gradient step is non-expansive

A function f is β_s**-smooth** when its gradient ∇f is β_s-Lipschitz: the gradient changes by at most β_s per unit of distance, so the function curves no more sharply than $\frac{\beta_s}{2}\|\theta\|^2$. For a function that is both convex and smooth, the gradient satisfies a property called **co-coercivity** (Nesterov 2004, Theorem 2.1.5). In words: when two gradients differ by a lot, the two points must be far apart along the direction in which the gradients differ. Precisely,

$$\langle \nabla f(u) - \nabla f(v),\, u - v \rangle \geq \frac{1}{\beta_s} \|\nabla f(u) - \nabla f(v)\|^2. \tag{7.4}$$

The proof needs more than a few lines. It is in Nesterov's book, and Section G.2 in the appendices derives it step by step.

What this chapter uses is a consequence for gradient descent. Take two starting points u and v and apply the same gradient step to both, $\psi(\theta) = \theta - \eta \nabla f(\theta)$. If the learning rate satisfies $0 \leq \eta \leq 2/\beta_s$, the two points do not end up farther apart than they started:

$$\|\psi(u) - \psi(v)\| \leq \|u - v\|. \tag{7.5}$$

The reason is that the step moves both points by an amount that depends on the gradient difference $g = \nabla f(u) - \nabla f(v)$, and co-coercivity says this difference points enough "towards closing the distance". Expand the square of $\psi(u) - \psi(v) = (u - v) - \eta g$, then use co-coercivity to replace $\langle g, u - v \rangle$ by the smaller quantity $\|g\|^2/\beta_s$:

$$\|\psi(u) - \psi(v)\|^2 = \|u - v\|^2 - 2\eta\langle g, u - v\rangle + \eta^2 \|g\|^2 \leq \|u - v\|^2 - \eta\left(\frac{2}{\beta_s} - \eta\right)\|g\|^2 \leq \|u - v\|^2. \tag{7.6}$$

The last step holds because $\eta \leq 2/\beta_s$ makes the subtracted term non-negative.

A one-dimensional case shows why the condition on η is needed. For $f(\theta) = \frac{\beta_s}{2}\theta^2$, the gradient is $\beta_s\theta$, so the step is $\psi(\theta) = \theta - \eta\beta_s\theta = (1 - \eta\beta_s)\theta$, and it multiplies every distance by $|1 - \eta\beta_s|$. It is non-expansive exactly when $|1 - \eta\beta_s| \leq 1$, that is $\eta \leq 2/\beta_s$. Larger steps overshoot the minimum and blow differences up. The stability of SGD rests on this fact.

7.2.5. Fact 5 — McDiarmid's inequality

A function of many independent inputs, none of which can move it by much, concentrates near its mean. If $Z_1, \ldots, Z_n$ are independent and changing only Z_i, with the others held fixed, changes $\Phi(Z_1, \ldots, Z_n)$ by at most c_i, then

$$\Pr[\Phi - \mathbb{E}\Phi \geq t] \leq \exp\Big(-\frac{2t^2}{\sum_i c_i^2}\Big). \tag{7.7}$$

The derivation, via the Doob martingale and Azuma's inequality, is in Concentration inequalities. Its idea is to reveal the inputs one at a time: each revealed input shifts the conditional mean of Φ by at most c_i, and a sum of n such bounded, mean-zero shifts concentrates in the same way as a sum of independent bounded variables does.

To use it you set a failure probability β and solve for the matching t. Setting $\exp(-2t^2/\sum_i c_i^2) = \beta$ and taking logarithms gives $t = \sqrt{\frac{1}{2}\sum_i c_i^2 \ln(1/\beta)}$. So with probability at least $1-\beta$, $\Phi < \mathbb{E}\Phi + \sqrt{\frac{1}{2}\sum_i c_i^2 \ln(1/\beta)}$.

In this chapter γ always denotes a stability parameter, and β the failure probability.

7.3. Risk, empirical risk and the gap

7.3.1. Context

Training minimizes the loss on the data you have. What you care about is the loss on data you will see later. For a model chosen *before* looking at the data, the training loss is an unbiased estimate of the test loss. For a model *fitted* to the data, it is biased downward, because the fitting process picked the model that looks good on exactly these records. The size of that bias is the generalization gap.

7.3.2. Definitions

A training set $D = (z_1, \dots, z_n)$ is a list of n records drawn i.i.d. from a distribution $\mathcal{D}$, the source of all data, past and future. A learning algorithm $\mathcal{T}$ maps D to a model $\mathcal{T}(D)$, and the loss $\ell(\theta; z) \geq 0$ measures how badly model θ does on record z.

The quantity you care about is the average loss on a new record from $\mathcal{D}$. This is the **population risk**, or test loss, $\mathcal{L}_{\mathcal{D}}(\theta) = \mathbb{E}_{z\sim\mathcal{D}}\,\ell(\theta; z)$. You cannot compute it, because you do not know $\mathcal{D}$. What you can compute is the average loss over the training set, the **empirical risk** or training loss, $\mathcal{L}(\theta; D) = \frac{1}{n}\sum_{i=1}^{n} \ell(\theta; z_i)$. The **generalization gap** of the trained model is the test loss minus the training loss, $\mathrm{gap}(D) = \mathcal{L}_{\mathcal{D}}(\mathcal{T}(D)) - \mathcal{L}(\mathcal{T}(D); D)$; it is positive when the model looks better on its training data than it really is.

The tool for studying the gap is a training set that differs from D in one record. The **replace-one neighbour** $D^{(i)} = (z_1, \dots, z_{i-1}, z_i', z_{i+1}, \dots, z_n)$ is the training set with record i replaced by z_i'. In probability statements, $z_1', \dots, z_n'$ are fresh i.i.d. draws from $\mathcal{D}$, independent of D.

7.3.3. Statement

A model that was fixed before the data were drawn has a training loss that is right on average: averaging over training sets, its training loss equals its test loss. For a fixed model θ that does not depend on D,

$$\mathbb{E}_D\big[\mathcal{L}(\theta; D)\big] = \mathcal{L}_{\mathcal{D}}(\theta). \tag{7.8}$$

For $\theta = \mathcal{T}(D)$ this fails in general, and $\mathbb{E}[\mathcal{L}(\mathcal{T}(D); D)]$ is usually smaller than $\mathbb{E}[\mathcal{L}_{\mathcal{D}}(\mathcal{T}(D))]$.

7.3.4. Derivation

1. **Split the average.** The expectation of an average is the average of the expectations (linearity of expectation), so $\mathbb{E}_D[\mathcal{L}(\theta; D)] = \frac{1}{n}\sum_i \mathbb{E}[\ell(\theta; z_i)]$.
2. **Each term is the test loss.** Each z_i is a draw from $\mathcal{D}$ and θ is fixed, so $\mathbb{E}[\ell(\theta; z_i)]$ is the average loss of θ on a draw from $\mathcal{D}$, which is $\mathcal{L}_{\mathcal{D}}(\theta)$ by definition. The average of n copies of $\mathcal{L}_{\mathcal{D}}(\theta)$ is $\mathcal{L}_{\mathcal{D}}(\theta)$.
3. **Why it fails for a trained model.** If $\theta = \mathcal{T}(D)$, step 2 breaks: z_i and $\mathcal{T}(D)$ are dependent, because z_i was used to choose $\mathcal{T}(D)$. The algorithm picked the model that does well on these particular z_i, so z_i is no longer a typical draw from the model's point of view.

7.3.5. Interpretation

The gap is not noise that averages out. It is a systematic bias caused by reusing the same data to choose and to evaluate. Its sign is usually positive: models look better on the data they were fitted to. The rest of this chapter bounds it through one property of the algorithm, without counting the models it could output.

7.3.6. Example: an overfit logistic regression

Take the running example of this chapter. Features x are uniform on the unit sphere in $\mathbb{R}^{10}$. Labels are $y = \pm 1$ with $\Pr[y = 1 \mid x] = \sigma(5x_1)$, so the label tends to follow the sign of the first coordinate but is noisy near $x_1 = 0$. The model is λ-regularized logistic regression, which minimizes the average logistic loss plus $\frac{\lambda}{2}\|\theta\|^2$ (details in Section 7.11). With $n = 50$ and $\lambda = 0.01$, averaged over 100 training sets, the training loss is 0.4603 and the test loss is 0.5781. The expected gap, estimated with the noise-reduction trick described in the regularized-ERM section, is about 0.119, close to the difference of the two averages. With $n = 1000$ it shrinks to about 0.006.

7.3.7. Check yourself

- You evaluate a fixed, pretrained model on a fresh sample. Is the sample loss biased? *(No. The model does not depend on the sample, so step 2 applies.)*
- You pick the best of 100 pretrained models on a validation set. Is the validation loss of the winner biased? *(Yes, downward. The choice depends on the validation data, so the choice is itself a learning algorithm run on that data.)*

7.4. Uniform stability and the expected gap

7.4.1. Context

To control the gap you need to say how much $\mathcal{T}(D)$ depends on the training set. The simplest way to say it: replace one training record, retrain, and see how much the loss of the trained model changes, anywhere.

7.4.2. Definition

An algorithm is stable in this sense when replacing any one training record by any other moves the loss of the trained model by at most γ, at every possible test point. The bound must hold in the worst case: for every training set, every position, every replacement and every test point. Formally, $\mathcal{T}$ is γ-**uniformly stable** if for every training set D, every index i, every replacement z_i' and every test point z,

$$\left|\ell(\mathcal{T}(D); z) - \ell(\mathcal{T}(D^{(i)}); z)\right| \le \gamma. \tag{7.9}$$

If $\mathcal{T}$ is randomized (SGD is, through the order in which it visits records), the condition is on the expectation over $\mathcal{T}$'s internal randomness: $\left|\mathbb{E}_{\mathcal{T}}[\ell(\mathcal{T}(D); z) - \ell(\mathcal{T}(D^{(i)}); z)]\right| \le \gamma$.

Usually γ depends on n, because with more records each one carries less weight, and the interesting question is how fast it goes to zero. Figure 7.1 shows the definition at work on a one-dimensional logistic regression: one record's label is flipped, and the fitted model moves a lot under weak regularization and barely under strong regularization.

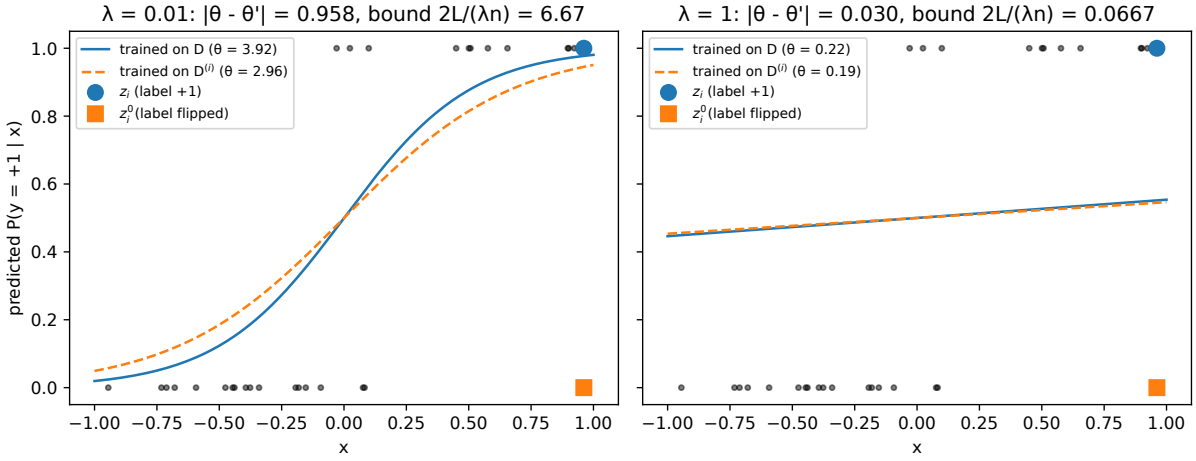

Figure 7.1.: One-dimensional logistic regression trained on 30 points, on D and on $D^{(i)}$, where the most typical positive record is replaced by the same point with its label flipped. Left: $\lambda = 0.01$. Right: $\lambda = 1$. The titles compare the change in the weight with the bound $2L/(\lambda n)$ derived later.

7.4.3. Statement

The test loss of the trained model can be measured on a fresh point z_i'. Swap the roles of z_i and z_i', and the same number becomes the loss on z_i of a model trained *without* z_i. So the expected test loss is the average loss of each record under a model that never saw it, while the training loss is the average loss of each record under a model that did. Their difference is the expected gap. For any algorithm, the expected gap is exactly this average replace-one effect:

$$\mathbb{E}_D[\mathrm{gap}(D)] = \frac{1}{n}\sum_{i=1}^{n} \mathbb{E}_{D,z_i'}\Big[\ell(\mathcal{T}(D^{(i)}); z_i) - \ell(\mathcal{T}(D); z_i)\Big]. \tag{7.10}$$

Each bracket is a replace-one change at a test point, which uniform stability caps at γ. Consequently, if $\mathcal{T}$ is γ-uniformly stable,

$$\left|\mathbb{E}_D[\mathrm{gap}(D)]\right| \le \gamma. \tag{7.11}$$

7.4.4. Derivation (the renaming trick)

1. **Write the test loss with a fresh point.** The test loss $\mathcal{L}_{\mathcal{D}}(\mathcal{T}(D))$ is the loss on a point the model has not seen. The point z_i' is such a point: it is independent of D and has distribution $\mathcal{D}$. So, holding D fixed, its average loss is the test loss, $\mathbb{E}[\ell(\mathcal{T}(D); z_i') \mid D] = \mathcal{L}_{\mathcal{D}}(\mathcal{T}(D))$. Averaging over D as well, $\mathbb{E}[\mathcal{L}_{\mathcal{D}}(\mathcal{T}(D))] = \mathbb{E}[\ell(\mathcal{T}(D); z_i')]$ for every i.
2. **Rename $z_i \leftrightarrow z_i'$.** The two points z_i and z_i' are i.i.d. and independent of the other records. By Fact 2 (swapping two i.i.d. variables leaves their joint distribution unchanged), exchanging them does not change the joint distribution of $(z_1, \ldots, z_n, z_i')$, so it does not change any expectation. The swap turns D into $D^{(i)}$ and z_i' into z_i. Hence
$$\mathbb{E}[\ell(\mathcal{T}(D); z_i')] = \mathbb{E}[\ell(\mathcal{T}(D^{(i)}); z_i)]. \tag{7.12}$$
3. **Average over i.** Steps 1 and 2 hold for every i, so their average does too: $\mathbb{E}[\mathcal{L}_{\mathcal{D}}(\mathcal{T}(D))] = \frac{1}{n}\sum_i \mathbb{E}[\ell(\mathcal{T}(D^{(i)}); z_i)]$.
4. **Training loss.** By definition of the empirical risk, $\mathbb{E}[\mathcal{L}(\mathcal{T}(D); D)] = \frac{1}{n}\sum_i \mathbb{E}[\ell(\mathcal{T}(D); z_i)]$.
5. **Subtract** step 4 from step 3. The two sums run over the same i, so the difference is the average of the differences. This is Equation 7.10.
6. **Bound each term.** By Equation 7.9, applied at the test point $z = z_i$, each difference $\ell(\mathcal{T}(D^{(i)}); z_i) - \ell(\mathcal{T}(D); z_i)$ lies in $[-\gamma, \gamma]$ for every outcome. An average of numbers in $[-\gamma, \gamma]$ also lies there, so the expectation does, and so does the average over i. This is Equation 7.11. For a randomized $\mathcal{T}$, take the expectation over $\mathcal{T}$'s randomness first and use the randomized definition.

Step 2 on a tiny case. Readers often stall on the renaming step, so here it is with every outcome listed. Take $n = 1$: one record $z_1 \in \{0, 1\}$ with $\Pr[z_1 = 1] = p = 0.3$, and a fresh copy z_1'. The algorithm shrinks the data towards zero, $\mathcal{T}(D) = z_1/2$, and the loss is squared error $\ell(\theta; z) = (\theta - z)^2$. So $\mathcal{T}(D^{(1)}) = z_1'/2$. Table 7.2 lists all four outcomes, each with its probability (the product of the two independent probabilities) and the three losses that appear in the derivation.

Table 7.2.: Every outcome of the one-record case. The renamed column is the test column with the rows $(0, 1)$ and $(1, 0)$ exchanged. Those rows have the same probability, so the averages agree.

(z_1, z_1')	Probability	Train $\ell(\mathcal{T}(D); z_1)$	Test $\ell(\mathcal{T}(D); z_1')$	Renamed $\ell(\mathcal{T}(D^{(1)}); z_1)$
$(0, 0)$	$0.7 \times 0.7 = 0.49$	0	0	0
$(0, 1)$	$0.7 \times 0.3 = 0.21$	0	$(0-1)^2 = 1$	$(\frac{1}{2} - 0)^2 = 0.25$
$(1, 0)$	$0.3 \times 0.7 = 0.21$	$(\frac{1}{2} - 1)^2 = 0.25$	$(\frac{1}{2} - 0)^2 = 0.25$	$(0-1)^2 = 1$
$(1, 1)$	$0.3 \times 0.3 = 0.09$	0.25	0.25	0.25
Average		0.075	0.285	0.285

Row by row, the test and renamed columns differ. But the renamed column contains the same values as the test column, attached to the mirror-image outcome, and mirror-image outcomes have the same probability $p(1-p) = 0.21$. That is all step 2 says: averaging over a table does not care how you label its rows.

The averages are probability-weighted sums of each column. Train: $0.21\times0.25+0.09\times0.25 = 0.075$. Test: $0.21\times1+0.21\times0.25+0.09\times0.25 = 0.285$. So the expected gap is $0.285-0.075 = 0.21$. The right side of Equation 7.10 is the renamed average minus the train average, $0.285 - 0.075 = 0.21$ too. The stability of this algorithm is $\gamma = 0.75$: changing z_1 from 0 to 1 moves the model from 0 to $\frac{1}{2}$, and at the test point $z = 1$ the loss drops from $(0-1)^2 = 1$ to $(\frac{1}{2}-1)^2 = 0.25$, a change of 0.75. The gap 0.21 is below $\gamma = 0.75$, as Equation 7.11 requires.

7.4.5. Interpretation

Equation 7.10 is an identity, not a bound. It says the expected gap *is* the average **replace-one self-influence**: how much the loss on z_i goes up when z_i is taken out of the training set and replaced by a fresh point. A model that relies heavily on individual records to fit them overfits, and conversely, a model that overfits must be relying on individual records. The memorization section below measures this quantity directly.

Uniform stability, by contrast, is a worst-case notion. It asks for a bound over all training sets, all replacements and all test points, while the identity only needs the average over i and over the data. This is why the bound γ can be far from the true gap, and why weaker, average-case notions of stability exist (Bousquet & Elisseeff 2002; Shalev-Shwartz et al. 2010).

What makes the bound useful is what it leaves out: no model class appears. The bound holds for any algorithm, however rich the set of models it could output. This is why stability gives guarantees for algorithms such as SGD on large models, where counting the models the algorithm could output gives nothing useful.

7.4.6. Example: a memorizing lookup table

Store the training set; predict the stored label at a training point and $+1$ everywhere else, and score with the **0-1 loss**, which is 1 for a wrong prediction and 0 for a right one. With continuous features, a fresh point almost surely misses the table, so it gets the prediction $+1$. In the running example, where half the labels are -1, that prediction is wrong half the time: the test error is $\frac{1}{2}$ and the training error is 0, for every n. Now replace (x_i, y_i) by a different point. The prediction at x_i falls back to $+1$; if $y_i = -1$, the loss at $z = (x_i, y_i)$ jumps from 0 to 1. So $\gamma = 1$, and the gap $\frac{1}{2} \leq 1$ is consistent with the theorem but never shrinks.

7.4.7. Check yourself

- In step 1, why is z_i' needed at all; why not write the test loss as $\mathbb{E}[\ell(\mathcal{T}(D); z_i)]$? *(Because z_i is part of D, so $\mathcal{T}(D)$ depends on it. Only a point independent of D gives an unbiased estimate of $\mathcal{L}_{\mathcal{D}}(\mathcal{T}(D))$.)*

- In Table 7.2, what would break if z_1 and z_1' had different distributions? *(Rows* $(0,1)$ *and* $(1,0)$ *would have different probabilities, and the test and renamed averages would differ. Step 2 needs the two points to be exchangeable, that is, to have a joint distribution that does not change when they are swapped.)*

7.5. High probability: the Bousquet–Elisseeff bound

7.5.1. Context

Equation 7.11 controls the gap on average over training sets. You train once, on one D, so you need the gap of *your* model to be small with high probability. The gap is a function of n independent records, and stability bounds how much one record can move it. That is exactly the situation of McDiarmid's inequality (Fact 5): a function of independent inputs that no single input can move by much stays close to its mean, with an exponentially small chance of exceeding it.

7.5.2. Statement

The bound has three parts: the training loss you observe, the expected gap γ from the previous section, and a deviation term from McDiarmid that says how far one training set can stray from the average. If $\mathcal{T}$ is γ-uniformly stable and the loss lies between 0 and K, then with probability at least $1-\beta$ over D,

$$\mathcal{L}_{\mathcal{D}}(\mathcal{T}(D)) \le \mathcal{L}(\mathcal{T}(D); D) + \gamma + (2n\gamma + K)\sqrt{\frac{\ln(1/\beta)}{2n}}. \tag{7.13}$$

This is Theorem 12 of Bousquet & Elisseeff (2002), rewritten for replace-one stability. They define stability by *removing* a record instead of replacing it. Replacing can be done by removing z_i and then adding z_i', two removals' worth of change, so replace-one stability is at most twice removal stability (Exercise 1 in the exercise book). Substituting $\gamma = 2\gamma_{\text{remove}}$ in Equation 7.13 gives their $2\gamma_{\text{remove}} + (4n\gamma_{\text{remove}} + K)\sqrt{\ln(1/\beta)/(2n)}$.

7.5.3. Derivation

The plan is to bound how much one record can move the gap, feed that to McDiarmid, and then use the expected-gap bound for the mean. Let $\Phi(D) = \mathcal{L}_{\mathcal{D}}(\mathcal{T}(D)) - \mathcal{L}(\mathcal{T}(D); D)$ be the gap as a function of the training set.

1. **Effect of one record on the test loss.** Replacing z_i moves $\ell(\mathcal{T}(D); z)$ by at most γ at every z, by uniform stability. The test loss is an average of these losses over z, and an average of numbers that each move by at most γ moves by at most γ: $|\mathcal{L}_{\mathcal{D}}(\mathcal{T}(D)) - \mathcal{L}_{\mathcal{D}}(\mathcal{T}(D^{(i)}))| \le \gamma$.
2. **Effect on the training loss.** $\mathcal{L}(\mathcal{T}(D); D)$ and $\mathcal{L}(\mathcal{T}(D^{(i)}); D^{(i)})$ share $n-1$ terms, one for each record other than i. Each shared term $\frac{1}{n}\ell(\cdot; z_j)$ is evaluated at the same point z_j under two models, so by stability it moves by at most γ/n. The unshared terms are $\frac{1}{n}\ell(\mathcal{T}(D); z_i)$ and $\frac{1}{n}\ell(\mathcal{T}(D^{(i)}); z_i')$, evaluated at two different points, so stability says nothing about them; but both lie in $[0, K/n]$, so they differ by at most K/n. Total: at most $\frac{n-1}{n}\gamma + \frac{M}{n} \le \gamma + \frac{M}{n}$.

3. **Bounded differences.** Φ is the test loss minus the training loss, and by the triangle inequality ($|a-b| \le |a| + |b|$) its change is at most the sum of the two changes: replacing z_i moves Φ by at most $c_i = 2\gamma + K/n$. Uniform stability holds for every training set and every replacement, so this holds for all values of the inputs, as McDiarmid requires.
4. **McDiarmid** (Fact 5). All n constants are equal, so $\sum_i c_i^2 = n(2\gamma + K/n)^2$. Its square root is $\sqrt{n}(2\gamma + K/n)$, and $\sqrt{n}(2\gamma + K/n)/\sqrt{2} = (2n\gamma + K)/\sqrt{2n}$ after multiplying inside and out by $\sqrt{n}$. So with probability at least $1-\beta$,

$$\Phi < \mathbb{E}\Phi + \sqrt{n}\Big(2\gamma + \frac{M}{n}\Big)\sqrt{\frac{\ln(1/\beta)}{2}} = \mathbb{E}\Phi + (2n\gamma + K)\sqrt{\frac{\ln(1/\beta)}{2n}}. \tag{7.14}$$

5. **Expected gap.** $\mathbb{E}\Phi \le \gamma$ by Equation 7.11. Substitute, and move the training loss to the right-hand side.

Applying the same argument to $-\Phi$ gives the matching lower bound, so the gap is controlled from both sides.

7.5.4. Interpretation: γ must be $o(1/\sqrt{n})$

The width of the bound beyond γ has two parts, and they behave differently. The part $K\sqrt{\ln(1/\beta)/(2n)}$ is what Hoeffding's inequality gives for one fixed model: the average of n independent losses in $[0, K]$ exceeds its mean by more than this with probability at most β (Concentration inequalities). It is a rate you cannot avoid even without any learning. The extra part comes from stability, $2n\gamma\sqrt{\ln(1/\beta)/(2n)} = \gamma\sqrt{2n\ln(1/\beta)}$, and it goes to zero only if $\gamma\sqrt{n} \to 0$, which is what $\gamma = o(1/\sqrt{n})$ means. Figure 7.2 shows three regimes, and the rate in each follows from putting the given γ into $\gamma\sqrt{2n\ln(1/\beta)}$:

- $\gamma \sim 1/n$ (regularized ERM): $\gamma\sqrt{n} \sim 1/\sqrt{n}$, so the width falls like $1/\sqrt{n}$, a constant factor above the fixed-model rate.
- $\gamma \sim n^{-3/4}$: $\gamma\sqrt{n} \sim n^{-3/4+1/2}$, so it still falls, but more slowly, like $n^{-1/4}$.
- $\gamma \sim 1/\sqrt{n}$: $\gamma\sqrt{n}$ is a constant, so it does not fall at all. The bound is vacuous, even though Equation 7.11 still says the *expected* gap is at most $1/\sqrt{n}$.

The loss in step 3 comes from charging every one of the n records the full 2γ in McDiarmid, even though the effects of different records largely average out. Later work removed most of this loss. Feldman & Vondrák (2018) proved a bound of order $\sqrt{(\gamma + 1/n)\ln(1/\beta)}$, which is meaningful whenever $\gamma = o(1)$, that is whenever γ goes to zero at any rate. Feldman & Vondrák (2019) and then Bousquet, Klochkov & Zhivotovskiy (2020) reached, for $K = 1$ and up to constant factors (which is what $\lesssim$ means),

$$\text{gap} \lesssim \gamma \ln n \, \ln(1/\beta) + \sqrt{\frac{\ln(1/\beta)}{n}}, \tag{7.15}$$

which is within log factors of the expected-gap bound plus the fixed-model rate. With these, $\gamma \sim 1/\sqrt{n}$ also gives a $\tilde{O}(1/\sqrt{n})$ gap, where $\tilde{O}$ means "of this order up to log factors".

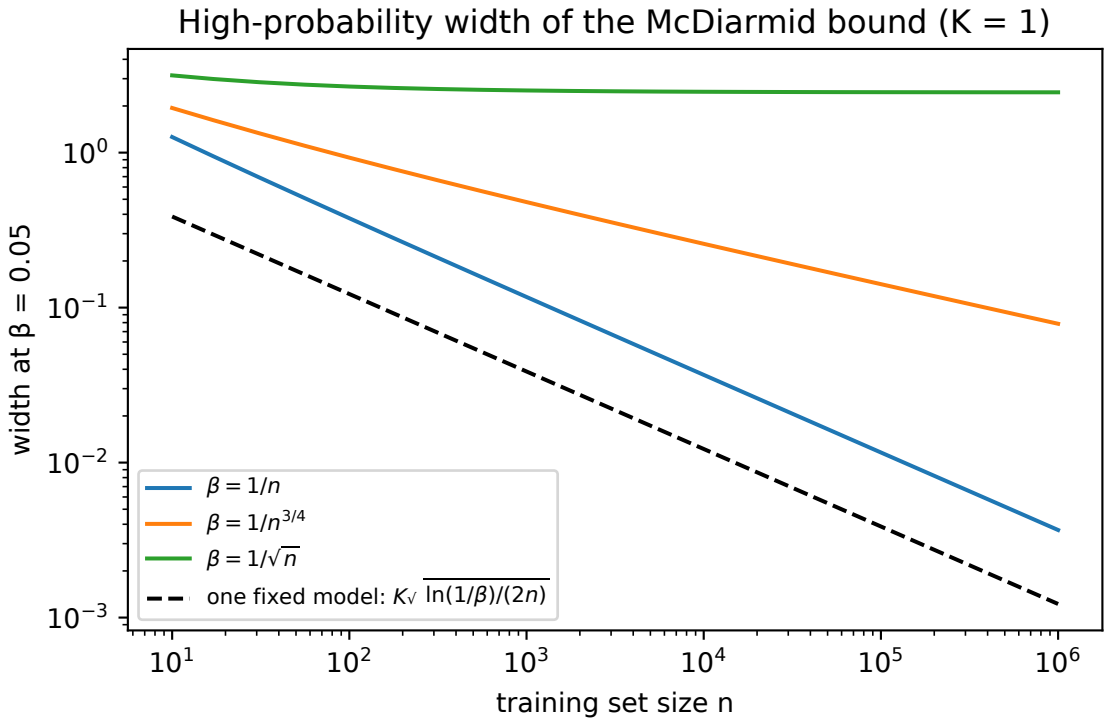

Figure 7.2.: Width of the high-probability bound, Equation 7.13, with $K = 1$ and $\beta = 0.05$, for stability $\gamma = 1/n$, $n^{-3/4}$ and $n^{-1/2}$, against the Hoeffding width for a single fixed model.

7.5.5. Example: regularized logistic regression

The next section shows that regularized logistic regression with $\|x\| \le 1$ has $\gamma = 2/(\lambda n)$ and weights of norm at most $1/\lambda$. To use Equation 7.13 you also need K, the largest loss. Its margin $y\langle\theta, x\rangle$ is at least $-\|\theta\|\|x\| \ge -1/\lambda$, and the logistic loss is largest at the most negative margin, so every loss is at most $K = \ln(1 + e^{1/\lambda})$. Take $n = 10{,}000$ and $\beta = 0.05$, so that $\ln(1/\beta) = \ln 20$ and the common factor is $\sqrt{\ln 20/20{,}000} = 0.01224$. Then the width beyond the training loss is $\gamma + (2n\gamma + K) \times 0.01224$, where $2n\gamma = 4/\lambda$:

- $\lambda = 1$: $\gamma = 2 \times 10^{-4}$, $K = \ln(1+e) = 1.313$, width $2 \times 10^{-4} + (4 + 1.313) \times 0.01224 = 0.065$.
- $\lambda = 0.1$: $\gamma = 0.002$, $K = \ln(1 + e^{10}) = 10.000$, width $0.002 + (40 + 10) \times 0.01224 = 0.614$.

In both cases the stability term $2n\gamma$ is three quarters or more of the width (4 against $K = 1.313$, and 40 against $K = 10.000$). The expected gap itself is far smaller: at $\lambda = 1$ it is already 2.53×10^{-4} at $n = 1{,}000$ (Table 7.4), and it falls like $1/n$. The high-probability bound is valid but loose, mostly because McDiarmid charges every record the worst case 2γ.

7.5.6. Check yourself

- Why does step 2 pay K/n for the replaced record, not γ/n? *(The replaced term is evaluated at two different points, z_i and z_i'. Stability compares two models at the same point, so it does not apply.)*
- If $\gamma = 0$ (a constant algorithm), what does Equation 7.13 reduce to? *(Hoeffding for a single fixed model: $\mathcal{L}_{\mathcal{D}}(\mathcal{T}(D)) \le \mathcal{L}(\mathcal{T}(D); D) + K\sqrt{\ln(1/\beta)/(2n)}$.)*

7.6. Regularized ERM is stable

7.6.1. Context

Regularized ERM is the workhorse of classical machine learning: ridge regression, regularized logistic regression, support vector machines. The regularizer is usually justified as a prior or as a way to control model complexity. Stability gives a third reading: it limits how far one record can pull the solution. The penalty $\frac{\lambda}{2}\|\theta\|^2$ makes the objective a bowl with curvature at least λ, and one record, which carries weight $1/n$ in the objective, can only tilt such a bowl so far.

7.6.2. Statement

The setting is a convex loss whose gradient never exceeds L in norm. Let $\ell(\cdot; z)$ be convex, differentiable and L-Lipschitz for every z, and let θ_D be the minimizer of the regularized training loss $\mathcal{L}_\lambda(\cdot; D)$:

$$\theta_D = \arg\min_\theta \ \mathcal{L}_\lambda(\theta; D), \qquad \mathcal{L}_\lambda(\theta; D) = \frac{1}{n}\sum_{i=1}^{n} \ell(\theta; z_i) + \frac{\lambda}{2}\|\theta\|^2. \tag{7.16}$$

Replacing one record changes $\mathcal{L}_\lambda(\cdot; D)$ by a term of size about L/n in gradient, and the curvature λ converts that into a weight change of order $L/(\lambda n)$; Fact 1 then multiplies by L to get the loss change. Precisely,

$$\|\theta_D - \theta_{D^{(i)}}\| \le \frac{2L}{\lambda n} \quad \text{and} \quad \left|\ell(\theta_D; z) - \ell(\theta_{D^{(i)}}; z)\right| \le \frac{2L^2}{\lambda n} \text{ for all } z. \tag{7.17}$$

The first bound is the sensitivity of ERM, that is how far the minimizer can move when one record changes, which Optimization also derives. The second is uniform stability with $\gamma = 2L^2/(\lambda n)$ (Shalev-Shwartz & Ben-David 2014, Corollary 13.6; Bousquet & Elisseeff 2002).

7.6.3. Derivation

Write $\theta = \theta_D$, $\theta' = \theta_{D^{(i)}}$, $G = \mathcal{L}_\lambda(\cdot; D)$, $G' = \mathcal{L}_\lambda(\cdot; D^{(i)})$. The idea is to look at the gradient of G at the *other* minimizer θ': it is small, because G and G' differ in only one term, and strong convexity says a small gradient means you are close to the minimizer.

1. **Optimality.** The gradient of a differentiable convex function is zero at its minimizer: $\nabla G(\theta) = 0$ and $\nabla G'(\theta') = 0$.
2. **The two objectives differ in one term.** Only the i-th loss differs, so $G - G' = \frac{1}{n}(\ell(\cdot; z_i) - \ell(\cdot; z_i'))$. Since $\nabla G'(\theta') = 0$, subtracting it changes nothing, and $\nabla G(\theta') = \nabla G(\theta') - \nabla G'(\theta') = \frac{1}{n}(\nabla \ell(\theta'; z_i) - \nabla \ell(\theta'; z_i'))$. Each gradient has norm at most L (Fact 1), so this has norm at most $2L/n$.
3. **Strong convexity.** G is a convex function plus $\frac{\lambda}{2}\|\theta\|^2$, so it is λ-strongly convex. Fact 3 says its gradient changes by at least $\lambda\|\theta' - \theta\|$ along the direction from θ to θ'. With $\nabla G(\theta) = 0$ from step 1,

$$\lambda\|\theta' - \theta\|^2 \le \langle \nabla G(\theta') - \nabla G(\theta),\, \theta' - \theta\rangle = \langle \nabla G(\theta'),\, \theta' - \theta\rangle \le \frac{2L}{n}\|\theta' - \theta\|, \tag{7.18}$$

   where the last step is the Cauchy–Schwarz inequality, $\langle a, b\rangle \le \|a\|\,\|b\|$, with the norm from step 2. Divide by $\lambda\|\theta' - \theta\|$ to get $\|\theta' - \theta\| \le 2L/(\lambda n)$.
4. **From weights to losses.** By Fact 1, a weight change of at most $2L/(\lambda n)$ changes every loss by at most L times that, $2L^2/(\lambda n)$.

A by-product is used elsewhere in this chapter. Setting the gradient of $\mathcal{L}_\lambda(\cdot; D)$ to zero gives $\lambda\theta_D = -\frac{1}{n}\sum_i \nabla \ell(\theta_D; z_i)$. The right side is an average of vectors of norm at most L, so its norm is at most L, and $\|\theta_D\| \le L/\lambda$.

7.6.4. Interpretation

Since $\gamma = 2L^2/(\lambda n)$ falls like $1/n$, which is $o(1/\sqrt{n})$, both the expected-gap and the high-probability bounds go to zero as the training set grows.

Regularization buys stability linearly: doubling λ halves γ. It is not free, though. A larger λ also pulls the solution towards zero and away from the best fit, so the test loss as a function of λ is U-shaped (Figure 7.4, right): too little regularization overfits, too much underfits.

The bound is loose in three places, one per derivation step. Step 2 assumes the two gradients point in opposite directions with full norm L. Step 3 uses only the curvature λ of the regularizer

and ignores the curvature of the data term, which also resists movement. Step 4 assumes the worst test point. In the experiment below, steps 2 and 4 each cost about a factor of 2, and step 3 costs more when λ is small and the data curvature matters.

7.6.5. Example: replace-one change in logistic regression

The running example uses unit-norm features, so $L = 1$ by Fact 1 and $\gamma = 2/(\lambda n)$. The script fits the model on D, then on $D^{(i)}$ for 10 random i, where z_i is replaced by the same point with its label flipped. It records the largest weight change and the largest loss change. To find the test point where the loss changes most, it checks 2,000 random test points and the four points $\pm(\theta' - \theta)/\|\theta' - \theta\|$ with either label, which lie in the direction the weights moved, where the loss change is largest.

Table 7.3.: Replace-one changes of regularized logistic regression against the bounds in Equation 7.17. Ratio is the largest loss change divided by the loss bound.

n	λ	Weight bound $2L/(\lambda n)$	Largest weight change	Loss bound $2L^2/(\lambda n)$	Largest loss change	Ratio
100	0.01	2.0	0.406	2.0	0.340	0.17
100	0.1	0.2	0.0824	0.2	0.0474	0.24
100	1	0.02	0.00976	0.02	0.00505	0.25
1,000	0.1	0.02	0.00809	0.02	0.00499	0.25
10,000	0.01	0.02	0.00336	0.02	0.00285	0.14
10,000	1	2×10^{-4}	9.76×10^{-5}	2×10^{-4}	5.00×10^{-5}	0.25

Table 7.3 and Figure 7.3 show the $1/(\lambda n)$ scaling closely where the penalty dominates the curvature, that is for $\lambda \geq 0.1$: the rows with $n = 100, \lambda = 1$ and $n = 1{,}000, \lambda = 0.1$ share $\lambda n = 100$ and have nearly the same loss change (0.00505 and 0.00499). The third row with $\lambda n = 100$, at $n = 10{,}000$ and $\lambda = 0.01$, moves less (0.00336 in the weights, against 0.00976 and 0.00809), because there the data's own curvature adds to λ, as explained below. For $\lambda = 1$ the ratio is 0.25, and both factors of 2 can be read off.

The first factor of 2 comes from step 2. With margin $m = y\langle\theta, x\rangle$, the gradient for label y is $-y\,\sigma(-m)x$, and for the flipped label $-y$ the margin becomes $-m$ and the gradient is $y\,\sigma(m)x$. Their difference is $-y\,\sigma(-m)x - y\,\sigma(m)x = -yx$, because $\sigma(-m) + \sigma(m) = 1$. Its norm is $\|x\| = 1$, not the worst case $2L = 2$. So the weights move by about $1/(\lambda n)$, half the bound: 0.00976 against 0.02.

The second factor of 2 comes from step 4. With $\lambda = 1$ the weights are small, so test margins are near zero. There the slope of the logistic loss is $\sigma(0) = \frac{1}{2}$, not $L = 1$, so the loss moves by about half the weight change: 0.00505 against 0.00976.

For $\lambda = 0.01$ the ratio drops to about 0.15 (0.17 and 0.14 in the table): with weak regularization the data term adds curvature beyond λ, which step 3 ignored.

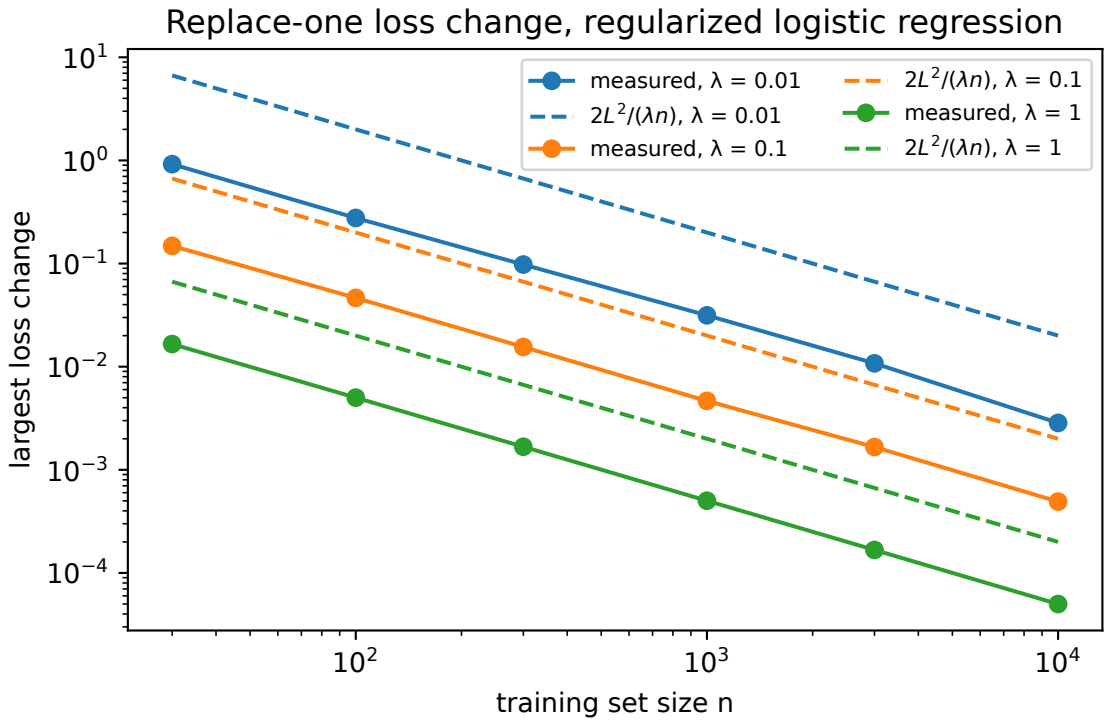

Figure 7.3.: Largest replace-one loss change of regularized logistic regression as a function of n, for three values of λ (solid), against the bound $2L^2/(\lambda n)$ (dashed). Both fall like $1/n$.

7.6.6. Example: the generalization gap against the bound

Equation 7.11 bounds the expected gap by the same γ, here $2/(\lambda n)$. The script averages the gap over 100 training sets for each (n, λ). It computes the test loss exactly by numerical integration. To cancel most of the noise from the random training sets, it also subtracts, on the same training set, the gap of a fixed reference model. A fixed model's training loss is an unbiased estimate of its test loss (the first section of this chapter), so that gap has mean exactly zero and subtracting it leaves the expected value unchanged; but it rises and falls with the same lucky or unlucky training sets, so the subtraction removes much of the variation.

Table 7.4.: Expected generalization gap of regularized logistic regression, averaged over 100 training sets, against the stability bound.

λ	n	Train loss	Test loss	Expected gap	Bound $2/(\lambda n)$	Gap / bound
0.01	50	0.4603	0.5781	0.119	4.0	0.030
0.01	1,000	0.5311	0.5381	0.00596	0.2	0.030
0.1	50	0.6073	0.6401	0.0319	0.4	0.080
0.1	200	0.6288	0.6373	0.00830	0.1	0.083
0.1	1,000	0.6346	0.6365	0.00178	0.02	0.089
1	50	0.6806	0.6854	0.00459	0.04	0.115
1	1,000	0.6852	0.6855	0.000253	0.002	0.127

The gap falls like $1/n$, as the bound predicts, and stays a fixed fraction of it for each λ: about 3% for $\lambda = 0.01$ and 11% to 13% for $\lambda = 1$ (Table 7.4). Part of the slack is the factor of about 4 already seen in Table 7.3, where the ratio was 0.25. The rest comes from averaging: the gap averages over test points and replacements, while the bound takes the worst of both.

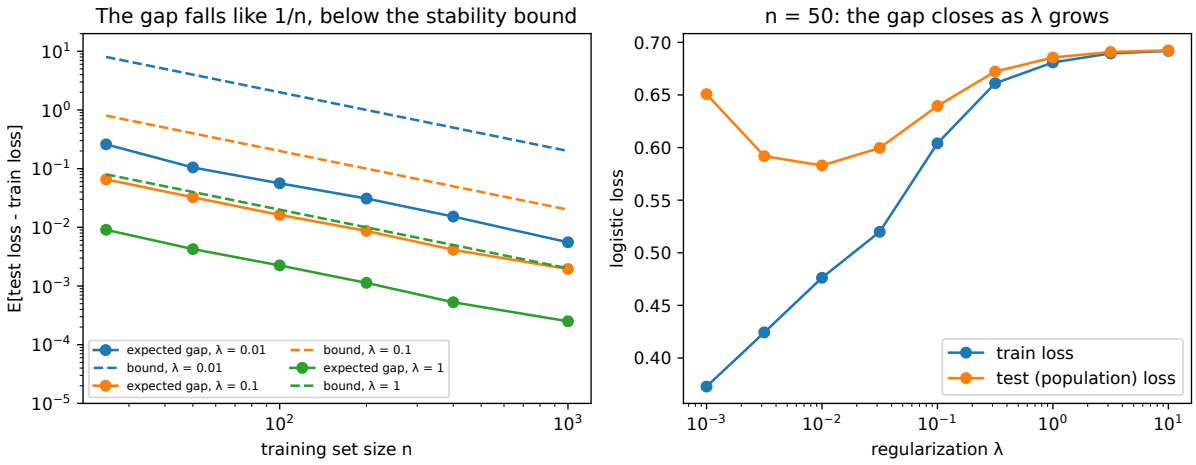

Figure 7.4.: Left: expected generalization gap of regularized logistic regression against n (solid), with the stability bound $2/(\lambda n)$ (dashed). Right: train and test loss against λ at $n = 50$. Stronger regularization closes the gap, but too much of it raises the test loss.

7.6.7. Check yourself

- Where does the derivation use convexity of ℓ, and where Lipschitzness? *(Convexity makes $\mathcal{L}_\lambda(\cdot; D)$ λ-strongly convex in step 3. Lipschitzness bounds the gradients in step 2 and turns weights into losses in step 4.)*
- Squared loss on bounded data is not globally Lipschitz. How can you still apply the result to ridge regression? *(Use $\|\theta_D\| \le$ a bound derived from optimality, as in the by-product, and the Lipschitz constant of the squared loss on that bounded set.)*

7.7. SGD is stable if you stop early

7.7.1. Context

Large models are not trained to an exact minimizer. They are trained by SGD for some number of steps: at each step, pick one training record at random and move the weights a little against the gradient of its loss. Hardt, Recht & Singer (2016) showed that SGD itself is stable, with a γ that grows with the total learning rate. This turns "train for fewer epochs" into a generalization guarantee.

7.7.2. Statement

The idea is that two SGD runs, one on D and one on $D^{(i)}$, can only drift apart on the steps that happen to pick record i. Each such step pushes them apart by at most $2\eta_t L$, and it happens with probability $1/n$; every other step, by Fact 4, does not push them apart. So the expected distance grows by at most $2\eta_t L/n$ per step.

The assumptions are those of Fact 4 plus a gradient bound. Let $\ell(\cdot; z)$ be convex, β_s-smooth (gradient changes by at most β_s per unit distance) and L-Lipschitz (gradient norm at most L) for every z. Run SGD for T steps from a starting point θ_0: step $t = 1, \dots, T$ updates $\theta_t = \theta_{t-1} - \eta_t \nabla \ell(\theta_{t-1}; z_{I_t})$, and the output is θ_T. Each index I_t is drawn uniformly from $\{1, \dots, n\}$ and $\eta_t \le 2/\beta_s$. Then SGD is uniformly stable (in expectation over the indices) with

$$\gamma \le \frac{2L^2}{n} \sum_{t=1}^{T} \eta_t. \tag{7.19}$$

This is Theorem 3.8 of Hardt, Recht & Singer (2016), who write β for the smoothness and $\varepsilon_{\text{stab}}$ for the stability.

7.7.3. Derivation

Run SGD on D and on $D^{(i)}$ with the **same** index sequence $I_1, I_2, \dots$ and the same starting point. This pairing, called a **coupling**, is legitimate because the stability condition for a randomized algorithm compares the *average* loss of each run, and each run's average depends only on its own distribution. Using the same random indices for both runs does not change either run's distribution, and it makes the two runs as similar as possible. Let $r_t = \|\theta_t - \theta'_t\|$ be the distance

between the two runs after t steps, with $r_0 = 0$ because both start at θ_0. Step t uses the index I_t and the learning rate η_t and turns r_{t-1} into r_t.

1. **Same record picked** ($I_t \neq i$, probability $1 - 1/n$). Both runs take a gradient step on the same function $\ell(\cdot; z_{I_t})$. By Fact 4 (a gradient step with $\eta_t \leq 2/\beta_s$ on a convex smooth function does not increase distances), $r_t \leq r_{t-1}$.
2. **Differing record picked** ($I_t = i$, probability $1/n$). One run steps on z_i, the other on z_i', so Fact 4 does not apply. Instead, write $\theta_t - \theta_t' = (\theta_{t-1} - \theta_{t-1}') - \eta_t \nabla \ell(\theta_{t-1}; z_i) + \eta_t \nabla \ell(\theta_{t-1}'; z_i')$ and use the triangle inequality on the three terms: $r_t \leq \|\theta_{t-1} - \theta_{t-1}'\| + \eta_t \|\nabla \ell(\theta_{t-1}; z_i)\| + \eta_t \|\nabla \ell(\theta_{t-1}'; z_i')\| \leq r_{t-1} + 2\eta_t L$, since each gradient has norm at most L.
3. **Take expectations** over I_t. The index I_t is drawn fresh at step t, so it is independent of r_{t-1}, which depends only on earlier indices. Weighting the two cases by their probabilities, $\mathbb{E} r_t \leq (1 - \frac{1}{n}) \mathbb{E} r_{t-1} + \frac{1}{n}(\mathbb{E} r_{t-1} + 2\eta_t L) = \mathbb{E} r_{t-1} + \frac{2\eta_t L}{n}$.
4. **Unroll.** Starting from $r_0 = 0$ and adding the increments of steps $t = 1, \ldots, T$, $\mathbb{E} r_T \leq \frac{2L}{n} \sum_{t=1}^{T} \eta_t$.
5. **From weights to losses.** By Fact 1, at every test point z the loss difference is at most $L r_T$, so its expectation is at most $L\, \mathbb{E} r_T$: $\left|\mathbb{E}[\ell(\theta_T; z) - \ell(\theta_T'; z)]\right| \leq L\, \mathbb{E} r_T$. Multiplying the bound of step 4 by L gives Equation 7.19.

7.7.4. Interpretation

The derivation says that the two runs only drift apart when the differing record is used. Figure 7.5 shows this as a staircase: each single run jumps when index i is drawn and otherwise does not grow. Since i is drawn with probability $1/n$ and an epoch is n steps, a jump happens on average once per epoch.

As a result, stability degrades linearly with training time. With a constant step η and E epochs, so $T = En$ steps, the sum of the learning rates is $\eta E n$, and Equation 7.19 gives $\gamma \leq (2L^2/n)\eta E n = 2L^2 \eta E$. The n cancels: for a fixed number of epochs the bound does not improve with more data. One pass ($E = 1$) gives $\gamma \leq 2L^2\eta$.

This makes early stopping a trade-off. Training longer lowers the optimization error but raises γ, and the excess test loss pays for both. To see the balance, split the excess test loss of the SGD output $\bar{\theta}$ over the best weights θ^* into three pieces: $\mathcal{L}_{\mathcal{D}}(\bar{\theta}) - \mathcal{L}_{\mathcal{D}}(\theta^*) = [\mathcal{L}_{\mathcal{D}}(\bar{\theta}) - \mathcal{L}(\bar{\theta}; D)] + [\mathcal{L}(\bar{\theta}; D) - \mathcal{L}(\theta^*; D)] + [\mathcal{L}(\theta^*; D) - \mathcal{L}_{\mathcal{D}}(\theta^*)]$. The first piece is the gap, at most γ on average. The second is the optimization error. The third has mean zero, because θ^* is a fixed model. For convex L-Lipschitz losses, SGD with constant step η reaches an optimization error of at most $\frac{\|\theta^*\|^2}{2\eta T} + \frac{\eta L^2}{2}$ for the averaged iterate (see Optimization; Shalev-Shwartz & Ben-David 2014, ch. 14). The first term falls with training time and the gap bound $2L^2\eta T/n$ rises with it. With $u = \eta T$, the sum to balance is $\frac{\|\theta^*\|^2}{2u} + \frac{2L^2 u}{n}$. Setting its derivative $-\frac{\|\theta^*\|^2}{2u^2} + \frac{2L^2}{n}$ to zero gives $u^* = \frac{\|\theta^*\|\sqrt{n}}{2L}$, and at that value both terms equal $\frac{L\|\theta^*\|}{\sqrt{n}}$, so the excess test loss is at most $\frac{2L\|\theta^*\|}{\sqrt{n}}$, plus the $\eta L^2/2$ term. Training much longer than u^* buys optimization accuracy that the growing stability term gives back.

The bound is loose because step 1 only uses that a step does not expand distances. In practice a gradient step on a curved loss often contracts them, so the true divergence saturates instead of growing linearly (Figure 7.5).

7.7.5. Example: unregularized logistic regression with SGD

Take $n = 100$ records of the running example and a constant step $\eta = 0.25$. To apply the theorem you need the smoothness β_s. Along the margin m, the logistic loss $\ln(1 + e^{-m})$ has second derivative $\sigma(m)\sigma(-m) = \sigma(m)(1 - \sigma(m))$, a product of two numbers that sum to 1, which is at most $\frac{1}{2} \cdot \frac{1}{2} = \frac{1}{4}$. With $\|x\| \le 1$ the curvature in weight space is no larger, so the loss is $\frac{1}{4}$-smooth, $\beta_s = \frac{1}{4}$, and the condition $\eta \le 2/\beta_s = 8$ holds. The script averages over 100 coupled pairs of runs, with z_1 replaced by a fresh draw. With $L = 1$ and $\eta = 0.25$, the loss bound $2L^2\eta E$ and the distance bound $2L\eta E$ are both $0.5E$:

Table 7.5.: SGD on unregularized logistic regression, $n = 100$, $\eta = 0.25$, averaged over 100 runs. With $L = 1$ the two bounds coincide.

Epochs	Train loss	Test loss	Gap	Bound $2L^2\eta E$	Mean $\|\theta_T - \theta'_T\|$	Bound $2L\eta E$
1	0.559	0.596	0.036	0.5	0.130	0.5
2	0.515	0.567	0.052	1.0	0.189	1.0
5	0.478	0.557	0.079	2.5	0.277	2.5
10	0.470	0.567	0.097	5.0	0.363	5.0
20	0.467	0.582	0.115	10.0	0.355	10.0
40	0.467	0.588	0.121	20.0	0.395	20.0

The qualitative prediction holds (Table 7.5, Figure 7.6): the gap grows with the number of epochs, and the test loss is lowest after about 5 epochs and rises afterwards, while the training loss keeps falling. Quantitatively the bound is loose, by a factor of 14 after one epoch (0.5/0.036) and of 165 after 40 (20.0/0.121), because the divergence saturates near 0.4 instead of growing linearly.

7.7.6. Check yourself

- Why must both runs use the same index sequence? *(Otherwise they would step on different records at almost every step, and step 1 could not use non-expansiveness. The bound concerns the distribution of each run, so you may couple them as you like.)*
- What breaks for non-convex losses? *(Fact 4: a gradient step on a non-convex function can expand distances, by up to a factor $1 + \eta_t\beta_s$. Hardt, Recht & Singer still get a bound, but it grows polynomially in T rather than linearly in $\sum_t \eta_t$.)*

7.8. An unstable algorithm: 1-nearest neighbour

7.8.1. Context

Stability is sufficient for generalization, in the sense of a vanishing gap. Seeing an algorithm without it makes clear what it rules out. The nearest neighbour (NN) rule with one neighbour, 1-NN, predicts the label of the closest training point. It fits every training record perfectly, using that record itself, which is exactly the dependence on single records that stability forbids.

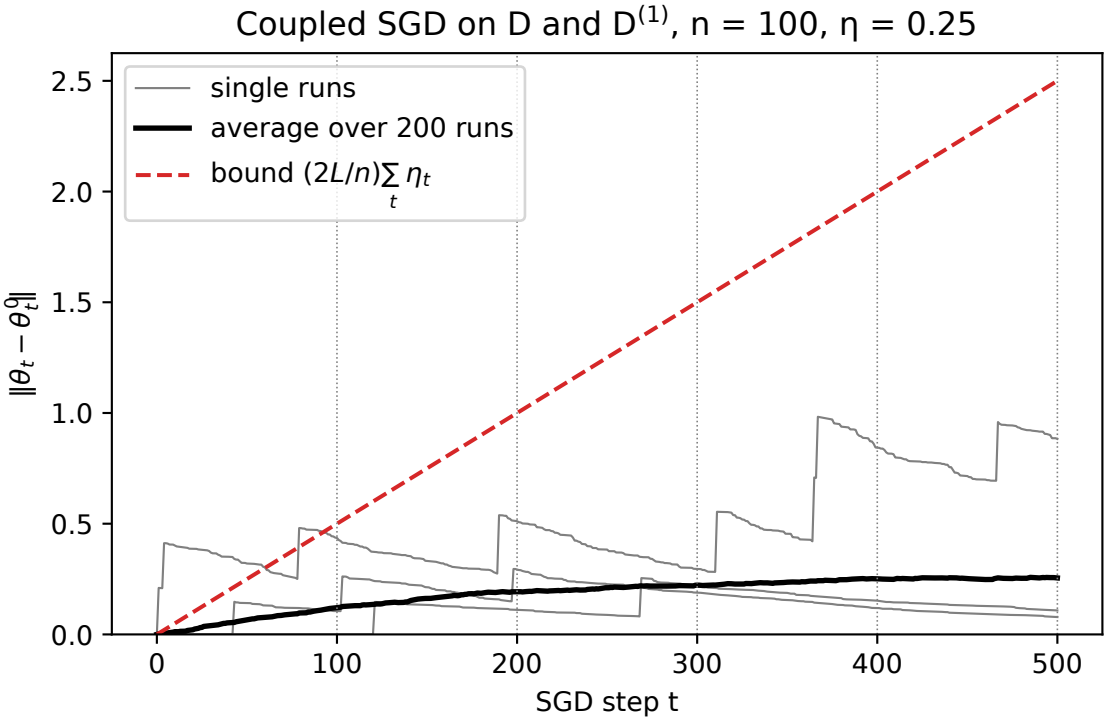

Figure 7.5.: Distance between coupled SGD runs on D and $D^{(1)}$ ($n = 100$, $\eta = 0.25$), for three single runs and the average over 200 runs, against the bound $(2L/n)\sum_t \eta_t$. Single runs jump when record 1 is drawn and contract otherwise. Dotted lines mark epochs.

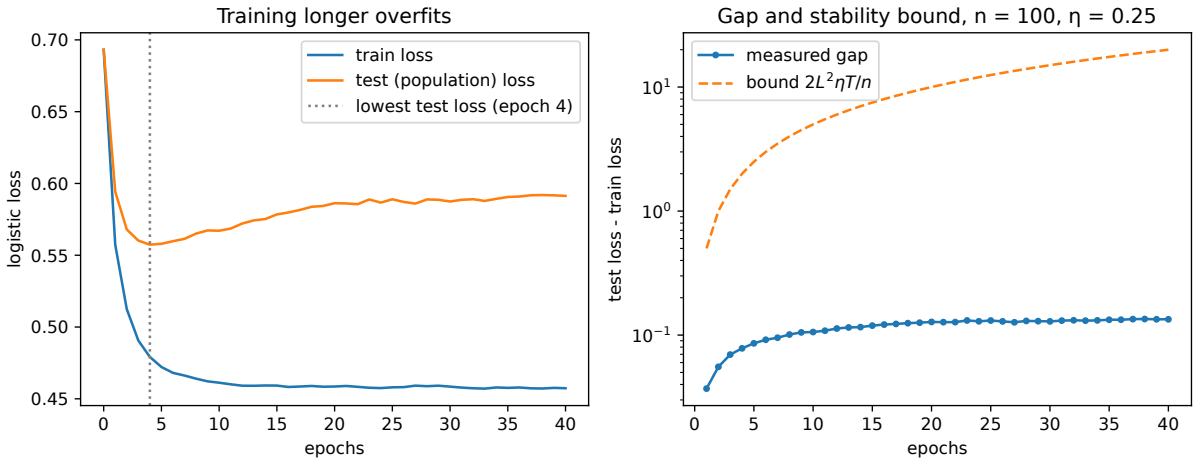

Figure 7.6.: Left: train and test loss of SGD against the number of epochs. Right: the measured gap against the stability bound $2L^2\eta T/n$, on a log scale. Both grow with training time; the bound grows faster.

7.8.2. Statement

1-NN is as unstable as an algorithm can be, and its gap does not close. With 0-1 loss, 1-NN is γ-uniformly stable only for $\gamma = 1$, the largest possible value. Its training error is 0, and as $n \to \infty$ its test error tends to $\mathbb{E}[2p(x)(1 - p(x))]$, where $p(x) = \Pr[y = 1 \mid x]$ is the probability that the label at x is $+1$ (Cover & Hart 1967). So whenever the labels are noisy, its gap stays bounded away from zero.

7.8.3. Derivation

1. **Training error is 0.** Each training point is its own nearest neighbour (assume distinct points), so it is predicted with its own label.
2. $\gamma = 1$**.** It is enough to find one training set, one replacement and one test point where the loss changes by 1. Take any D and the test point $z = z_i = (x_i, y_i)$. On D the prediction at x_i is y_i: loss 0. Replace z_i by $z_i' = (x_i, -y_i)$, the same point with the opposite label. On $D^{(i)}$ the nearest neighbour of x_i is z_i', so the prediction is $-y_i$: loss 1.
3. **The gap equals the test error.** By step 1 the training loss is 0, so $\text{gap}(D) = \mathcal{L}_{\mathcal{D}}(\mathcal{T}(D))$. As n grows, the training points fill the space, so the nearest neighbour of a test point x lies at (essentially) x, and its label is an independent draw that is $+1$ with probability $p(x)$. (Section G.4 in the appendices makes this precise, assuming p is continuous and x lies in a closed and bounded set.) The test label is another independent draw with the same probability. The two disagree when one is $+1$ and the other -1, which happens with probability $p(1 - p) + (1 - p)p = 2p(1 - p)$. Averaging over x gives the limit.

7.8.4. Interpretation

Zero training error says nothing here. 1-NN is a reasonable classifier: the best possible classifier, the **Bayes classifier**, predicts the more likely label at each x and has error $\mathbb{E}[\min(p, 1 - p)]$, and since $2p(1 - p) = 2\min(p, 1 - p)\max(p, 1 - p) \leq 2\min(p, 1 - p)$, the limiting error of 1-NN is at most twice that. But its training error carries no information about how close it gets.

The result is consistent with the theorem but not explained by it. The gap of 1-NN is below $\gamma = 1$, so Equation 7.11 holds; it just says nothing useful when the loss is at most 1 anyway.

More neighbours give more stability. k-NN with majority vote averages k labels, so replacing one record rarely changes a prediction. Its worst-case γ is still 1, because some training set leaves a test point with a vote split as evenly as possible, and replacing one of its neighbours flips the majority, but average-case stability notions capture its behaviour (Devroye & Wagner 1979; Exercise 6 in the exercise book).

7.8.5. Example: 1-NN against regularized logistic regression

In the running example the Bayes error is 0.250 and the 1-NN limit $\mathbb{E}[2p(1 - p)]$ is 0.338. The table compares 1-NN with the stable regularized logistic regression, averaging over 10 training sets, with 0-1 error measured on 2,000 test points:

Table 7.6.: 0-1 error of 1-nearest neighbour and of regularized logistic regression.

n	1-NN train	1-NN test	Logistic ($\lambda = 0.01$) train	Logistic test
50	0.000	0.404	0.170	0.301
200	0.000	0.380	0.232	0.274
1,000	0.000	0.367	0.244	0.266
4,000	0.000	0.352	0.249	0.259

The gap of 1-NN is its test error, which falls towards 0.338 and no further. The gap of the stable logistic regression, test minus train, falls from $0.301 - 0.170 = 0.131$ at $n = 50$ to $0.259 - 0.249 = 0.010$ at $n = 4{,}000$ (Table 7.6, Figure 7.7).

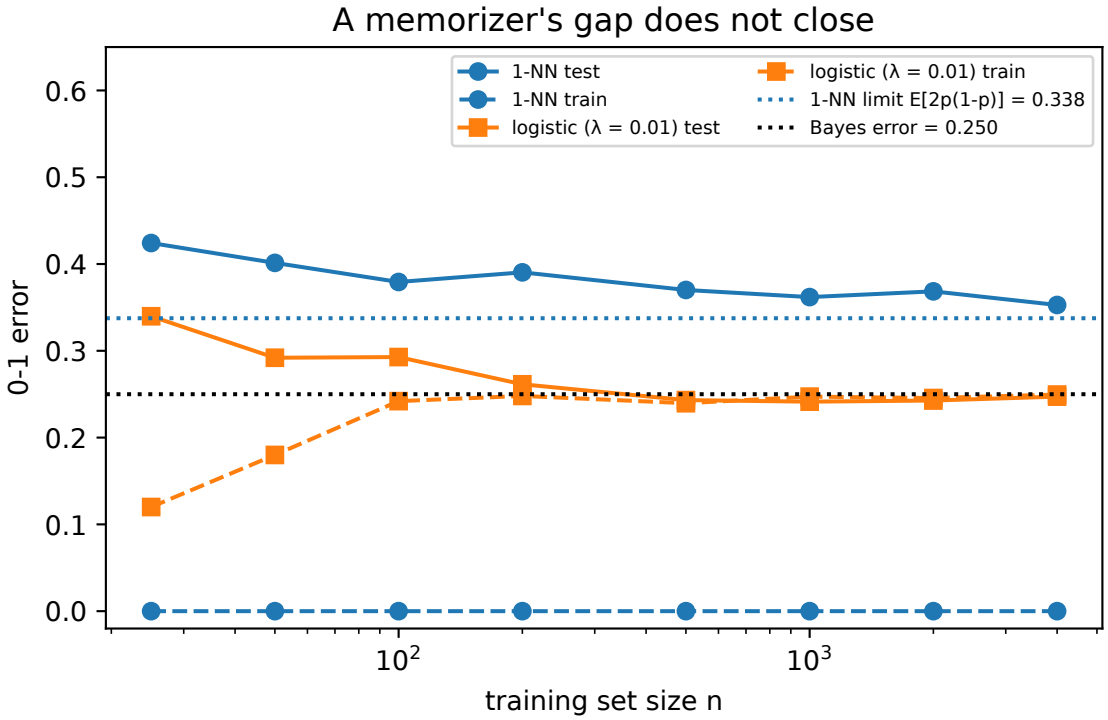

Figure 7.7.: Train (dashed) and test (solid) 0-1 error of 1-nearest neighbour and of regularized logistic regression against n, with the Bayes error and the 1-NN limit $\mathbb{E}[2p(1-p)]$.

7.8.6. Check yourself

- Is the memorizing lookup table less stable than 1-NN? *(No; both have $\gamma = 1$. But 1-NN generalizes its memory to nearby points, so its test error is far better.)*
- Would label noise of zero ($p(x) \in \{0, 1\}$) rescue 1-NN's gap? *(In the limit, yes: $2p(1-p) = 0$. The gap of a memorizer is driven by records whose label could have gone either way.)*

7.9. Overfitting is memorization of individual records

7.9.1. Context

Equation 7.10 says the expected gap is the average, over training records, of how much each record's own loss rises when that record is replaced. This quantity, the **self-influence** (or **memorization score**) of record i, can be measured directly by retraining. Measuring it shows *which* records carry the gap.

7.9.2. Statement

Give the bracket of Equation 7.10 a name: for each training record, its self-influence is its loss under the model trained without it (with a fresh point in its place) minus its loss under the model trained with it,

$$\mathrm{mem}_i(D) = \ell(\mathcal{T}(D^{(i)}); z_i) - \ell(\mathcal{T}(D); z_i). \tag{7.20}$$

Then $\mathbb{E}[\mathrm{gap}(D)] = \frac{1}{n}\sum_i \mathbb{E}[\mathrm{mem}_i(D)]$, by Equation 7.10. Feldman (2020) uses the same idea with removal instead of replacement and accuracy instead of loss: the probability that the model is right on record i when trained with it, minus the same probability when trained without it, $\Pr[\mathcal{T}(D) \text{ is right on } x_i] - \Pr[\mathcal{T}(D \setminus z_i) \text{ is right on } x_i]$.

7.9.3. Derivation

Nothing new: this is Equation 7.10 with the bracket given a name. The content is in the measurement.

7.9.4. Interpretation

The gap is a sum of per-example contributions. A model with a large gap has, on average, records whose fit depends on themselves. Uniform stability caps every contribution at γ; the identity says the average is what matters for the expected gap.

The contributions are uneven. Typical records are fitted well whether or not they are present, because their neighbours carry the same information. Atypical records, such as mislabeled points or members of rare subgroups, are fitted only if they themselves are in the training set, so they carry most of the gap.

That does not make memorization a defect to remove at any cost, because it can be necessary. Feldman (2020) shows that when the data distribution has a long tail of rare subpopulations, each seen about once, an algorithm that does not memorize those singletons loses accuracy on the tail. So for natural data, a large gap can come with good test accuracy. The empirical evidence points the same way. Zhang et al. (2017) found that deep networks fit even randomly relabeled training data perfectly, and Feldman & Zhang (2020) estimated memorization scores on image benchmarks and found the highest scores on atypical and mislabeled records.

7.9.5. Example: self-influence in logistic regression

The script draws training sets of $n = 40$ points, fits the model, then for each i replaces z_i by a fresh draw, refits, and records mem_i. Over 100 training sets, with $\pm$ one standard error, the measured gap and the average self-influence are close. At $\lambda = 0.01$ the gap is 0.1482 ± 0.0073 and the average self-influence is 0.1422 ± 0.0025. At $\lambda = 0.1$ the gap is 0.0420 ± 0.0017 and the average self-influence is 0.0416 ± 0.0003.

The two agree within their errors, as the identity requires. The self-influence estimate is less noisy, because it averages n refits per training set.

To see which records carry the gap, split them by whether the label goes with the trend ($y_i x_{i1} \geq 0$, the more likely label, since $\Pr[y = 1 \mid x] = \sigma(5x_1)$ favours the sign of x_1) or against it. About a quarter go against it (24% and 25% in the two runs). At $\lambda = 0.01$, their average self-influence is 0.284, against 0.097 for the others: three times larger. At $\lambda = 0.1$ the two are 0.055 and 0.037. Figure 7.8 shows the full picture: the least typical records are the most memorized, and regularization flattens the profile.

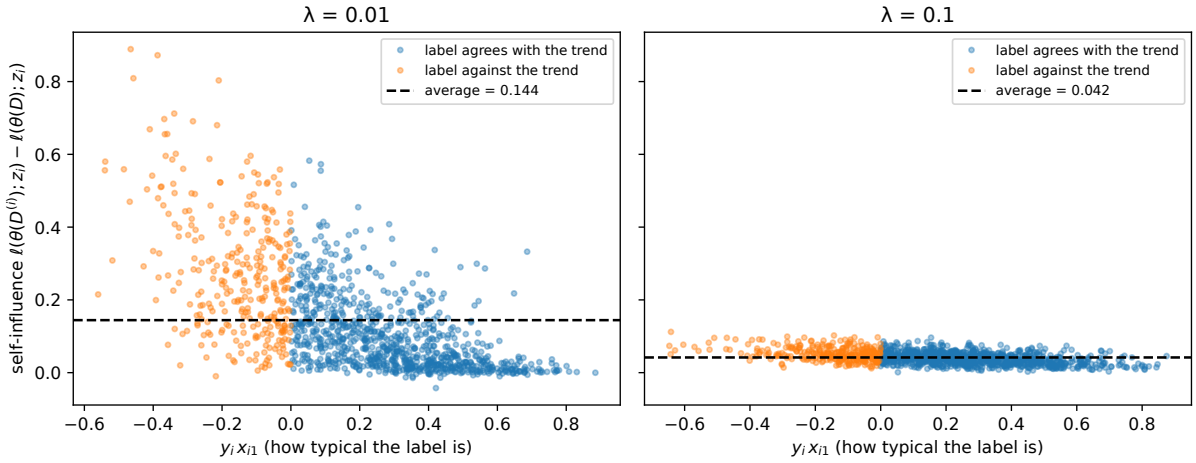

Figure 7.8.: Self-influence $\ell(\theta(D^{(i)}); z_i) - \ell(\theta(D); z_i)$ of each training record against $y_i x_{i1}$, which measures how typical its label is, for $n = 40$ and two values of λ. Records whose label goes against the trend have the largest self-influence. The dashed line is the average, which equals the expected gap.

7.9.6. Check yourself

- Uniform stability bounds every mem_i. Why is it a stronger requirement than a small expected gap? *(A small gap only needs the average to be small. A few heavily memorized records are compatible with a small gap but not with small uniform stability.)*
- Why does regularization shrink the self-influence of atypical records the most? *(It caps how far any one record can pull the weights, $2L/(\lambda n)$, and atypical records are the ones that pull hardest.)*

7.10. Choosing what to measure after looking

7.10.1. Context

Everything so far concerns a model trained on one set of records and judged on new data. A **holdout set** is a sample kept aside for judging models. For a model fixed before it was drawn, its loss is unbiased (Section 7.3), so it seems to solve the judging problem. In practice, though, a holdout set is rarely used once. You look at its verdict, change a feature or a setting, and ask it again. Each new question then depends on the earlier answers, and so on the holdout set itself. The guarantee for a fixed model no longer covers such a question, for the same reason the training loss of a trained model is biased: the data that judge a choice also helped to make it.

7.10.2. Statement

Write $H = (z_1, \dots, z_n)$ for a holdout set of n records drawn independently from $\mathcal{D}$. A **question** is a function f that maps one record to a number between 0 and 1, such as "is this record classified correctly by a given model?". Its answer on the holdout set is the average of its values there, and its true value is the average over new data:

$$f(H) = \frac{1}{n}\sum_{i=1}^{n} f(z_i), \qquad f(\mathcal{D}) = \mathbb{E}_{z\sim\mathcal{D}}\, f(z). \tag{7.21}$$

Suppose you ask k questions $f_1, \dots, f_k$. Three cases differ in how the questions were chosen.

Questions fixed in advance. If all k questions were chosen before H was drawn, the largest error among their answers is small on average over the draw of H, and it grows only with the logarithm of k:

$$\mathbb{E}\Big[\max_{j\le k} \big|f_j(H) - f_j(\mathcal{D})\big|\Big] \le \sqrt{\frac{\ln(2k)}{2n}}. \tag{7.22}$$

Questions chosen after looking. If question j may depend on the answers to questions $1, \dots, j-1$, no bound that grows slowly with k holds in general. In the record below, a holdout set of 1,000 records answers 1,000 questions fixed in advance and then one chosen from their answers. That last answer is off by 0.31, while the bound Equation 7.22 would allow about 0.06 on average if it were fixed in advance.

Sample splitting. If question j is answered on its own part H_j of n/k records, which no earlier answer used, the bound holds again, in any order and however the questions were chosen. The price is a factor k inside the square root, because each answer sees only n/k records:

$$\mathbb{E}\Big[\max_{j\le k} \big|f_j(H_j) - f_j(\mathcal{D})\big|\Big] \le \sqrt{\frac{k\ln(2k)}{2n}}. \tag{7.23}$$

7.10.3. Derivation

1. **One average.** Take a fixed question f and write $Z = f(H) - f(\mathcal{D})$ for the error of its answer. This error is an average of n independent values in $[0, 1]$, minus their common mean. Hoeffding's lemma (Concentration inequalities) bounds the moment generating function of each centred value, scaled by $1/n$, by $e^{\lambda^2/(8n^2)}$, and independence multiplies the n bounds. For every real λ,
$$\mathbb{E}\, e^{\lambda Z} \le e^{\lambda^2/(8n)}, \tag{7.24}$$
and since λ may be negative, the same bound holds for $-Z$.
2. **The largest of many.** Write $Z_j = f_j(H) - f_j(\mathcal{D})$ for the error of question j, and apply step 1 to the $2k$ variables $\pm Z_j$, whose maximum, written max below, is the largest error. For $\lambda > 0$, Jensen's inequality for the convex function e^x moves the expectation outside the exponential, and the exponential of a maximum is at most the sum of the exponentials. Together,
$$e^{\lambda\, \mathbb{E} \max} \le \mathbb{E}\, e^{\lambda \max} \le \sum_{\text{all } 2k} \mathbb{E}\, e^{\lambda(\pm Z_j)} \le 2k\, e^{\lambda^2/(8n)}. \tag{7.25}$$
Taking logarithms and dividing by λ bounds the expected maximum by a sum of two terms,
$$\mathbb{E} \max \le \frac{\ln(2k)}{\lambda} + \frac{\lambda}{8n}, \tag{7.26}$$
and the two terms are equal, each $\sqrt{\ln(2k)/(8n)}$, when $\lambda = \sqrt{8n \ln(2k)}$. Their sum is then
$$\mathbb{E} \max \le 2\sqrt{\frac{\ln(2k)}{8n}} = \sqrt{\frac{\ln(2k)}{2n}}, \tag{7.27}$$
which is Equation 7.22. This step never uses independence between the questions, only step 1 for each one.
3. **Where looking breaks it.** Step 1 needs f to be fixed while the records are drawn, so that $f(z_1), \dots, f(z_n)$ are independent draws with mean $f(\mathcal{D})$. A question chosen from earlier answers depends on H. Then its values on the records of H are not typical draws, exactly as $\ell(\mathcal{T}(D); z_i)$ was not in Section 7.3, and step 1 fails.
4. **Splitting restores it.** Fix the parts $H_1, \dots, H_{j-1}$ that earlier answers used, and any randomness of the analyst, which must be independent of the holdout set. Question f_j, which is chosen from those answers only, is then fixed, and H_j is independent of it, so step 1 holds given those parts, with n/k records in place of n. Averaging over the earlier parts keeps the inequality, since it holds for each of their values, so each $\pm Z_j$ satisfies step 1 without conditioning. Step 2 then applies as before, with n/k in place of n, which is Equation 7.23.

7.10.4. Interpretation

A question chosen with the holdout set's help is a model trained on the holdout set. The person or program that picks the questions, together with the answers, is a learning algorithm whose input is H, and the answer to its final question is that algorithm's training loss. So it is optimistic, as a training loss is, and for the same reason. The records whose answers shaped the choice are no longer typical draws from the choice's point of view.

Sample splitting removes the bias by never letting a record answer a question it helped to choose. The data it needs grow like $k \ln(2k)$, roughly in proportion to k, against $\ln(2k)$ for questions fixed in advance. Between the two lies a middle ground: if the questions come in r rounds, and each round is fixed before its answers are seen, one part per round suffices. The factor k in front of $\ln(2k)$ in Equation 7.23 then becomes r, by the same argument with rounds in place of questions. The classical rule is the case of a single round: keep a test set for one final verdict, and use it once. Exercise 9 in the exercise book computes how optimistic the best of 100 models fixed in advance looks on a validation set, a holdout set used to choose among models, and shows that one fresh measurement removes the optimism.

Since the analyst is a learning algorithm run on H, a stable analyst would have a small bias, by Equation 7.11. That does not rescue the reused holdout set in practice, because the choices an analyst makes ("keep the feature if it looks predictive") are thresholds, and a threshold can flip when one record changes, which makes it as unstable as 1-NN. A later chapter shows how to reuse one holdout set safely for many more adaptively chosen questions than splitting allows, using a randomized form of the stability defined here.

7.10.5. Example: Freedman's paradox on a holdout set

The chapter's script builds a holdout set of $n = 1{,}000$ records with d features, each $+1$ or -1 at random, and a label that is also random and independent of every feature. No rule can beat an accuracy of $\frac{1}{2}$ on new data. An analyst measures, on the holdout set, how often each feature agrees with the label, which is d questions fixed in advance. The analyst keeps the features whose agreement rate is more than one standard deviation away from $\frac{1}{2}$. For an average of n fair coin flips that standard deviation is $\sqrt{1/(4n)} = 0.0158$. Each kept feature votes $+1$ or -1, flipped if it agreed with the label less than half the time. The majority wins, and a tie counts as $+1$. Then the analyst asks one more question: the vote's accuracy on the same holdout set. Table 7.7 averages 100 repetitions.

Table 7.7.: A holdout set of 1,000 records reused for a question chosen after looking, averaged over 100 repetitions. Every feature is independent of the label, so the true accuracy of any vote is $\frac{1}{2}$.

Features d	Kept	Largest error of the d fixed questions	Bound Equation 7.22	Vote, measured on H	Vote, chosen on one half and measured on the other	Vote on new data
100	33.3	0.0436	0.0515	0.6080	0.5032	0.5
1,000	325.9	0.0538	0.0616	0.8053	0.5018	0.5

The d questions fixed in advance behave as Equation 7.22 says: their largest error stays below the bound. The one question chosen after looking is off by 0.31 with 1,000 features. The reason is that every kept feature agrees with the holdout labels slightly more often than chance, and

the vote adds these small agreements up, record by record. Splitting the holdout set into halves, one to choose the features and one to measure the vote, brings the measured accuracy back to $\frac{1}{2}$ (Figure 7.9). This is Freedman's paradox (Freedman 1983), first described for screening regression variables. Hastie, Tibshirani & Friedman (2009, §7.10.2) give the same warning for cross-validation, under the title "the wrong and the right way" to do it.

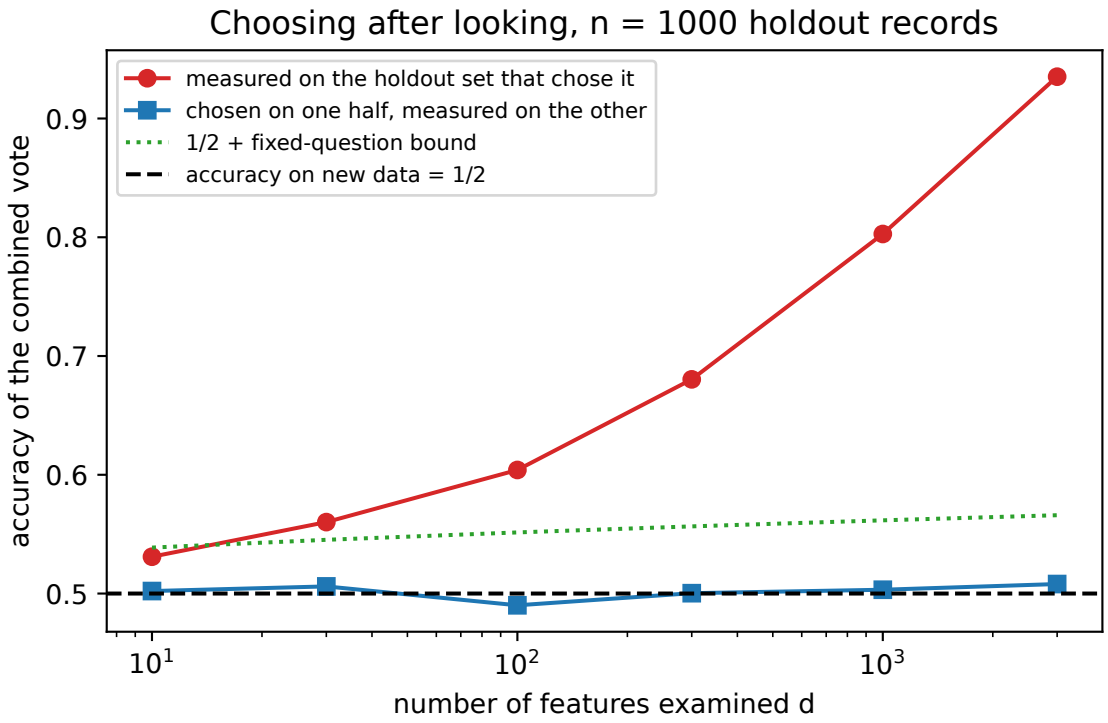

Figure 7.9.: Accuracy of the combined vote against the number of features examined, for a holdout set of 1,000 records and labels independent of every feature. Measured on the holdout set that chose the features, the accuracy climbs far above $\frac{1}{2}$. Chosen on one half and measured on the other, it stays at $\frac{1}{2}$, within the fixed-question bound.

7.10.6. Check yourself

- You trained 50 models on data other than H and report the best one's accuracy on a holdout set H of n records. Is that a question fixed in advance? *(The 50 accuracy questions are, since no model depends on H. Picking the largest answer is then covered by Equation 7.22 with $k = 50$. The bound stops applying only when later models are built from earlier holdout answers.)*
- In the record, why does splitting into two halves suffice, although the analyst asks $d + 1$ questions? *(The questions come in two rounds. The d agreement questions are fixed in advance, and the vote is fixed once they are answered. One part per round is enough.)*

7.11. Code: check every bound by simulation

The script code/stability.py draws every figure in this chapter and computes the numbers quoted in it. The running example has features x uniform on the unit sphere in $\mathbb{R}^{10}$ and labels with $\Pr[y = 1 \mid x] = \sigma(5x_1)$. The model is logistic regression without intercept, fitted by Newton's method with backtracking. Because $\|x\| = 1$, the logistic loss is 1-Lipschitz and $\frac{1}{4}$-smooth. The test loss of a model is computed without sampling error. The features are spread evenly over the sphere and the label depends only on x_1, so rotating the other nine coordinates changes nothing; the test loss therefore depends only on θ_1 and the norm of the other coordinates of θ. That makes it a two-dimensional integral, done on a grid. From the repository root:

```
uv run python code/part01-prerequisites/stability.py
```

Output (seed 0), summarized in Table 7.8:

Table 7.8.: Summary of the script's output.

Experiment	Result
Renaming, $n = 1$, $p = 0.3$ (Table 7.2)	Train 0.0750; test 0.2850; renamed 0.2850; gap 0.2100; $\gamma = 0.75$
Replace-one change, regularized logistic (Table 7.3)	Loss change between 0.14 and 0.25 of $2L^2/(\lambda n)$, for n from 100 to 10,000 and λ from 0.01 to 1
Expected gap, regularized logistic (Table 7.4)	Falls like $1/n$; about 3% of the bound at $\lambda = 0.01$, 11% to 13% at $\lambda = 1$
High-probability width, $n = 10{,}000$, $\beta = 0.05$	$\lambda = 1$: 0.065; $\lambda = 0.1$: 0.614
Self-influence, $n = 40$	$\lambda = 0.01$: gap 0.1482 ± 0.0073, self-influence 0.1422 ± 0.0025. $\lambda = 0.1$: 0.0420 ± 0.0017 and 0.0416 ± 0.0003
SGD, $n = 100$, $\eta = 0.25$ (Table 7.5)	Gap 0.036 after 1 epoch, 0.121 after 40; bound 0.5 and 20.0
1-NN against logistic (Table 7.6)	1-NN test error 0.404 → 0.352 with train error 0; limit 0.338; Bayes 0.250
Reused holdout set, $n = 1{,}000$ (Table 7.7)	Vote over noise features: 0.8053 measured on the holdout set that chose it, 0.5018 with a split, 0.5 on new data

tests/test_stability.py checks that the output still matches the numbers in this chapter.

What to take from it. The $1/(\lambda n)$ scaling holds, but the constant is loose: replace-one changes and gaps follow $1/(\lambda n)$ closely when $\lambda \geq 0.1$ (with weaker regularization the data's own curvature makes them smaller still), yet sit between 4 and 36 times below the bound, because the bound takes the worst case at every step. The identity, unlike the bounds, is exact: the average self-influence matches the measured gap within simulation error. The SGD bound gets the direction right and the size wrong: the gap grows with training time, but the divergence between coupled runs saturates while the bound grows linearly. Memorizers do not generalize their training error: 1-NN has training error 0 and test error 0.35, while regularized logistic regression has train and test

errors that meet. Finally, a holdout set that helped choose a question is a training set for that question: its answer can be off by 0.3 while every question fixed in advance stays within the bound.

7.13. Cheat sheet

Table 7.9 collects every result. $D^{(i)}$ replaces record i by a fresh draw; γ is uniform stability, the largest change in loss at any test point when one record is replaced; β is the failure probability.

Table 7.9.: Every result of the chapter.

Result	Assumptions	Statement
Gap identity	None	$\mathbb{E}[\text{gap}] = \frac{1}{n}\sum_i \mathbb{E}[\ell(\mathcal{T}(D^{(i)}); z_i) - \ell(\mathcal{T}(D); z_i)]$
Expected gap	γ-uniformly stable	$\lvert\mathbb{E}[\text{gap}]\rvert \le \gamma$
High probability (Bousquet–Elisseeff)	γ-uniformly stable, $0 \le \ell \le K$	$\text{gap} \le \gamma + (2n\gamma + K)\sqrt{\ln(1/\beta)/(2n)}$
Improved high probability (Feldman–Vondrák; Bousquet–Klochkov–Zhivotovskiy)	Same, $K = 1$	$\text{gap} \lesssim \gamma \ln n \ln(1/\beta) + \sqrt{\ln(1/\beta)/n}$
Regularized ERM	Convex, L-Lipschitz loss, $\frac{\lambda}{2}\lVert\theta\rVert^2$	$\lVert\theta_D - \theta_{D^{(i)}}\rVert \le 2L/(\lambda n)$, $\gamma = 2L^2/(\lambda n)$
SGD (Hardt–Recht–Singer)	Convex, β_s-smooth, L-Lipschitz, $\eta_t \le 2/\beta_s$	$\gamma \le (2L^2/n)\sum_t \eta_t$
1-NN, lookup table	0-1 loss	$\gamma = 1$; training error 0
Questions fixed in advance	k questions with values in $[0,1]$, chosen before H is drawn	$\mathbb{E}\max_j \lvert f_j(H) - f_j(\mathcal{D})\rvert \le \sqrt{\ln(2k)/(2n)}$
Sample splitting	Question j answered on its own n/k records	$\mathbb{E}\max_j \lvert f_j(H_j) - f_j(\mathcal{D})\rvert \le \sqrt{k\ln(2k)/(2n)}$

Rules of thumb

- A gap bound from stability needs $\gamma \to 0$; a high-probability bound from McDiarmid needs $\gamma = o(1/\sqrt{n})$.
- Regularization strength and training time are the two stability knobs: $\gamma \propto 1/\lambda$ for ERM, $\gamma \propto \eta T$ for SGD.
- Training error 0 is a warning, not a result: it means the model may depend entirely on individual records.
- The records a model memorizes most are the atypical ones.
- A holdout set that helped choose a question is a training set for it. Give each round of choices its own data, and use the final test set once.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

8. Cryptography basics

8.1. Why this matters

Some computations must hide something: a key, a message, a value split among several holders. To reason about them you need a precise answer to one question: **what does it mean that an observer with limited computing power learns nothing it was not supposed to learn?** Cryptography answers it with a small set of definitions and proof techniques. This chapter teaches them as mathematics: definitions you can state, bounds you can derive, and toy constructions you can run.

The whole subject is one idea, used over and over. **Security is a game.** A challenger secretly picks one of two worlds, runs a procedure in that world, and shows the result to an adversary, who guesses which world it is in. The challenger picks the world by flipping a fair coin, so that an adversary who learns nothing from what it sees is right exactly half the time, whatever it answers. Its **advantage** measures how much better than that coin flip it does. A scheme is then called **secure** when the advantage is tiny for every efficient adversary, and "tiny" is made precise in one of two ways: by negligible functions, which shrink faster than any power of the key length (the asymptotic view), or by explicit numbers such as 2^{-64} (the concrete view). Finally, security proofs rarely jump from the real world to the ideal one in a single move. They **change one thing at a time**, through a chain of intermediate worlds called **hybrids**, and add up the advantage gained at each step.

Table 8.1 lists where each result is used.

Table 8.1.: The results in this chapter and where each is typically used.

Result	Typical use
Negligible functions, polynomial-time adversaries	Saying "this attack essentially never works" in a way that survives polynomially many repetitions
Indistinguishability and the hybrid argument	The skeleton of every security proof
Concrete security and the birthday bound	How much data a key may protect; how long random identifiers and hashes must be
Pseudorandom generators and functions	Stretching a short random key into many random-looking values
One-time pad, indistinguishability under chosen-plaintext attack (CPA)	What encryption promises, and why it must be randomized
The simulation paradigm	Proving that what a participant sees reveals nothing beyond what it is allowed to learn
Learning with errors and Regev encryption	Lattice-based encryption that can add ciphertexts, at the price of growing noise

Later parts build protocols from these primitives. The probability tools used here (union bound, $1 + x \le e^x$, the normal tail) are proved in Concentration inequalities, and total variation (TV) distance is studied in Divergences; each is restated below where it is used.

Notation. An adversary is $\mathcal{A}$, and a second adversary built from it by a reduction is $\mathcal{B}$. The number of queries an adversary makes (or of random draws in the birthday bound) is Q, and an adversary's advantage is ν; cryptography texts usually write these q and ε, letters this book keeps for the sampling rate and the privacy parameter. Because Q counts queries, two distributions are written P_0 and P_1 here, and lowercase p is the modulus of the arithmetic in secret sharing and learning with errors, not a density. The bit length of blocks, messages and inputs is n, the number of share holders is h, and the dimension of a learning-with-errors secret is d.

A warning about the code. Every scheme in this chapter's script is a toy, written to make the definitions concrete. Its parameters are far too small to be secure, nothing runs in constant time, and NumPy's generator is not a cryptographic source of randomness. Never use it to protect anything.

8.2. Toolkit: five facts every derivation uses

8.2.1. Fact 1 — Advantage and guessing probability are the same thing

A **distinguisher** $\mathcal{A}$ is any procedure that receives one sample and outputs a bit, 0 or 1. Think of output 1 as "I think this sample came from Y". If $\mathcal{A}$ is any good at telling distribution X from distribution Y, it says 1 more often on samples from Y than on samples from X, so the natural measure of its skill is the gap between those two frequencies. That gap is its **advantage**:

$$\mathrm{Adv}_{\mathcal{A}}(X, Y) = \big|\Pr[\mathcal{A}(X) = 1] - \Pr[\mathcal{A}(Y) = 1]\big|. \tag{8.1}$$

Here $\Pr[\mathcal{A}(X) = 1]$ is the probability that $\mathcal{A}$ outputs 1 when its input is drawn from X. A distinguisher that ignores its input says 1 equally often on both and has advantage 0; one that is always right has advantage 1.

Games are often phrased differently, as a guessing contest. The challenger flips a fair bit b: if $b = 1$ it gives $\mathcal{A}$ a sample from Y, and if $b = 0$ a sample from X. $\mathcal{A}$ outputs a guess, and it **wins** if its guess equals b. So $\Pr[\mathcal{A}\text{ wins}]$, also written $\Pr[b' = b]$ with b' the guess, is the probability that the guess is correct; it is not the probability that b is 1, which is $\frac{1}{2}$ by construction. The coin is fair on purpose. With a fair coin, an adversary who learns nothing from its sample, and so has nothing to go on, wins exactly half the time, whether it guesses at random or always says 1. Any win rate above $\frac{1}{2}$ must therefore come from information in the sample.

The two phrasings measure the same thing. There are two ways to win, and they cannot happen in the same game: the coin says Y and $\mathcal{A}$ says 1, or the coin says X and $\mathcal{A}$ says 0. Each world occurs with probability $\frac{1}{2}$, so the win probability is the average of the two conditional win rates. Writing $\Pr[\mathcal{A}(X) = 0] = 1 - \Pr[\mathcal{A}(X) = 1]$ and collecting terms,

$$\Pr[\mathcal{A}\text{ wins}] = \tfrac{1}{2}\Pr[\mathcal{A}(Y) = 1] + \tfrac{1}{2}\Pr[\mathcal{A}(X) = 0] = \tfrac{1}{2} + \tfrac{1}{2}\big(\Pr[\mathcal{A}(Y) = 1] - \Pr[\mathcal{A}(X) = 1]\big). \tag{8.2}$$

So an advantage of ν means winning with probability $\frac{1}{2} + \frac{\nu}{2}$: the know-nothing score, plus half the advantage. The bracket has no absolute value, so it can be negative, but then $\mathcal{A}$ wins less

than half the time, and flipping its output (saying 0 where it said 1) turns it into a distinguisher that wins $\frac{1}{2} + \frac{\nu}{2}$.

Here it is with a coin. X is a fair coin, Y lands heads with probability 0.6, and $\mathcal{A}$ outputs 1 on heads. Each row of Table 8.2 is one outcome of the game. Its probability is $\frac{1}{2}$ for the challenger's bit times the probability of the coin outcome in that world: $\frac{1}{2} \times 0.5 = 0.25$ for each outcome of the fair coin, $\frac{1}{2} \times 0.4 = 0.20$ for tails of the biased coin and $\frac{1}{2} \times 0.6 = 0.30$ for heads.

Table 8.2.: The distinguishing game for a fair against a 0.6-biased coin, with the distinguisher "output 1 on heads".

b	Coin	Outcome	Probability	$\mathcal{A}$ outputs	$\mathcal{A}$ wins?
0	fair	tails	0.25	0	yes
0	fair	heads	0.25	1	no
1	biased	tails	0.20	0	no
1	biased	heads	0.30	1	yes

$\mathcal{A}$ wins in the first and last rows, with probability $0.25 + 0.30 = 0.55$. Its advantage is $\Pr[\mathcal{A}(Y) = 1] - \Pr[\mathcal{A}(X) = 1] = 0.6 - 0.5 = 0.1$, and indeed $0.55 = \frac{1}{2} + \frac{0.1}{2}$.

8.2.2. Fact 2 — No distinguisher beats total variation

The **total variation distance** between two distributions P_0 and P_1 on a finite set is the total amount of probability that P_0 puts on outcomes in excess of P_1:

$$\mathrm{TV}(P_0, P_1) = \sum_{\omega:\, P_0(\omega) > P_1(\omega)} (P_0(\omega) - P_1(\omega)). \tag{8.3}$$

It is 0 when the distributions are equal and 1 when they never produce the same outcome. Every distinguisher, however much time it uses, has advantage at most $\mathrm{TV}(P_0, P_1)$. The reason is that a distinguisher can only react to which outcome it sees, and the most it can do is say 1 on exactly the outcomes that P_0 favours.

1. **Describe any distinguisher by its reaction to each outcome.** A randomized distinguisher outputs 1 on outcome ω with some probability $g(\omega) \in [0, 1]$. Nothing else about it matters for its advantage.
2. **Write the gap as a sum over outcomes.** The probability of output 1 under P_0 is $\sum_\omega P_0(\omega) g(\omega)$, and likewise under P_1, so $\Pr[\mathcal{A}(P_0) = 1] - \Pr[\mathcal{A}(P_1) = 1] = \sum_\omega g(\omega)(P_0(\omega) - P_1(\omega))$.
3. **Maximize term by term.** Each term is largest when $g(\omega) = 1$ where $P_0(\omega) - P_1(\omega)$ is positive and $g(\omega) = 0$ where it is negative. That choice gives exactly the TV distance. The same argument with P_0 and P_1 swapped bounds the gap of the other sign, and the excess of P_1 over P_0 is the same total, because both distributions sum to 1.

So the best unbounded distinguisher attains the TV distance, and this splits security into three regimes. Two distributions with TV distance 0 are identical, and then no adversary has any advantage: this is **perfect** security. TV distance at most a small ν is **statistical** security: even an adversary with unlimited time gains at most ν. Cryptography's main business is the third case, where the TV distance is large but no *efficient* distinguisher can exploit it.

8.2.3. Fact 3 — Advantages add along a chain

If you walk from distribution H_0 to distribution H_m through intermediate distributions $H_1, \dots, H_{m-1}$, a distinguisher cannot tell the two ends apart better than the sum of how well it tells each consecutive pair apart. In symbols, for any distinguisher $\mathcal{A}$,

$$\mathrm{Adv}_{\mathcal{A}}(H_0, H_m) \le \sum_{i=1}^{m} \mathrm{Adv}_{\mathcal{A}}(H_{i-1}, H_i). \tag{8.4}$$

The reason is a telescoping sum: in $\sum_{i=1}^{m} (\Pr[\mathcal{A}(H_{i-1}) = 1] - \Pr[\mathcal{A}(H_i) = 1])$, each intermediate term appears once with a plus sign and once with a minus sign and cancels, leaving $\Pr[\mathcal{A}(H_0) = 1] - \Pr[\mathcal{A}(H_m) = 1]$. Taking absolute values, the triangle inequality ($|a_1 + \cdots + a_m| \le |a_1| + \cdots + |a_m|$) gives the bound. This is the arithmetic behind every hybrid proof.

8.2.4. Fact 4 — A bijection maps uniform to uniform

If you shuffle the elements of a finite set by a fixed one-to-one rule, a uniformly random element stays uniformly random. Formally, if U is uniform on a finite set S and $f : S \to S$ is a bijection, then each $t \in S$ comes from exactly one u, namely $f^{-1}(t)$, so $\Pr[f(U) = t] = \Pr[U = f^{-1}(t)] = 1/|S|$. The one-time pad, secret sharing and the mask in learning with errors are all this fact, with $f(u) = u + c$ for a fixed c: adding a uniform random value to anything fixed gives a uniform result.

8.2.5. Fact 5 — Union bound and $1 - x \le e^{-x}$

Both are proved in Concentration inequalities; here is what they say and why they hold. The **union bound** says that the probability that at least one of several events happens is at most the sum of their probabilities, $\Pr[\mathcal{A}_1 \cup \cdots \cup \mathcal{A}_Q] \le \sum_i \Pr[\mathcal{A}_i]$: the sum counts every outcome where some event happens at least once, and outcomes where several happen more than once. The inequality $1 - x \le e^{-x}$ holds for every real x because the straight line $1 - x$ is the tangent to the convex curve e^{-x} at $x = 0$, and a convex curve lies above its tangents. For $x_i \in [0, 1]$, multiplying the nonnegative inequalities $1 - x_i \le e^{-x_i}$ gives $\prod_i (1 - x_i) \le e^{-\sum_i x_i}$.

In this chapter they bound the probability that something goes wrong in at least one of Q steps: the union bound from above, and the product inequality from below (applied to the probability that nothing goes wrong).

8.3. Security parameter, adversaries and negligible functions

8.3.1. Context

A key of 40 bits can be found by trying every key; a key of 256 bits cannot. Security is therefore never absolute. It is a statement about how the attacker's success shrinks as you pay more, measured by a **security parameter** λ (think of the key length in bits). The asymptotic theory needs two notions: which attackers count as efficient, and which success probabilities count as tiny.

8.3.2. Definitions

An attacker counts as efficient if its running time grows at most polynomially with λ. Precisely, an adversary is **probabilistic polynomial time (PPT)** if it is a randomized algorithm whose running time is bounded by a polynomial in λ. Running time is always measured against the length of the input, and λ written in binary is only about $\log_2 \lambda$ bits long, so the adversary is given λ in unary, as the string of λ ones written 1^λ. Then "polynomial in its input length" means polynomial in λ.

A success probability counts as tiny if it shrinks faster than one over any polynomial. The point of this choice is that an efficient adversary can repeat its attack a polynomial number of times, so "tiny" must stay tiny after multiplication by any polynomial. A function $\mu : \mathbb{N} \to [0, 1]$ is **negligible** if, for every exponent c, it eventually falls below λ^{-c} and stays there:

$$\forall c > 0 \;\; \exists \lambda_0 \;\; \forall \lambda \geq \lambda_0 : \quad \mu(\lambda) < \lambda^{-c}. \tag{8.5}$$

Putting the two together, a scheme is **secure** if every PPT adversary has negligible advantage in its security game.

8.3.3. Closure: polynomially many tries keep it negligible

Statement. If μ is negligible and poly is a polynomial, then $\text{poly}(\lambda)\mu(\lambda)$ is negligible. The sum of two negligible functions is negligible.

Derivation. The idea is that a negligible function beats every inverse polynomial, so you can ask it to beat one that is steep enough to also cancel the polynomial poly.

1. **Bound the polynomial by a power.** A polynomial of degree $c' - 1$ is eventually below $\lambda^{c'}$, because $\lambda^{c'}$ grows faster than any of its terms. So $\text{poly}(\lambda) \leq \lambda^{c'}$ for all $\lambda \geq \lambda_1$.
2. **Ask μ for a steeper decay.** Fix any $c > 0$. Apply Equation 8.5 to μ with exponent $c + c'$ instead of c: $\mu(\lambda) < \lambda^{-(c+c')}$ for $\lambda \geq \lambda_2$.
3. **Multiply the two bounds.** For $\lambda \geq \max(\lambda_1, \lambda_2)$, $\text{poly}(\lambda)\mu(\lambda) < \lambda^{c'}\lambda^{-(c+c')} = \lambda^{-c}$. Since c was arbitrary, $\text{poly} \cdot \mu$ meets the definition of negligible.
4. **Handle a sum the same way.** Apply Equation 8.5 to each term with exponent $c + 1$: $\mu_1 + \mu_2 < 2\lambda^{-(c+1)}$, and $2\lambda^{-(c+1)} \leq \lambda^{-c}$ is the same as $2 \leq \lambda$, which holds once $\lambda \geq 2$.

This is why the definitions use polynomials and negligible functions together. A PPT adversary can repeat an attack a polynomial number of times. By the union bound (Fact 5: the chance that at least one try succeeds is at most the sum of the per-try chances), its overall success is at most the number of tries times the per-try success, which is still negligible.

8.3.4. Examples

Each example compares $\mu(\lambda)$ with λ^{-c}, usually by taking $\log_2$ of both sides, which turns the comparison of tiny numbers into a comparison of exponents.

1. **$2^{-\lambda}$ is negligible.** $\lambda^c 2^{-\lambda} = 2^{c \log_2 \lambda - \lambda}$, and the exponent goes to $-\infty$ for every c because λ grows faster than $c \log_2 \lambda$. So $\lambda^c 2^{-\lambda} \to 0$: 2^λ outgrows every polynomial.

2. $\lambda^{-\log_2 \lambda}$ **is negligible**, although it decays more slowly than any exponential. For fixed c, compare the exponents of λ: $\lambda^{-\log_2 \lambda} < \lambda^{-c}$ exactly when $\log_2 \lambda > c$, that is, for all $\lambda > 2^c$.
3. $2^{-\sqrt{\lambda}}$ **is negligible.** Taking $\log_2$, $2^{-\sqrt{\lambda}} < \lambda^{-c}$ exactly when $\sqrt{\lambda} > c \log_2 \lambda$. Since $\sqrt{\lambda}/\log_2 \lambda \to \infty$, this holds for all large λ.
4. λ^{-10} **is not negligible.** The definition must hold for every c, so one bad c is enough. Take $c = 11$: $\lambda^{-10} < \lambda^{-11}$ never holds for $\lambda \geq 1$.
5. **A function that is** $2^{-\lambda}$ **for even** λ **and** $1/\lambda$ **for odd** λ **is not negligible.** The definition needs the bound for *all* large λ, and the odd values violate it for $c = 2$, since $1/\lambda > \lambda^{-2}$ for $\lambda > 1$.

8.3.5. Interpretation: asymptotics say nothing at a fixed λ

"Negligible" is a statement about the limit. At a specific parameter it can be misleading. Table 8.3 evaluates the four examples at $\lambda = 128$. Since $128 = 2^7$, $\log_2 \lambda = 7$, so $\lambda^{-\log_2 \lambda} = (2^7)^{-7} = 2^{-49}$ and $\lambda^{-10} = (2^7)^{-10} = 2^{-70}$; and $\sqrt{128} = 11.31$.

Table 8.3.: Four functions at $\lambda = 128$. The negligible $2^{-\sqrt{\lambda}}$ is far larger than the non-negligible λ^{-10}.

$\mu(\lambda)$	Negligible?	Value at $\lambda = 128$
$2^{-\lambda}$	yes	$2^{-128} = 2.9 \times 10^{-39}$
$\lambda^{-\log_2 \lambda}$	yes	$2^{-49} = 1.8 \times 10^{-15}$
$2^{-\sqrt{\lambda}}$	yes	$2^{-11.31} = 3.9 \times 10^{-4}$
λ^{-10}	no	$2^{-70} = 8.5 \times 10^{-22}$

The non-negligible λ^{-10} is smaller than two of the negligible functions. The crossing points follow from comparing exponents, as in the examples. $2^{-\sqrt{\lambda}}$ only drops below λ^{-10} for good at $\lambda = 20{,}520$, where $\sqrt{\lambda}$ overtakes $10 \log_2 \lambda$. $\lambda^{-\log_2 \lambda}$ crosses it at $\lambda = 2^{10} = 1024$, where $\log_2 \lambda = 10$. Figure 8.1 plots the "bits of security" $-\log_2 \mu(\lambda)$ of each, the number of halvings it takes to get from 1 down to $\mu(\lambda)$. A polynomial λ^{-c} has $c \log_2 \lambda$ bits of security. The negligible functions eventually rise above every such curve, but they can take a long time to do so.

8.3.6. Example: guessing a key

Suppose the key is uniform over all 2^λ strings of λ bits. An adversary that tries t distinct keys finds the right one with probability $t/2^\lambda$, because each key it tries is the right one with probability $2^{-\lambda}$ and the tries cover disjoint possibilities. If $t = t(\lambda)$ is a polynomial, this is a polynomial times $2^{-\lambda}$, which is negligible by the closure property. Brute force is the attack every definition must allow, and it is why the best one can hope for is "negligible", never zero.

8.3.7. Check yourself

- Is $\mu(\lambda) = 2^{-(\log_2 \lambda)^2}$ negligible? *(Yes. Write* $2^{(\log_2 \lambda)^2} = (2^{\log_2 \lambda})^{\log_2 \lambda} = \lambda^{\log_2 \lambda}$*, so* $\mu(\lambda) = \lambda^{-\log_2 \lambda}$*, example 2.)*

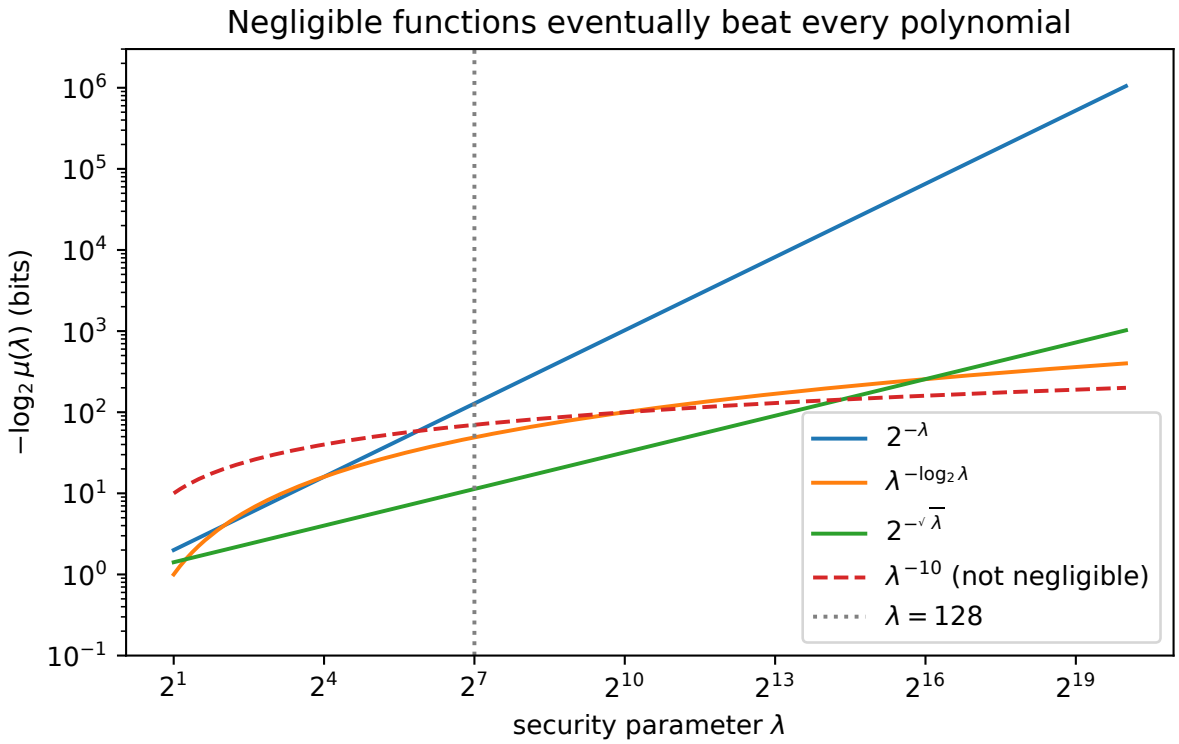

Figure 8.1.: Bits of security $-\log_2 \mu(\lambda)$ for three negligible functions and the non-negligible λ^{-10}, on log–log axes. Each negligible curve eventually overtakes the dashed one; $2^{-\sqrt{\lambda}}$ does so only beyond $\lambda = 20{,}520$.

- If an attack succeeds with probability $1/\lambda^3$ per try, does running it λ^4 times break the scheme? *(Yes, almost surely. The tries are independent, so* $\Pr[\textit{all tries fail}] = (1-\lambda^{-3})^{\lambda^4} \leq e^{-\lambda^{-3}\cdot\lambda^4} = e^{-\lambda}$ *by* $1-x \leq e^{-x}$ *(Fact 5). A non-negligible success probability can be amplified to near 1.)*

8.4. Computational indistinguishability and the hybrid argument

8.4.1. Context

Most security definitions say "these two things look the same". A ciphertext looks like random bits; the output of a generator looks like true randomness; a participant's view looks like something it could have produced alone. Computational indistinguishability makes "look the same" precise, and the hybrid argument is the tool for proving it.

You already know distinguishers from machine learning. A classifier trained to tell real images from generated ones is a distinguisher. If it outputs 1 for "real", then $\Pr[\mathcal{A}(\text{real}) = 1]$ is its true-positive rate and $\Pr[\mathcal{A}(\text{generated}) = 1]$ is its false-positive rate, so its advantage is its true-positive rate minus its false-positive rate at the chosen threshold. Deciding which of two distributions produced a sample is a hypothesis test, and Hypothesis testing studies the best such tests.

8.4.2. Definition

Because security is about how things behave as λ grows, the objects compared are not single distributions but families, one distribution for each value of λ. Two families $X = \{X_\lambda\}$ and $Y = \{Y_\lambda\}$ are **computationally indistinguishable**, written $X \approx_c Y$, if no efficient distinguisher has more than a negligible advantage: for every PPT distinguisher $\mathcal{A}$

$$\mathrm{Adv}_{\mathcal{A}}(X_\lambda, Y_\lambda) = \left|\Pr[\mathcal{A}(1^\lambda, X_\lambda) = 1] - \Pr[\mathcal{A}(1^\lambda, Y_\lambda) = 1]\right| \text{ is negligible in } \lambda. \tag{8.6}$$

If the TV distance itself is negligible, so that even unbounded distinguishers gain almost nothing, they are **statistically indistinguishable** ($\approx_s$), and if they are equal, **perfectly indistinguishable** ($\equiv$). By Fact 2, every distinguisher's advantage is at most the TV distance, so $\equiv$ implies $\approx_s$, which implies $\approx_c$.

8.4.3. The hybrid lemma for many samples

Statement. If one sample cannot be told apart, can many? The answer is yes, as long as "many" is polynomial. Let X and Y be efficiently samplable (an efficient algorithm can draw from each) with $X \approx_c Y$, and let $m = m(\lambda)$ be a polynomial. Then m independent copies are still indistinguishable:

$$(X_1, \ldots, X_m) \approx_c (Y_1, \ldots, Y_m). \tag{8.7}$$

Quantitatively, a distinguisher with advantage ν on m copies yields one with advantage ν/m on a single copy, with about the same running time.

Derivation. The idea is to walk from all-X to all-Y by swapping one sample at a time. If the two ends are ν apart, the m steps must add up to ν (Fact 3), so a typical step is worth ν/m. And a single step changes a single sample, so it is a one-sample problem.

1. **Define the hybrids.** Let $H_i = (Y_1, \dots, Y_i, X_{i+1}, \dots, X_m)$: the first i entries come from Y, the rest from X. Then H_0 is all-X and H_m is all-Y, and consecutive hybrids differ in a single position.
2. **Build a one-sample distinguisher.** Given a distinguisher $\mathcal{A}$ for m samples, let $\mathcal{B}$ on a single input z pick a position i uniformly from $\{1, \dots, m\}$, sample $Y_1, \dots, Y_{i-1}$ and $X_{i+1}, \dots, X_m$ itself (this is where efficient samplability is needed), put z in position i, and output $\mathcal{A}(Y_1, \dots, Y_{i-1}, z, X_{i+1}, \dots, X_m)$.
3. **Identify what $\mathcal{A}$ sees.** If $z \sim X$, the tuple handed to $\mathcal{A}$ has $i-1$ entries from Y followed by entries from X, so it is distributed as H_{i-1}. If $z \sim Y$, it has i entries from Y, so it is H_i.
4. **Average over the random position.** Each i is chosen with probability $\frac{1}{m}$, so $\Pr[\mathcal{B}(X) = 1] - \Pr[\mathcal{B}(Y) = 1] = \frac{1}{m} \sum_{i=1}^{m} (\Pr[\mathcal{A}(H_{i-1}) = 1] - \Pr[\mathcal{A}(H_i) = 1])$.
5. **Telescope.** As in Fact 3, but without absolute values, the intermediate terms cancel and the sum equals $\Pr[\mathcal{A}(H_0) = 1] - \Pr[\mathcal{A}(H_m) = 1]$, whose absolute value is $\mathcal{A}$'s advantage ν. So $\mathcal{B}$ has advantage exactly ν/m.
6. **Conclude by contradiction.** Suppose ν were not negligible. Negating Equation 8.5, there would be a c with $\nu(\lambda) \geq \lambda^{-c}$ for infinitely many λ. With $m(\lambda) \leq \lambda^{c'}$ for some exponent c', this gives $\nu/m \geq \lambda^{-(c+c')}$ for those same λ, so the efficient $\mathcal{B}$ would have non-negligible advantage on one sample, contradicting $X \approx_c Y$.

The same argument without the running-time bookkeeping shows $\mathrm{TV}(P_0^{\otimes m}, P_1^{\otimes m}) \leq m\,\mathrm{TV}(P_0, P_1)$, where $P^{\otimes m}$ is the distribution of m independent samples from P.

8.4.4. Interpretation

Every hybrid proof has this shape: a chain from the real world to an ideal world, each step justified by one assumption, and a loss equal to the number of steps. The loss factor m is usually pessimistic, because changing one sample at a time is how the proof is organized, not how the best attacker works. An attacker who sees all m samples at once can pool them, and the example below shows that pooling gains far less than a factor m.

8.4.5. Example: how many flips reveal a biased coin?

X is a fair coin and Y lands heads with probability $\frac{1}{2} + \xi$, with $\xi = 0.01$. From one flip, the best advantage is the TV distance, which is the excess probability of heads, $\xi = 0.01$ (Fact 2). With m flips, the hybrid bound gives at most mh. Table 8.4 and Figure 8.2 compare that with the best possible advantage (the exact TV distance between the two binomial counts of heads) and with a simple distinguisher, majority vote: output 1 iff more than half the flips are heads.

Table 8.4.: Advantage in telling m flips of a 0.51-coin from m fair flips (seed 0, 200,000 simulated games per entry).

Flips m	Majority vote (simulation)	Best possible (TV)	Hybrid bound $\min(1, mh)$
1	0.008	0.010	0.010
100	0.082	0.080	1.000
10,000	0.481	0.683	1.000

The hybrid bound is tight for one sample and loose afterwards, and a normal approximation shows why. The number of heads has mean $m/2$ for the fair coin and $m/2 + mh$ for the biased one, and in both cases a standard deviation of about $\sqrt{m}/2$ (each flip has variance $\frac{1}{4}$ or very close to it). So the two counts are two bell curves whose centres are $mh/(\sqrt{m}/2) = 2\xi\sqrt{m}$ standard deviations apart. The best test puts its threshold where the two curves cross, halfway between the means, at $\xi\sqrt{m}$ standard deviations from each. Write Φ for the standard normal cumulative distribution function, $\Phi(z) = \Pr[Z \le z]$ for $Z \sim \mathcal{N}(0,1)$. The biased count lands above the threshold with probability $\Phi(\xi\sqrt{m})$ and the fair one with probability $1 - \Phi(\xi\sqrt{m})$, so the best advantage is about $2\Phi(\xi\sqrt{m}) - 1$. At $m = 100$, $\xi\sqrt{m} = 0.1$ and $2\Phi(0.1) - 1 = 0.080$; at $m = 10{,}000$, $\xi\sqrt{m} = 1$ and $2\Phi(1) - 1 = 0.683$, the two TV values in the table. The true advantage therefore grows like $\xi\sqrt{m}$, not ξm: the means of the counts separate by mh, but each count fluctuates by about $\sqrt{m}/2$. To reach a constant advantage you need $\xi\sqrt{m}$ of order 1, that is about $1/\xi^2$ samples, while the hybrid bound would allow it after $1/\xi$.

Majority vote stalls at about $\frac{1}{2}$, because its threshold $m/2$ sits at the centre of the fair curve instead of halfway between the two. For large m the biased count is almost surely above $m/2$, but so is the fair count about half the time. At $m = 10{,}000$ the biased mean is $2\xi\sqrt{m} = 2$ standard deviations above $m/2$, so the biased count clears $m/2$ with probability about $\Phi(2) = 0.977$, and $0.977 - 0.5 \approx 0.48$, close to the simulated 0.481. The best test puts the threshold halfway between the two means, at $m/2 + mh/2$ (Exercise 3 in the exercise book).

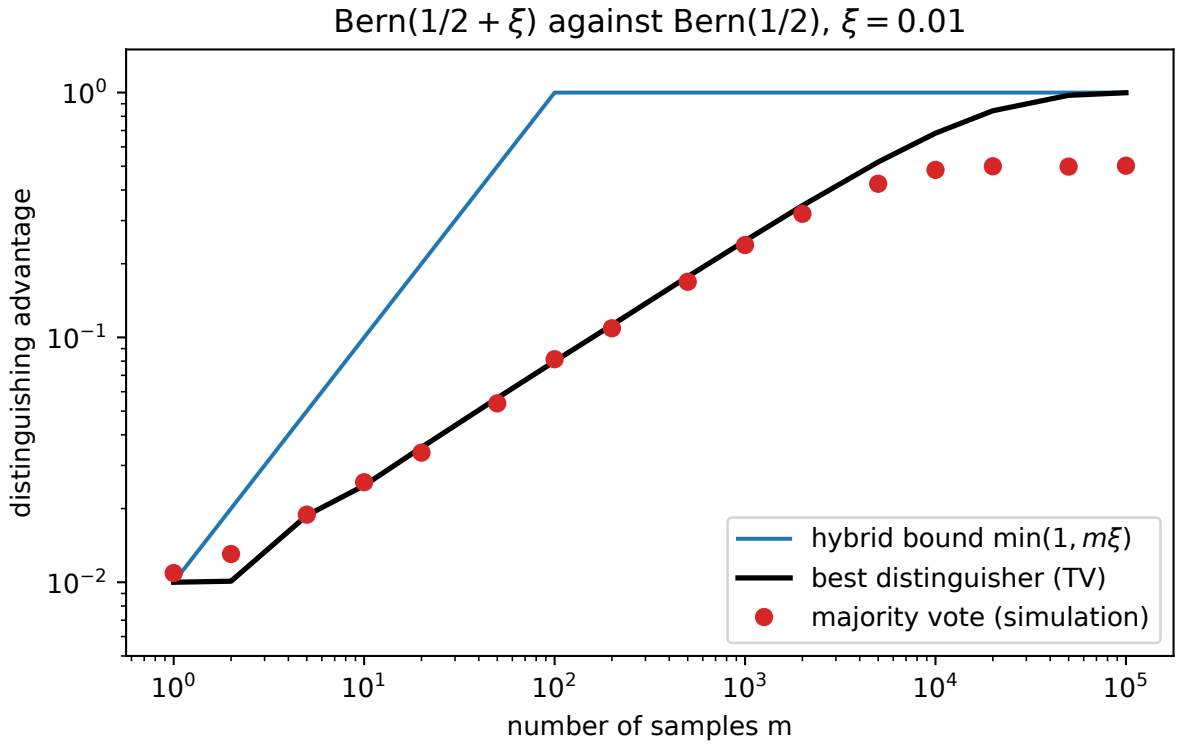

Figure 8.2.: Advantage of telling m flips of a coin with bias $\frac{1}{2} + 0.01$ from fair flips: majority vote (simulation), the best possible distinguisher (exact TV distance), and the hybrid bound mh.

8.4.6. Check yourself

- Where does the hybrid lemma use that X and Y are efficiently samplable? *(In step 2: D' must generate the other $m-1$ entries itself, in polynomial time.)*
- Why does the lemma need m to be polynomial? *(The loss is a factor m. For superpolynomial m, ν/m can be negligible even when ν is not, so step 6 no longer gives a contradiction.)*

8.5. Concrete versus asymptotic security

8.5.1. Context

Real systems fix λ: AES uses 128-bit keys, not "a key of length λ". A statement that holds "for all large enough λ" does not say whether 128 is large enough. Concrete security replaces "PPT" and "negligible" by explicit numbers.

8.5.2. Definition

Instead of "efficient" and "negligible", concrete security names the attacker's resources and the advantage they buy. A primitive is (t, Q, ν)**-secure** if every adversary that runs in time at most t and makes at most Q queries to its oracles (the procedures the game lets it call, such as "encrypt this message for me") has advantage at most ν. Brute force over κ-bit keys sets the benchmark: trying t keys succeeds with probability $t/2^\kappa$. A primitive has κ**-bit security** if, roughly, no attack does better than that: every adversary with time t has advantage at most $t/2^\kappa$.

Security proofs then become **reductions** with explicit losses: "if $\mathcal{A}$ breaks scheme Σ with (t, Q, ν), then $\mathcal{B}$ breaks primitive Π with (t', Q', ν')". Read in reverse, this says that if Π is hard to break, so is Σ, and the losses say how much security is lost on the way. The hybrid lemma is an example with $t' \approx t$ and $\nu' = \nu/m$. A reduction is **tight** when $\nu' \approx \nu$. A loose reduction forces larger parameters for the same guarantee, because the primitive must then be secure against advantages much smaller than the one you want for the scheme.

8.5.3. Example: what 128-bit security buys

Suppose an attacker has an exascale machine that tests 10^{18} keys per second, and runs it for a year. A year is about 3.16×10^7 seconds, so that is about 3.16×10^{25} keys, which is $2^{84.7}$ keys (since $\log_2 10 \approx 3.32$). Each key is right with probability 2^{-128}, so against a 128-bit key it succeeds with probability $2^{84.7-128} = 9.3 \times 10^{-14}$. Trying all 2^{128} keys would take $2^{128}/2^{84.7} = 2^{43.3}$ years, which is 1.08×10^{13} years. The advantage is not zero, but it is smaller than the probability of most hardware failures during the computation.

8.5.4. Example: what a Q-query bound means

The next section derives that a pseudorandom permutation on n-bit blocks is also a pseudorandom function, up to an extra advantage of $Q^2/2^{n+1}$ after Q queries (Equation 8.10). In words, the extra advantage is the probability that Q random n-bit values contain a repeat, which grows with the square of Q. For a 128-bit block cipher, $Q^2/2^{129} = 2^{2k-129}$ when $Q = 2^k$. With 16-byte (128-bit) blocks:

- $Q = 2^{32}$ blocks (2^{36} bytes, 64 GiB of data): at most $2^{64-129} = 2^{-65}$.
- $Q = 2^{48}$ blocks (2^{52} bytes, 4 PiB): at most $2^{96-129} = 2^{-33}$.
- $Q = 2^{64}$ blocks: the bound reaches $2^{128-129} = \frac{1}{2}$ and says nothing.

So a Q-query bound is a data limit. This is why block-cipher modes recommend changing keys long before 2^{64} blocks: the guarantee degrades with the square of the data processed under one key.

8.5.5. Check yourself

- A reduction loses a factor of 2^{20} (it turns advantage ν into $\nu/2^{20}$). If the primitive has 128-bit security, what does the scheme have? *(About $128-20 = 108$ bits: a scheme adversary with advantage ν gives a primitive adversary with advantage $\nu/2^{20} \le t/2^{128}$, so $\nu \le t/2^{108}$.)*
- Why is "(t, ν)-secure" usually summarized by the ratio t/ν? *(An adversary can trade time for success probability, for example by guessing a fraction of the key space: trying t of 2^κ keys gives $\nu = t/2^\kappa$, so the ratio $t/\nu = 2^\kappa$ stays constant along that trade-off.)*

8.6. Pseudorandom generators and functions

8.6.1. Context

Truly random bits are expensive to produce and to share. A short random key is cheap. Pseudorandom generators stretch a short key into a long string, and pseudorandom functions turn it into a huge table of random-looking values that can be looked up on demand. Both are defined by games.

8.6.2. Pseudorandom generators

A generator is pseudorandom if its output, on a random seed, cannot be told from truly random bits by any efficient distinguisher. Write U_k for the uniform distribution on $\{0,1\}^k$, the strings of k bits. A deterministic, efficient $G : \{0,1\}^\lambda \to \{0,1\}^{\ell(\lambda)}$ with $\ell(\lambda) > \lambda$, so that the output is longer than the seed, is a **pseudorandom generator (PRG)** if

$$G(U_\lambda) \approx_c U_{\ell(\lambda)}. \tag{8.8}$$

As a game: the challenger sends either $G(s)$ for a uniform seed s, or a uniform ℓ-bit string, and the adversary guesses which.

A PRG is never statistically secure. The outputs of G form a tiny subset of all ℓ-bit strings, so an adversary that can check membership in that subset wins easily. The catch is that checking takes exponential time. Let $\mathcal{A}(y) = 1$ iff $y = G(s)$ for some seed s.

1. On $G(U_\lambda)$, $\mathcal{A}$ always outputs 1, because the input is an output of G by construction.
2. There are 2^λ seeds, so at most 2^λ of the 2^ℓ strings are outputs of G. On U_ℓ, $\mathcal{A}$ therefore outputs 1 with probability at most $2^\lambda/2^\ell = 2^{\lambda-\ell}$, which is at most $\frac{1}{2}$ because $\ell \geq \lambda + 1$.
3. So $\mathcal{A}$ has advantage at least $1 - \frac{1}{2} = \frac{1}{2}$, and by Fact 2 the TV distance is at least $\frac{1}{2}$. But $\mathcal{A}$ loops over 2^λ seeds. Pseudorandomness is only a statement about efficient distinguishers.

PRGs exist if one-way functions exist (Håstad, Impagliazzo, Levin & Luby 1999). In practice, stream ciphers such as ChaCha20 are modelled as PRGs.

8.6.3. Pseudorandom functions

A **random function** from $\mathcal{X}$ to $\mathcal{Y}$ is a table that assigns each input its own independent, uniform output. A keyed function $F : \{0,1\}^\lambda \times \mathcal{X} \to \mathcal{Y}$, written $F_k(x)$ for key k, is a **pseudorandom function (PRF)** if no efficient adversary can tell whether it is talking to F_k with a random key or to a truly random function. Because the adversary may choose its questions, the game gives it an oracle O, a box it can query, and hides behind a fair coin which function is in the box:

1. The challenger flips b. If $b = 0$ it samples a key k and sets $O = F_k$. If $b = 1$ it sets $O = f$, a uniformly random function from $\mathcal{X}$ to $\mathcal{Y}$.
2. The adversary sends queries $x_1, \ldots, x_Q$, adaptively (each may depend on earlier answers), and receives $O(x_1), \ldots, O(x_Q)$.
3. It outputs a guess b'. Its advantage is $|\Pr[b' = 1 \mid b = 1] - \Pr[b' = 1 \mid b = 0]|$, the gap of Fact 1 between how often it says "random" in the two worlds.

A random function on 128-bit inputs is a table with 2^{128} entries, which nobody can store. A PRF gives the same appearance from a 128-bit key. In practice the hash-based message authentication code (HMAC) is modelled as a PRF; the toy code uses HMAC-SHA256.

8.6.4. From a PRG to a PRF: the GGM tree

Goldreich, Goldwasser & Micali (1986) build a PRF from any length-doubling PRG; the construction is called the GGM tree after them. Split the PRG's output into its two halves, $G(s) = G_0(s) \,\|\, G_1(s)$, each as long as the seed. The idea is to use the PRG repeatedly to grow a binary tree of keys, picking the left or right half at each level according to the next bit of the input.

1. Start at the root with the key, $k_\varnothing = k$.
2. For an input $x = x_1 x_2 \cdots x_n$, walk down the tree: the node reached after the first i bits is $k_{x_1 \cdots x_i} = G_{x_i}(k_{x_1 \cdots x_{i-1}})$, the left or right half of the PRG applied to its parent.
3. Output the leaf: $F_k(x) = k_x$.

Proof sketch. The proof replaces the tree by random values one level at a time. Let hybrid H_j replace every node at depth j by an independent uniform string, sampled when first needed, and compute everything below it with G. H_0 is the real F_k, and H_n, where every leaf is independent and uniform, is a random function. Between H_{j-1} and H_j, the only change is at depth j: in H_{j-1} the nodes there are the two halves of G applied to uniform parents, and in H_j they are uniform. Each query is a path from root to leaf, with one node per depth, so a Q-query adversary touches at most Q parents at depth $j-1$. Telling H_{j-1} from H_j therefore means telling Q outputs of G on uniform seeds from Q uniform strings. By the hybrid lemma that costs at most Q times the PRG advantage. Summing over the n levels (Fact 3): $\mathrm{Adv}_{\mathrm{PRF}} \le nq \cdot \mathrm{Adv}_{\mathrm{PRG}}$. The full proof is in Goldreich, *Foundations of Cryptography*, Vol. 1, §3.6, and Section I.1 in the appendices derives it step by step, including how the reduction handles queries chosen adaptively.

8.6.5. The birthday bound

Statement. Many arguments about random values fail only if two of them coincide, so you need to know how likely a coincidence is. The answer is the birthday bound: among Q values there are about $Q^2/2$ pairs, each pair coincides with probability $1/N$, so collisions become likely once $Q^2/2$ is comparable to N, after about $\sqrt{N}$ draws rather than N. Precisely, draw Q values independently and uniformly from a set of size N. The probability that two of them coincide satisfies

$$1 - e^{-Q(Q-1)/(2N)} \;\le\; \Pr[\text{collision}] \;\le\; \frac{Q(Q-1)}{2N} \le \frac{Q^2}{2N}. \tag{8.9}$$

Derivation. The upper bound counts pairs; the lower bound computes the exact probability of no collision and bounds it with $1 - x \le e^{-x}$.

1. **Upper bound.** There are $\binom{Q}{2} = Q(Q-1)/2$ pairs, and each pair coincides with probability $1/N$ (whatever the first value is, the second matches it with probability $1/N$). A collision means at least one pair coincides, so the union bound (Fact 5) gives $\Pr[\text{collision}] \le Q(Q-1)/(2N)$.
2. **Exact value.** Draw the values one at a time. If no collision has happened yet, the first i values are distinct, and the $(i+1)$-th avoids all of them with probability $1 - i/N$. Multiplying these conditional probabilities, $\Pr[\text{no collision}] = \prod_{i=0}^{Q-1}(1 - i/N)$.
3. **Lower bound.** By $1 - x \le e^{-x}$ applied to each factor, $\Pr[\text{no collision}] \le \exp\big(-\sum_{i<Q} i/N\big) = e^{-Q(Q-1)/(2N)}$, using $\sum_{i<Q} i = Q(Q-1)/2$. Subtracting from 1 gives the lower bound on a collision.
4. **The 50% point.** Setting $1 - e^{-Q^2/(2N)} = \frac{1}{2}$ means $Q^2/(2N) = \ln 2$, so $Q \approx \sqrt{2N \ln 2} \approx 1.18\sqrt{N}$ (since $2 \ln 2 = 1.386$ and $\sqrt{1.386} = 1.18$). Collisions appear after about $\sqrt{N}$ draws, not N.

The two bounds are close. Write $x = Q(Q-1)/(2N)$, so the union bound is x and the lower bound is $1 - e^{-x}$. On $[0, 1]$ the curve $1 - e^{-x}$ is concave (it bends downwards), so it lies above the straight chord joining its values at 0 and 1, which is $(1 - 1/e)x$. So when $x \le 1$, the lower bound is at least $1 - 1/e \approx 0.63$ times the union bound, and the union bound has the right order.

Examples. Table 8.5 gives the exact probability and both bounds for three cases. The union-bound column is $Q(Q-1)/(2N)$; for the class, $23 \times 22/730 = 0.693$.

Table 8.5.: Collision probability, exact against the two bounds of Equation 8.9.

Case	Q	N	Exact	Union bound	$1 - e^{-Q(Q-1)/(2N)}$
Shared birthday in a class	23	365	0.507	0.693	0.500
Hashing trick: 1,000 features into 2^{20} buckets	1,000	2^{20}	0.379	0.476	0.379
Random 32-bit identifiers for 100,000 records	100,000	2^{32}	0.688	1.164	0.688

With the hashing trick, 1,000 features hashed into a million buckets already collide with probability 0.379. Random 32-bit identifiers for 100,000 records are more likely than not to clash; the union bound is above 1 and says nothing.

Figure 8.3 checks Equation 8.9 by simulation for $N = 2^{16}$. At $Q = 256 = \sqrt{N}$ the exact probability is 0.3927, the simulation (100,000 trials) gives 0.3920, and the union bound gives 0.4980. The 50% point is $Q = 301$, in line with $1.18\sqrt{N} = 1.18 \times 256 \approx 302$.

8.6.6. The switching lemma

A block cipher such as AES is a keyed *permutation*: different inputs never give the same output. It is modelled as a **pseudorandom permutation (PRP)**, defined by the PRF game with the random function f replaced by a uniformly random permutation of $\mathcal{X}$ (a random one-to-one shuffle of the inputs). Most proofs, however, want a PRF. The switching lemma bridges the gap. The only visible difference between a random function and a random permutation is that the function sometimes repeats an output and the permutation never does, so an adversary can tell them apart only about as often as Q random values collide.

Statement. For any adversary making Q queries,

$$\left| \Pr[\mathcal{A}^{\text{random function}} = 1] - \Pr[\mathcal{A}^{\text{random permutation}} = 1] \right| \le \frac{Q(Q-1)}{2|\mathcal{X}|} \le \frac{Q^2}{2|\mathcal{X}|}. \tag{8.10}$$

Here $\mathcal{A}^O$ means the adversary run with oracle O.

Derivation. The plan is to run both oracles from the same pre-drawn list of answers, and show they behave identically unless that list contains a repeat.

1. **Simplify the adversary.** Assume its Q queries are distinct: repeating a query teaches it nothing, since both oracles answer the same question the same way every time.

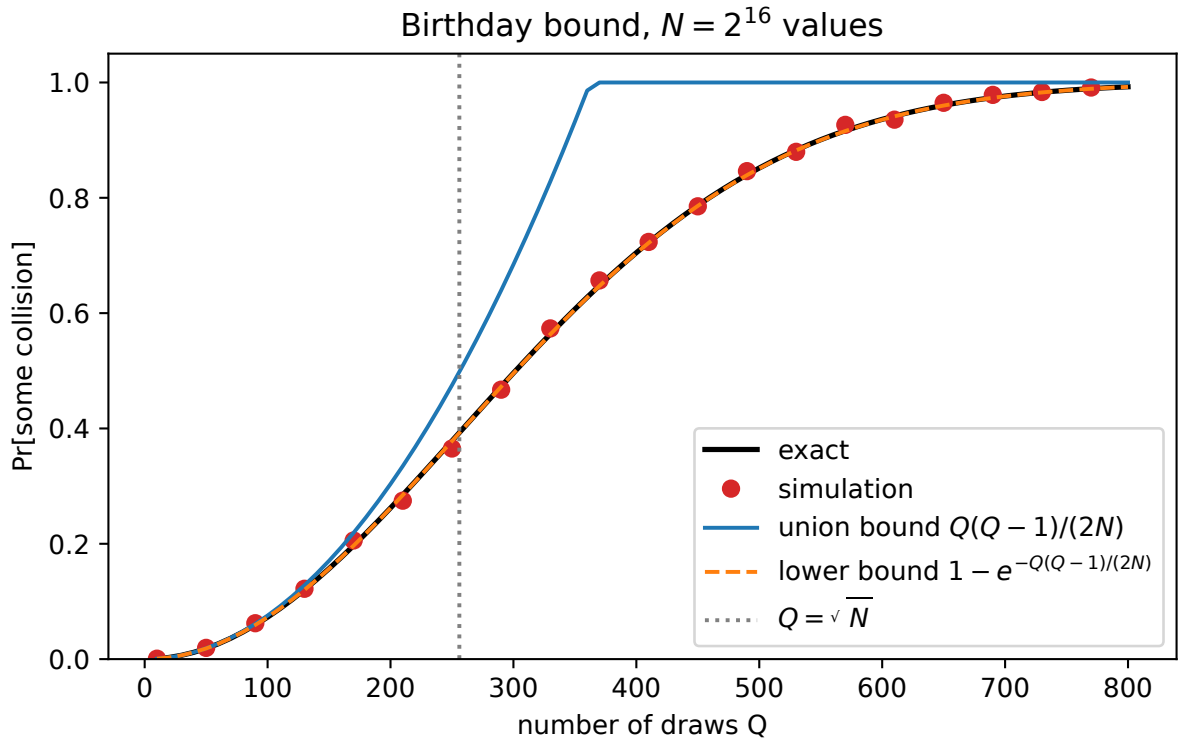

Figure 8.3.: Probability of a collision among Q uniform draws from $N = 2^{16}$ values: exact, simulated, the union bound $Q(Q-1)/(2N)$ and the lower bound $1 - e^{-Q(Q-1)/(2N)}$.

2. **Pre-sample the answers.** The random-function oracle can be run by drawing $Y_1, \dots, Y_Q$ independently and uniformly from $\mathcal{X}$ in advance and answering the i-th query with Y_i. On distinct queries this is exactly a random function, because a random function gives each new input a fresh uniform output.
3. **Do the same for the permutation.** A random permutation answers the i-th distinct query with a value that is uniform over the $|\mathcal{X}| - i + 1$ values not yet used, whatever the queries are: every unused value is the image of the new query under the same number of permutations consistent with the answers so far. So the permutation oracle can be run by pre-sampling a uniformly random sequence of Q *distinct* values.
4. **Compare the two.** Let Col be the event that the list $Y_1, \dots, Y_Q$ of step 2 has a collision. Every list has probability $|\mathcal{X}|^{-Q}$, so conditioning on no collision leaves every list of distinct values equally likely: exactly the permutation's answers. Hence $\Pr[\mathcal{A}^{\mathrm{RF}} = 1 \mid \neg\mathrm{Col}] = \Pr[\mathcal{A}^{\mathrm{RP}} = 1]$, writing RF for the random function and RP for the random permutation.
5. **Bound the difference.** Write $\rho = \Pr[\mathcal{A}^{\mathrm{RP}} = 1]$. Splitting on Col, $\Pr[\mathcal{A}^{\mathrm{RF}} = 1] = \Pr[\mathrm{Col}]\Pr[\mathcal{A}^{\mathrm{RF}} = 1 \mid \mathrm{Col}] + (1 - \Pr[\mathrm{Col}])\,\rho$. Subtracting ρ gives $\Pr[\mathcal{A}^{\mathrm{RF}} = 1] - \rho = \Pr[\mathrm{Col}](\Pr[\mathcal{A}^{\mathrm{RF}} = 1 \mid \mathrm{Col}] - \rho)$. The bracket is a difference of two probabilities, so its absolute value is at most 1, and the whole is at most $\Pr[\mathrm{Col}]$.
6. **Apply the birthday bound** (Equation 8.9) with $N = |\mathcal{X}|$.

The event Col is defined on the pre-sampled answers, before the adversary acts, which is what makes step 4 valid for adaptive adversaries: whatever the adversary does, the answers it receives are the same list. (Bellare & Rogaway 2006 point out that a commonly given proof, which conditions on events defined through the adversary's queries, has a gap; their "identical until bad" game-playing proof is the one above.)

Corollary. If F is a PRP with advantage ν against Q-query adversaries, it is a PRF with advantage at most $\nu + Q^2/(2|\mathcal{X}|)$. This is Fact 3 with three hybrids: going from F_k to a random permutation costs at most ν, and from a random permutation to a random function at most $Q^2/(2|\mathcal{X}|)$.

The bound is tight. The adversary "output 1 iff two answers collide" never outputs 1 against a permutation and outputs 1 against a function with probability exactly $\Pr[\mathrm{Col}]$. So Figure 8.3 is also the advantage of the best adversary in the switching lemma.

8.6.7. Check yourself

- Why can the PRG distinguisher in the "never statistically secure" argument not be used against a real PRG? *(It enumerates all 2^λ seeds, which is not polynomial time.)*
- How many outputs of a 64-bit block cipher can you safely use under one key, if you want the switching term below 2^{-20}? *(Need $Q^2/2^{65} \le 2^{-20}$, so $Q^2 \le 2^{45}$ and $Q \le 2^{22.5}$, about 6 million blocks: a 64-bit block is too small for bulk data.)*

8.7. Encryption: perfect secrecy and IND-CPA

8.7.1. Context

Encryption should hide the message. Shannon's one-time pad hides it perfectly but needs a key as long as all the data. Computational definitions accept a negligible advantage in exchange for short keys. The definition that matters in practice, IND-CPA, has a consequence that surprises many programmers: encryption must be randomized.

8.7.2. The one-time pad and perfect secrecy

Definition. Hiding the message perfectly means that the ciphertext is no more likely to be produced by one message than by another, so seeing it tells you nothing. An encryption scheme has **perfect secrecy** if the ciphertext distribution does not depend on the message: for all messages m, m' and ciphertexts c, $\Pr[\mathrm{Enc}_K(m) = c] = \Pr[\mathrm{Enc}_K(m') = c]$, where K is the random key. Equivalently, seeing c does not change the probability of any message (Shannon 1949). To see the equivalence, let the message $\mathbf{m}$ be random with any prior, write $\mathbf{c}$ for the resulting random ciphertext, and apply Bayes' rule: $\Pr[\mathbf{m} = m \mid \mathbf{c} = c] = \Pr[\mathbf{c} = c \mid \mathbf{m} = m] \Pr[\mathbf{m} = m] / \Pr[\mathbf{c} = c]$. If $\Pr[\mathbf{c} = c \mid \mathbf{m} = m]$ is the same for every m, it equals its average $\Pr[\mathbf{c} = c]$, the ratio is 1, and the posterior equals the prior.

The one-time pad. For n-bit messages, the key K is uniform on $\{0,1\}^n$ and $\mathrm{Enc}_K(m) = m \oplus K$, where $\oplus$ is bitwise exclusive or (XOR): each bit of the message is flipped where the key has a 1.

Derivation of perfect secrecy. Flipping a fixed message's bits by a uniform key gives a uniform result, by Fact 4.

1. Fix m. The map $k \mapsto m \oplus k$ is a bijection of $\{0,1\}^n$: applying it twice gives back k, since $m \oplus m = 0$, so it is its own inverse.
2. By Fact 4, $m \oplus K$ is uniform, whatever m is: $\Pr[\mathrm{Enc}_K(m) = c] = \Pr[K = m \oplus c] = 2^{-n}$, the same for every message.

Table 8.6 shows it for 2-bit messages: each message is sent to every ciphertext by exactly one key.

Table 8.6.: The one-time pad on 2-bit messages. Each row contains every ciphertext once, so the ciphertext is uniform for every message.

Key K	00	01	10	11
Ciphertext for $m = 01$	01	00	11	10
Ciphertext for $m = 10$	10	11	00	01

The price. Perfect secrecy requires at least as many keys as messages. To see why, fix a ciphertext c that occurs. Decryption must work, so each key decrypts c to one message, and at most $|\mathcal{K}|$ messages can produce c. If there are fewer keys than messages, $|\mathcal{K}| < |\mathcal{M}|$, some message m' never produces c, while some other message does, so the ciphertext distributions of those two messages differ. And the pad must not be reused: XOR-ing two ciphertexts under the same pad cancels the pad, $(m_1 \oplus K) \oplus (m_2 \oplus K) = m_1 \oplus m_2$, and reveals the XOR of the two messages.

8.7.3. IND-CPA security

Semantic security (Goldwasser & Micali 1984) says that whatever an efficient adversary can compute about the message from the ciphertext, it could compute without the ciphertext. That is hard to work with directly, because "whatever it can compute" ranges over all functions of the message. It is equivalent to the following game, which is easier to work with: the adversary picks two messages itself, receives an encryption of one of them, chosen by a fair coin, and must say which. If it cannot beat a coin flip even for messages of its own choosing, the ciphertext reveals nothing it could use.

The IND-CPA game (indistinguishability under chosen-plaintext attack):

1. The challenger samples a key k and a fair bit b.
2. The adversary may ask for encryptions $\mathrm{Enc}_k(m)$ of messages of its choice, at any time.
3. It submits two messages m_0, m_1 of equal length and receives the challenge $c^* = \mathrm{Enc}_k(m_b)$.
4. It outputs a guess b'.

The scheme is **IND-CPA secure** if every PPT adversary has negligible advantage $|\Pr[b' = 1 \mid b = 1] - \Pr[b' = 1 \mid b = 0]|$. By Equation 8.2 the win probability is $\frac{1}{2}$ plus half of this gap, so the advantage is also $2|\Pr[b' = b] - \frac{1}{2}|$. The encryption oracle in step 2 models reality: an attacker can often get chosen data encrypted, such as a request it sends or a value it plants in a database.

8.7.4. Why encryption must be randomized

Claim. No deterministic scheme is IND-CPA secure. If encryption always maps the same message to the same ciphertext, the adversary can simply encrypt m_0 itself and compare.

Attack. Ask the oracle for $c_0 = \mathrm{Enc}_k(m_0)$, then submit m_0, m_1. Output $b' = 0$ if $c^* = c_0$ and $b' = 1$ otherwise. If $b = 0$, determinism gives $c^* = c_0$, so $b' = 0$. If $b = 1$, correct decryption forces $\mathrm{Enc}_k(m_1) \neq \mathrm{Enc}_k(m_0)$ (otherwise the same ciphertext would have to decrypt to two messages), so $b' = 1$. The adversary is always right, and the advantage is 1.

The script runs this attack against $\mathrm{Enc}_k(m) = m \oplus F_k(0)$, a deterministic scheme built from the toy PRF. Over 20,000 games for each b the measured advantage is 1.000. The same weakness is visible without any oracle: deterministic encryption of a column of labels maps equal labels to equal ciphertexts, so the frequency of each ciphertext reveals the frequency of each label.

8.7.5. A randomized scheme from a PRF

Construction. The fix is to use a fresh pad for every encryption. Draw a fresh uniform r from a set $\mathcal{R}$ and use $F_k(r)$, a random-looking row of the PRF's table, as a one-time pad; send r along so the receiver can recompute the pad. So $\mathrm{Enc}_k(m) = (r,\ m \oplus F_k(r))$, and to decrypt (r, c) you compute $c \oplus F_k(r)$.

Statement. The scheme can fail in only two ways: the PRF is distinguishable from random, or the challenge reuses an r the adversary has already seen, so its pad is known. The bound adds

the two. For an adversary $\mathcal{A}$ making Q encryption queries, there is a PRF adversary $\mathcal{B}$, with about the same running time, such that

$$\Pr[\mathcal{A} \text{ wins}] \leq \frac{1}{2} + \mathrm{Adv}_{\mathrm{PRF}}(\mathcal{B}) + \frac{Q}{2|\mathcal{R}|}. \tag{8.11}$$

Derivation.

1. **Set up two hybrids. Hybrid 0** is the real game. **Hybrid 1** is the same game with F_k replaced by a truly random function f.
2. **Hybrid 0 to 1 costs the PRF advantage.** $\mathcal{B}$ runs the whole game for $\mathcal{A}$, using its own oracle in place of F_k, and outputs 1 iff $\mathcal{A}$ wins. With oracle F_k, $\mathcal{B}$ simulates hybrid 0; with oracle f, hybrid 1. So the winning probabilities in the two hybrids differ by at most $\mathrm{Adv}_{\mathrm{PRF}}(\mathcal{B})$.
3. **Inside hybrid 1, name the bad event.** Let E be the event that the challenge's r^* equals one of the Q values r_i used by the oracle. Each r_i is independent of r^* and equals it with probability $1/|\mathcal{R}|$, so by the union bound $\Pr[E] \leq Q/|\mathcal{R}|$.
4. **If E does not happen, the challenge is a one-time pad.** Then $f(r^*)$ is a value of the random function at a point never queried, so it is uniform and independent of everything else $\mathcal{A}$ sees. So $c^* = m_b \oplus f(r^*)$ is uniform whatever b is (Fact 4), and $\mathcal{A}$ wins with probability exactly $\frac{1}{2}$.
5. **Combine.** Split the win on whether E happens, and bound the win probability by 1 when it does: $\Pr[\text{win in hybrid 1}] \leq \frac{1}{2}\Pr[\neg E] + \Pr[E] = \frac{1}{2} + \frac{1}{2}\Pr[E] \leq \frac{1}{2} + \frac{Q}{2|\mathcal{R}|}$. Add the loss from step 2.

In advantage units, $\mathrm{Adv} = 2(\Pr[\text{win}] - \frac{1}{2})$, this is $\mathrm{Adv}_{\mathrm{CPA}} \leq 2\,\mathrm{Adv}_{\mathrm{PRF}} + Q/|\mathcal{R}|$. The term $Q/|\mathcal{R}|$ is real, not an artefact of the proof. The script gives the adversary $Q = 16$ encryptions of m_0 with 8-bit nonces ($|\mathcal{R}| = 256$); each reply $(r_i, m_0 \oplus F_k(r_i))$ reveals the pad $F_k(r_i)$. If r^* matches one of them, the adversary removes the pad, reads the challenge, and is always right; otherwise it outputs 1. So it says 1 every time when $b = 1$, and when $b = 0$ it says 1 exactly when there is no match. Its advantage is $1 - (1 - \Pr[E]) = \Pr[E]$, and since r^* misses each of the 16 independent nonces with probability $255/256$, $\Pr[E] = 1 - (255/256)^{16} = 0.0607$. The simulation measures 0.0605, and the bound $Q/|\mathcal{R}|$ is 0.0625. With 128-bit nonces the same attack has advantage below $16/2^{128} = 2^{-124}$ for $Q = 16$.

8.7.6. Check yourself

- Why does the IND-CPA game require $|m_0| = |m_1|$? *(Ciphertext length usually reveals message length. Without the requirement, every practical scheme would be trivially broken by comparing lengths.)*
- In the PRF scheme, where does the proof use that r is fresh for each encryption? *(In step 3: if r could repeat with high probability, E would be likely and the pad $f(r^*)$ would be known.)*

8.8. The simulation paradigm

8.8.1. Context

Encryption hides everything. Many procedures must reveal *something*: a participant learns its own share of a secret, or the final result, and should learn nothing else. "Nothing else" is hard to define directly, because the participant may combine what it sees in clever ways. The simulation paradigm defines it indirectly: whatever the participant sees, it could have produced by itself from what it is allowed to know (Lindell 2017 is a careful tutorial).

8.8.2. Definition

A randomized procedure gives a participant P a **view** $\text{View}_P(x)$: everything P sees during the run, which depends on all inputs x and on the procedure's randomness. P is allowed to learn $L(x)$, its **leakage**: for example its own input and its output. If P could fake its whole view from $L(x)$ alone, the real view cannot contain anything beyond $L(x)$. So the procedure **reveals nothing beyond** L to P if there is an efficient **simulator** S whose output, given only $L(x)$, has the same distribution as the real view:

$$S(L(x)) \equiv \text{View}_P(x) \quad \text{for every input } x. \tag{8.12}$$

Replace $\equiv$ by $\approx_s$ or $\approx_c$ for statistical or computational security.

The two sides are often called the **real world**, where the procedure runs, and the **ideal world**, where a trusted party hands P exactly $L(x)$ and the simulator fakes the rest.

Why this captures "nothing else". Suppose some function g of the view reveals a property of x. Then $g(S(L(x)))$ has the same distribution as $g(\text{View}_P(x))$, because applying the same function to two identically distributed things gives identically distributed results, and it is computed from $L(x)$ alone. So anything the view reveals is already revealed by $L(x)$. Semantic security has the same shape, with $L(m) = |m|$: the ciphertext may reveal the message's length and nothing more.

8.8.3. Worked example: additive secret sharing

Construction. Additive sharing splits a number into random pieces that add up to it, working in $\mathbb{Z}_p$, the integers $\{0, \dots, p-1\}$ with arithmetic mod p. To share a secret $x \in \mathbb{Z}_p$ among h holders, sample $r_1, \dots, r_{h-1}$ uniformly from $\mathbb{Z}_p$ and hand out

$$s_1 = r_1,\ \dots,\ s_{h-1} = r_{h-1}, \qquad s_h = x - (r_1 + \cdots + r_{h-1}) \bmod p. \tag{8.13}$$

All h shares sum to x. Shares also add: if (s_i) shares x and (t_i) shares y, then $(s_i + t_i)$ shares $x + y$.

Statement. Any $h-1$ shares look like independent uniform numbers, whatever the secret is, because the one missing share is what ties them to x. Precisely, any $h-1$ shares are independent and uniform on $\mathbb{Z}_p^{h-1}$, whatever x is. The simulator for a coalition of $h-1$ holders, with no leakage at all, outputs $h-1$ independent uniform elements of $\mathbb{Z}_p$, and Equation 8.12 holds with $\equiv$: perfect security.

Derivation by counting. The plan is to show that the coalition's shares are a one-to-one relabelling of the uniform randomness, and then apply Fact 4.

1. The randomness $(r_1, \dots, r_{h-1})$ is uniform on $\mathbb{Z}_p^{h-1}$: each of the p^{h-1} tuples has probability $p^{-(h-1)}$.
2. Fix x and a coalition that misses holder j. Its shares are a function of the randomness. If $j = h$, the coalition sees $(r_1, \dots, r_{h-1})$ itself. If $j < h$, it sees every r_i with $i \neq j$ together with s_h, and r_j can be recovered uniquely as $r_j = x - s_h - \sum_{i \neq j} r_i$, by rearranging the definition of s_h.
3. Either way the map from randomness to the coalition's shares can be undone, so it is a bijection of $\mathbb{Z}_p^{h-1}$, and every tuple of shares comes from exactly one tuple of randomness (Fact 4).
4. So every tuple of shares has probability $p^{-(h-1)}$, for every x. That is the simulator's output distribution.

Table 8.7 makes step 3 concrete for $h = 2$ and $p = 5$: the second share $x - r$ takes each value exactly once as r runs over $\mathbb{Z}_5$, for both secrets.

Table 8.7.: Two-holder additive sharing in $\mathbb{Z}_5$. Each row is a permutation of $\mathbb{Z}_5$, so the share is uniform for every secret.

r	0	1	2	3	4
Share $x - r \bmod 5$ for $x = 2$	2	1	0	4	3
Share $x - r \bmod 5$ for $x = 4$	4	3	2	1	0

The script repeats the count exhaustively for $h = 3$ and $p = 5$: for every secret and every coalition of two holders, each of the 25 pairs of shares occurs for exactly one of the 25 choices of randomness.

With leakage. If the coalition also learns x (for example because the secret is later published), the simulator receives $L = x$. It samples $h - 1$ uniform shares and sets the last one to x minus their sum. By the statement above, this matches the joint distribution of the real shares and x exactly. This is the typical form of a simulator: random where the view is random, and consistent with the leakage where the leakage pins it down.

8.8.4. Interpretation: perfect, statistical, and broken

Reducing mod p is what makes step 3 a bijection: subtracting r wraps around, so every value is hit once whatever x is. Over the integers it fails, because nothing wraps and the range of the share moves with the secret. Take $x \in \{0, \dots, 7\}$, r uniform on $\{0, \dots, R-1\}$, and the share $x - r$ without reduction. The share is uniform on $\{x - R + 1, \dots, x\}$, an interval of R values that moves with x. For secrets x and x' the two intervals overlap in $R - |x - x'|$ values, so $|x - x'|$ of the R values, each with probability $1/R$, are possible under one secret and impossible under the other. Their TV distance is therefore $|x - x'|/R$, and by Fact 2 that is the best adversary's advantage.

Figure 8.4 shows both cases. With $p = 11$, the shares of $x = 0$ and $x = 7$ have the same flat histogram; the empirical TV distance over 100,000 shares each is 0.0045, which is sampling noise

around the exact value 0. Over the integers with $R = 16$, the supports visibly differ; the empirical TV distance is 0.4423, against the exact $7/16 = 0.4375$. Taking $R = 2^{3+u}$ for secrets below 2^3 makes the TV distance at most $7/2^{3+u}$, which is below 2^{-u}: statistical rather than perfect security.

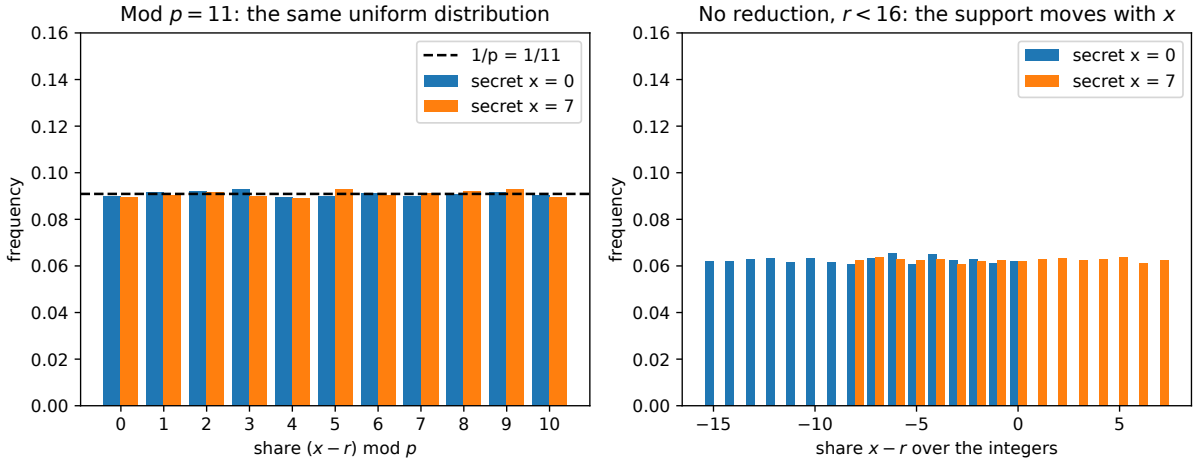

Figure 8.4.: Histograms of the second share for secrets $x = 0$ and $x = 7$. Left: reduced mod $p = 11$, both are uniform. Right: over the integers with $r < 16$, the support shifts with the secret.

8.8.5. Check yourself

- Two of three holders combine their shares of x. What do they learn? *(Nothing: two shares out of three are uniform on $\mathbb{Z}_p^2$ whatever x is. Only all three together determine x.)*
- Why must the simulator be efficient? *(An unbounded simulator could, in a computational setting, invert functions the participant cannot. The definition would then accept procedures whose views reveal information that is hard to compute from $L(x)$ but easy to read from the view.)*

8.9. Learning with errors

8.9.1. Context

Every primitive so far is generic. Learning with errors (LWE) is a specific hard problem, introduced by Regev (2005), with three attractions: it is as hard as worst-case lattice problems, no efficient quantum attack is known, and encryption built on it lets you add ciphertexts. Its one-line description is “linear algebra with noise”, and the noise is everything.

8.9.2. Definition

LWE hides a secret vector behind linear equations whose right-hand sides are slightly wrong. Fix a dimension d, a modulus p (an integer that need not be prime), and an error distribution χ on

small integers. Pick a secret s uniform in $\mathbb{Z}_p^d$, vectors of d integers mod p. An **LWE sample** is a random vector a together with the inner product $\langle a, s\rangle = \sum_j a_j s_j$, perturbed by a small error e:

$$(a,\ b = \langle a, s\rangle + e \bmod p), \qquad a \text{ uniform in } \mathbb{Z}_p^d,\ e \sim \chi. \tag{8.14}$$

There are two versions of the problem. **Search LWE** asks you to find s, given m samples. **Decision LWE** asks you to decide, given m pairs, whether they are LWE samples or uniform pairs in $\mathbb{Z}_p^d \times \mathbb{Z}_p$.

If you can solve search, you can solve decision: find a candidate s, then check whether the values $b - \langle a, s\rangle$ are small, which they are for LWE samples and are not for uniform pairs. So decision is no harder than search. Regev shows the converse for prime p polynomial in d, by guessing the coordinates of s one at a time and using the decision oracle to test each guess. Section I.2 in the appendices derives this reduction step by step.

Hardness. For χ a discretized Gaussian (a normal distribution rounded to integers) of standard deviation about αp with $\alpha p > 2\sqrt{d}$, Regev (2009) proves that solving LWE is at least as hard as solving worst-case lattice problems with a quantum algorithm. The lattice problems are GapSVP, the gap version of the shortest vector problem, and the shortest independent vectors problem, both to within an approximation factor $\tilde{O}(d/\alpha)$ (d/α up to logarithmic factors). Peikert (2009) and Brakerski, Langlois, Peikert, Regev & Stehlé (2013) give classical reductions. Treat these as cited results; the proofs are long.

8.9.3. Without noise, LWE is easy

With $e = 0$, the samples are a linear system $As = b$ over $\mathbb{Z}_p$, where the rows of $\mathcal{A}$ are the vectors a, and Gaussian elimination solves it from d independent equations.

Here it is with $d = 2$, $p = 7$ and $s = (3, 5)$. Take $a_1 = (1, 2)$ and $a_2 = (3, 1)$, so $b_1 = 3{+}10 = 13 \equiv 6$ and $b_2 = 9 + 5 = 14 \equiv 0$.

1. The second equation $3s_1 + s_2 = 0$ gives $s_2 = -3s_1 = 4s_1$, since $-3 \equiv 4 \pmod 7$.
2. Substitute into $s_1 + 2s_2 = 6$: $9s_1 \equiv 2s_1 = 6$, so $s_1 = 3$ and $s_2 = 12 \equiv 5$. Correct.

Now add the error $e = (1, 0)$, so $b = (0, 0)$. The same steps give $s_2 = 4s_1$ and $2s_1 = 0$, so $\hat{s} = (0, 0)$, completely wrong. The reason is that elimination solves $\mathcal{A}\hat{s} = b = As + e$ exactly, so in general it returns $\hat{s} = s + \mathcal{A}^{-1}e$, and $\mathcal{A}^{-1}$ has large entries mod p. Here $\mathcal{A}^{-1} = \begin{pmatrix} 4 & 6 \\ 2 & 4 \end{pmatrix}$ (check: the first row of $\mathcal{A}$ times the first column gives $1 \cdot 4 + 2 \cdot 2 = 8 \equiv 1$), and $\mathcal{A}^{-1}(1, 0) = (4, 2)$, which shifts s to $(7, 7) \equiv (0, 0)$. A unit error is amplified into a uniformly scrambled answer.

The script does the same at $d = 16$ and $p = 4096$ with 32 samples. (Mod a power of two, elimination may only divide by odd numbers, the invertible ones, so it picks odd pivots.) Without noise it recovers all 16 coordinates of s. With errors in $\{-1, 0, 1\}$, it recovers 0 of 16.

8.9.4. Regev's symmetric bit encryption

Construction. Picture $\mathbb{Z}_p$ as a clock with p positions. To encrypt a bit, take an LWE sample and move its b halfway round the clock if the bit is 1. Whoever knows s can subtract $\langle a, s\rangle$ and see whether what remains is near 0 or near halfway; the small error does not hide that. Concretely, take p even. The key is $s \in \mathbb{Z}_p^d$. To encrypt a bit m, draw a fresh a and $e \sim \chi$ and output

$$\mathrm{Enc}_s(m) = (a,\ b = \langle a, s\rangle + e + m \cdot \tfrac{p}{2} \bmod p). \tag{8.15}$$

To decrypt, compute $v = b - \langle a, s\rangle \bmod p$ and output 1 if v is closer to $p/2$ than to 0 (counting distance round the clock, so that values just below p are close to 0), that is if $p/4 < v < 3p/4$.

Statement (correctness). Decryption is correct whenever $|e| < p/4$.

Derivation. Removing $\langle a, s\rangle$ leaves the error plus the encoded bit; the error is too small to move it across the decision boundary.

1. $v = e + m\frac{p}{2} \bmod p$, by the definition of b.
2. If $m = 0$, $v \equiv e$ with $|e| < p/4$, so $v \in [0, p/4) \cup (3p/4, p)$ (a negative e wraps to just below p) and the output is 0.
3. If $m = 1$, $v = e + p/2 \in (p/4, 3p/4)$ and the output is 1.

Security, in one hybrid. Without s, the pair $(a, \langle a, s\rangle + e)$ looks uniform by decision LWE, so the message is added to something that looks uniform: a one-time pad. Under decision LWE, the pairs $(a, \langle a, s\rangle + e)$ in all ciphertexts can be replaced by uniform pairs (a, u). Then $b = u + m \cdot \frac{p}{2}$ is uniform whatever m is (Fact 4, with the bijection "add $m \cdot \frac{p}{2}$"). So an IND-CPA adversary winning with probability $\frac{1}{2} + \nu$ yields a decision-LWE distinguisher with advantage ν: it runs the game with the given pairs and outputs 1 iff the adversary wins, by the argument of step 2 in the PRF scheme.

Worked example with $d = 3$, $p = 4096$ and $s = (5, 1000, 3000)$. Here $p/2 = 2048$, and reducing mod 4096 means subtracting 4096.

- Encrypt $m = 1$ with $a_1 = (17, 2, 1)$ and $e_1 = -7$: $\langle a_1, s\rangle = 85 + 2000 + 3000 = 5085 \equiv 5085 - 4096 = 989$, so $b_1 = 989 - 7 + 2048 = 3030$. Decrypting, $v = 3030 - 989 = 2041$, which is 7 from $p/2 = 2048$: the output is 1.
- Encrypt $m = 1$ with $a_2 = (1, 1, 1)$ and $e_2 = 12$: $\langle a_2, s\rangle = 4005$, so $b_2 = 4005 + 12 + 2048 = 6065 \equiv 1969$.

8.9.5. Adding ciphertexts, and the noise budget

Statement. Because everything in a ciphertext is linear in a, the error and the encoded bit, adding ciphertexts adds all three. The bits add mod 2, since two half-turns round the clock are a full turn, and the errors pile up. So the componentwise sum of ciphertexts of $m_1, \ldots, m_k$ is a ciphertext of $m_1 \oplus \cdots \oplus m_k$ with error $e_1 + \cdots + e_k$. If every $|e_i| \le B$, the total error is at most kB, and it decrypts correctly whenever

$$k < \frac{p}{4B}. \tag{8.16}$$

Derivation.

1. The sum is $(\sum_i a_i,\ \sum_i b_i)$. By linearity of the inner product, $\sum_i b_i - \langle \sum_i a_i, s\rangle = \sum_i e_i + (\sum_i m_i)\frac{p}{2} \bmod p$.
2. Because p is even, $2 \cdot \frac{p}{2} = p \equiv 0$, so only the parity of $\sum_i m_i$ survives: $(\sum_i m_i)\frac{p}{2} \equiv (m_1 \oplus \cdots \oplus m_k)\frac{p}{2}$.
3. So the sum is an encryption of the XOR with error $\sum_i e_i$, and $|\sum_i e_i| \le kB$ by the triangle inequality. By the correctness statement, $kB < p/4$ suffices.

In the worked example, the sum is $a_1 + a_2 = (18, 3, 2)$ and $b_1 + b_2 = 4999 \equiv 903$. Then $\langle (18, 3, 2), s\rangle = 9090 \equiv 898$, and $v = 903 - 898 = 5 = e_1 + e_2$: it decrypts to $0 = 1 \oplus 1$.

Interpretation: the worst case and the typical case. Equation 8.16 is a worst-case guarantee: it assumes every error is as large as possible and all have the same sign. Independent errors with mean zero mostly cancel. Variances of independent variables add, so the sum of k errors with standard deviation σ has standard deviation $\sigma\sqrt{k}$, not kB. With χ uniform on the $2B + 1$ values $\{-B, \dots, B\}$, the variance is the average of j^2 over those values, $2\sum_{j=1}^{B} j^2/(2B + 1) = 2 \cdot \frac{B(B+1)(2B+1)}{6}/(2B + 1) = B(B + 1)/3$. By the central limit theorem the sum is approximately normal, and decryption fails when the summed error, read round the clock, lands more than $p/4$ from 0. So the normal approximation predicts

$$\Pr[\text{failure after } k \text{ additions}] \approx \Pr\left[\left|Z\sqrt{kB(B+1)/3}\right| > p/4 \text{ after wrapping mod } p\right], \quad Z \sim \mathcal{N}(0, 1). \tag{8.17}$$

Figure 8.5 and Table 8.8 compare the two for $p = 4096$ and $B = 32$, where Equation 8.16 guarantees correctness for $k < 32$ (since $p/(4B) = 4096/128 = 32$). The simulation adds k real toy ciphertexts (with $d = 4$) of random bits, 20,000 times, and checks the decrypted XOR.

Table 8.8.: Decryption failure rate of a sum of k Regev ciphertexts, $p = 4096$, errors uniform on $\{-32, \dots, 32\}$ (seed 0, 20,000 trials).

Ciphertexts added k	Empirical failure rate	Normal approximation
1	0.0000	0.0000
31	0.0000	0.0000
256	0.0007	0.0006
1,024	0.0868	0.0881
4,096	0.3814	0.3833

To see where a row comes from, take $k = 1024$: the standard deviation of the summed error is $\sqrt{1024 \times 32 \times 33/3} \approx 600$, and $p/4 = 1024$ is about 1.7 standard deviations, which a normal variable exceeds in absolute value with probability about 0.088. At $k = 256$ the standard deviation is about 300 and $p/4$ is 3.4 standard deviations away, far in the tail.

The worst-case budget is therefore very conservative. Failures only become measurable around $k = 256$, eight times the guaranteed 32, because the noise grows like $\sqrt{k}$ rather than k. But the budget is still finite. Once the noise is comparable to $p/4$, the decrypted value is spread round the whole clock, decryption becomes a coin flip, and the failure rate tends to $\frac{1}{2}$. Larger p (relative to the noise) buys more additions; that is the parameter trade-off of every LWE-based scheme that computes on ciphertexts.

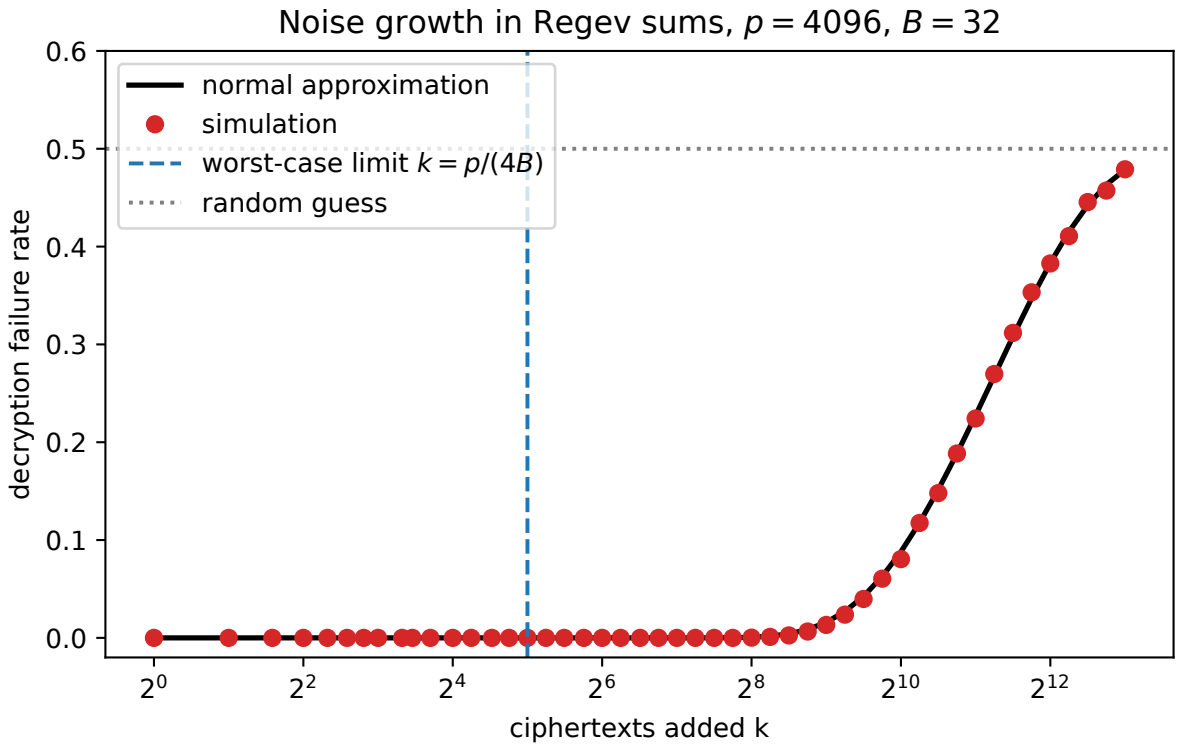

Figure 8.5.: Decryption failure rate of a sum of k Regev ciphertexts ($p = 4096$, errors uniform on $\{-32, \ldots, 32\}$): simulation against the normal approximation. The dashed line is the worst-case guarantee $k < p/(4B) = 32$.

8.9.6. Ring-LWE, briefly

A Regev ciphertext carries one bit in $d+1$ numbers, and the key has d numbers. Ring-LWE packs much more into the same space by replacing vectors with polynomials. **Ring-LWE** (Lyubashevsky, Peikert & Regev 2010) replaces vectors in $\mathbb{Z}_p^d$ by polynomials in $R_p = \mathbb{Z}_p[X]/(X^N+1)$, that is, polynomials of degree below N with coefficients mod p, multiplied with the rule $X^N = -1$, and replaces the inner product by polynomial multiplication. One ring sample $(a, a \cdot s + e)$ stands for N correlated LWE samples, carries N message coefficients, and is computed in $O(N \log N)$ time with the number-theoretic transform, a fast Fourier transform for arithmetic mod p. Its hardness rests on lattice problems restricted to ideal lattices, which have this extra structure. A middle ground, module-LWE, underlies the standardized key-encapsulation mechanism ML-KEM (FIPS 203, 2024).

8.9.7. Check yourself

- Why does p have to be even in the addition argument, and what happens for odd p with $\lfloor p/2 \rfloor$ as the encoding? *(For odd p, $2\lfloor p/2 \rfloor = p - 1 \equiv -1$, so every pair of 1-bits adds an extra error of -1. The error drifts by about $k/4$ on top of the random part.)*
- Is the LWE problem with χ uniform on $\{-B, \dots, B\}$ covered by Regev's theorem? *(Not directly. The theorem is for a Gaussian-shaped error; other small distributions need separate arguments. The toy uses a uniform error only because its worst case is easy to state.)*

8.10. Code: check the numbers by simulation

The script code/crypto_basics.py computes every number quoted in this chapter and draws its figures. Each bound, probability and toy scheme is a small typed function; the script calls them once for the table and loops them over parameters for the figures. From the repository root:

```
uv run python code/part01-prerequisites/crypto_basics.py
```

Table 8.9 summarizes the output (seed 0).

Table 8.9.: Output of the chapter's script (seed 0).

Experiment	Result
Example functions at $\lambda = 128$	$2^{-128} = 2.9 \times 10^{-39}$; $\lambda^{-\log_2 \lambda} = 1.8 \times 10^{-15}$; $2^{-\sqrt{\lambda}} = 3.9 \times 10^{-4}$; $\lambda^{-10} = 8.5 \times 10^{-22}$.
	$2^{-\sqrt{\lambda}} < \lambda^{-10}$ from $\lambda = 20{,}520$
Brute force at 10^{18} keys/s for a year	$2^{84.7}$ keys; success 9.3×10^{-14} against 128 bits; 1.08×10^{13} years for all 2^{128}
Birthday, $N = 2^{16}$, $Q = 256$	Exact 0.3927; simulated 0.3920; union bound 0.4980; 50% at $Q = 301$

Experiment	Result
Biased coin, $\xi = 0.01$	$m = 1$: majority 0.008, best 0.010, hybrid 0.010. $m = 100$: 0.082, 0.080, 1.000. $m = 10{,}000$: 0.481, 0.683, 1.000
IND-CPA, deterministic scheme	Advantage 1.000
IND-CPA, PRF scheme, $Q = 16$, 8-bit nonce	Simulated 0.0605; exact 0.0607; bound 0.0625
Secret shares, $x = 0$ against $x = 7$	Mod 11: TV 0.0045 (exact 0). Integers, $R = 16$: TV 0.4423 (exact 0.4375)
Gaussian elimination, $d = 16$, $p = 4096$	16/16 coordinates without noise; 0/16 with errors in $\{-1, 0, 1\}$
Regev sums, $p = 4096$, $B = 32$	See Table 8.8

tests/test_crypto_basics.py checks that the output still matches.

What to take from it. Asymptotic statements need concrete numbers, because a negligible function can be large at the parameter you use: at $\lambda = 128$, $2^{-\sqrt{\lambda}}$ is still 3.9×10^{-4}. The birthday bound is the right order and nearly tight: while it is below 1, the union bound overestimates the collision probability by at most a factor of about 1.6 (that is $1/(1 - 1/e)$, from the chord argument), and the switching lemma's best adversary attains the exact collision probability. Hybrid bounds are safe but can be loose: for the biased coin they overstate the advantage by a factor up to $\sqrt{m}$, because the hybrid argument pays ξ per flip while the true advantage grows like $\xi\sqrt{m}$. Determinism is fatal, and short nonces leak exactly as the proof predicts. Finally, noise is what makes LWE hard and what limits computing on its ciphertexts. Without it, elimination solves the problem; with it, every addition spends part of a finite budget.

8.12. Cheat sheet

Table 8.10 collects the results of this chapter.

Table 8.10.: Summary of the definitions and bounds in this chapter.

Result	Statement
Advantage	$\mathrm{Adv} = \lvert\Pr[\mathcal{A}(X)=1] - \Pr[\mathcal{A}(Y)=1]\rvert = 2\lvert\Pr[\mathrm{win}] - \frac{1}{2}\rvert$
Best unbounded distinguisher	Advantage $= \mathrm{TV}(X, Y)$
Negligible	$\mu(\lambda) < \lambda^{-c}$ eventually, for every c; closed under $\times$ poly and $+$
Hybrid lemma	m samples: advantage at most m times the one-sample advantage
Birthday bound	$1 - e^{-Q(Q-1)/(2N)} \le \Pr[\mathrm{collision}] \le Q(Q-1)/(2N)$; 50% at $Q \approx 1.18\sqrt{N}$
PRP/PRF switching	Extra advantage $\le Q^2/(2\lvert\mathcal{X}\rvert)$, and tight
GGM	$\mathrm{Adv}_{\mathrm{PRF}} \le nq \cdot \mathrm{Adv}_{\mathrm{PRG}}$
One-time pad	Perfect secrecy; needs $\lvert\mathcal{K}\rvert \ge \lvert\mathcal{M}\rvert$; never reuse the pad
IND-CPA	Deterministic schemes have advantage 1; $(r, m \oplus F_k(r))$ has $\Pr[\mathrm{win}] \le \frac{1}{2} + \mathrm{Adv}_{\mathrm{PRF}} + Q/(2\lvert\mathcal{R}\rvert)$
Simulation	Secure if $S(L(x)) \equiv$ (or $\approx$) $\mathrm{View}(x)$ for all x
Additive sharing in $\mathbb{Z}_p$	Any $h-1$ shares uniform: perfect security
LWE	$(a, \langle a, s\rangle + e)$; easy without e by elimination
Regev bit encryption	Correct if $\lvert e\rvert < p/4$; sums of k ciphertexts correct if $kB < p/4$; typical noise $\sim \sigma\sqrt{k}$

Rules of thumb

- Security of κ bits means an attacker with time t succeeds with probability about $t/2^{\kappa}$.
- Anything random of κ bits starts colliding after about $2^{\kappa/2}$ draws: budget identifiers, nonces and block counts accordingly.
- Encryption that hides equality must be randomized.
- In LWE schemes, noise is a budget: each operation spends some, and decryption fails when it runs out.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

Part II.

Threat models and attacks

This part teaches you to break models before it teaches you to protect them. Every defence in the rest of the book is measured against an attack: a guarantee is only as meaningful as the strongest adversary it stops, and an evaluation is only as honest as the attack it runs. So you start here, with the adversaries, what they see, what they want, and how well the best of them can do.

Who this part is for

You are expected to have read the Prerequisites, or to know their content. This part leans hardest on hypothesis testing (the Neyman–Pearson lemma, trade-off curves, receiver operating characteristic (ROC) curves read at a low false positive rate), on the total variation distance, and on the link between stability and generalization. Information theory appears in the chapters on attribute inference, memorization and linkage. You should also be comfortable with logistic regression, gradients of a small neural network, and an n-gram language model at the level of writing them in NumPy.

Differential privacy, the defence most of the book is about, is introduced in the next part, and it is designed against exactly the games defined here. The only privacy definitions in this part are the syntactic ones of the last chapter, k-anonymity and its successors, and they appear as targets: the chapter shows what each one promises and the attack that breaks it.

The common thread

Every attack in this part is the same object: a **game** in which a challenger trains or releases something that depends on a hidden **secret**, and an adversary guesses the secret from what the **threat model** lets it see. What changes from chapter to chapter is the secret: one bit of membership, a sensitive attribute, a memorized string, the whole dataset, a client's input, a property of the population behind the data, or a person's name. Table 8.11 lists them.

Table 8.11.: The chapters of this part, the question each one answers, and the earlier chapters it uses.

Chapter	The question it answers	Builds on
Threat models and privacy games	What can an adversary see and do, and how is an attack stated and scored?	3, 4, 8
Membership inference	Was this record in the training set?	4, 7, 9
Attribute inference and model inversion	Does the model reveal a person's sensitive attribute beyond what the population already does?	4, 5, 9, 10
Property inference	Can a model reveal a fact about its training population that no single record reveals?	3, 4, 9, 10

Chapter	The question it answers	Builds on
Memorization and training-data extraction	Can the model be made to emit its training text, and when?	5, 7, 9, 10
Gradient inversion	What does a gradient computed on private data reveal about that data?	6, 9
Linkage and re-identification	When does removing or hashing names fail to hide who a record belongs to?	1, 2, 5, 8, 9
Syntactic anonymity and how it breaks	What do k-anonymity, l-diversity and t-closeness guarantee, and which attacks get past each?	1, 3, 5, 11, 15
Reconstruction attacks	How many accurate statistics does it take to rebuild a whole private dataset?	2, 5, 9

Two ideas run through all nine chapters.

- **An attack is a hypothesis test.** When the secret is one bit, the best attack is the likelihood-ratio test of the Neyman–Pearson lemma, its **advantage** (true positive rate (TPR) minus false positive rate (FPR)) is at most the total variation distance between the adversary's two possible views, and its whole error trade-off is bounded by one curve. Membership inference, attribute inference and property inference are each this statement with a different pair of views. The strongest practical attacks, such as the likelihood ratio attack (LiRA) on membership, are explicit approximations of the optimal test.
- **The worst case is not the average case.** Attacks succeed first on outliers, on duplicated strings, on unique combinations of attributes and on the one example in a batch that a neuron isolates. An average over records can look harmless while a few records are fully exposed. This is why attacks are reported as the TPR at a low FPR rather than as accuracy or area under the curve (AUC), and why the defence of the next part has to hold for every record and every dataset.

A third idea closes the part and frames what comes after it. Reconstruction attacks show that answering too many statistics too accurately destroys privacy no matter how the answers are computed: this is the **Fundamental Law of Information Recovery**. Some noise is not optional, and the question becomes how little noise is enough.

The second half of the part also tells one story about releasing less. Releasing records with the names removed or replaced by codes fails to linkage. Releasing only coarsened records fails to attacks on the sensitive attribute. Releasing only statistics fails to reconstruction, and adding a fixed amount of noise to each statistic fails once enough of them are asked, as an attack on a deployed query system shows. A few hundred published averages can even reveal whether one person is in the data, the tracing attack of Lower bounds. Each step releases less and still fails, which is the motivation for the definition of the next part.

How to read this part

Order. The part opens with chapter 9, which sets up the vocabulary, and then has two halves. Chapters 10 to 14 attack trained models, from the smallest secret to the largest: one bit of membership, a sensitive attribute, a property of the training population, memorized text, and whole inputs recovered from gradients. Chapters 15 to 17 attack released data, from the weakest defence to the strongest: names removed (linkage), records hidden in crowds (syntactic anonymity), and only aggregate statistics published (reconstruction).

Read chapter 9 first. It fixes the vocabulary (challenger, adversary, view, game, advantage, baseline) that the others use without redefining. Then read chapter 10, since membership inference is the reference attack that chapters 11, 12 and 13 extend. Chapters 11 to 14 can then be read in any order. Read chapters 15 to 17 in order: chapter 16 starts from the linkage game of chapter 15 and uses the imputation baseline of chapter 11, and chapter 17 shows that even exact aggregate statistics, with no records released at all, give the data away. Chapters 16 and 17 matter most for what comes next: the attacks of chapter 16 are the requirements the next part's definition is built to meet, and the results of chapter 17 return as lower bounds there.

Structure of a chapter. Every chapter has the same shape as in the prerequisites: why the topic matters, a toolkit, one section per result with a context, statement, derivation, interpretation, worked example and two *check yourself* questions, then code, references and a cheat sheet. Exercises with worked solutions are collected in the exercise book, a companion website, with a link at the end of each chapter.

Toy experiments, real pipelines. The attacks in the literature run on image classifiers and large language models trained on GPUs. Here every experiment is a NumPy toy that runs in seconds: logistic regression on synthetic data, Gaussian mean estimation, a small multilayer perceptron written by hand, an n-gram language model with planted canaries. Each toy is chosen so that the optimal attack can be computed exactly and compared with the practical one. Where the published experiment needs a full pipeline (such as LiRA with 16 shadow models on CIFAR-10), the chapter describes that pipeline in prose and runs a faithful scaled-down version.

Run the code. From the repository root, for example,

```
uv run python code/part02-attacks/membership_inference.py
```

The scripts use fixed seeds, so their output matches the tables in the text.

Notation

The chapters share the conventions in Table 8.12, set in Threat models and privacy games. Where a chapter departs from them, it says so at its start.

Table 8.12.: Notation shared by the chapters of this part.

Symbol	Meaning
D, $\mathcal{D}$	A dataset of records; the data distribution (the population) they are drawn from
$\mathcal{T}$, $\theta = \mathcal{T}(D)$	A (possibly randomized) training algorithm, and the model it outputs
$\mathcal{A}$	The adversary
b, b'	The hidden bit of a two-world game, and the adversary's guess; $b = 1$ is the world where the target record is used (the member world)
π	A prior over a secret; π_1 is the prior probability of $b = 1$
V; P, Q	The adversary's view; its distributions when $b = 0$ and $b = 1$
TPR, FPR	$\Pr[b' = 1 \mid b = 1]$ and $\Pr[b' = 1 \mid b = 0]$
Adv	The advantage, TPR $-$ FPR, at most $\mathrm{TV}(P, Q)$
$T(P, Q)$	The trade-off function: the smallest false negative rate $1 - \mathrm{TPR}$ of any test at each FPR
$\ell(\theta; z)$	The loss of model θ on record z

What you will be able to do

By the end of this part you should be able to:

- state any privacy attack as a game, name its threat model and its baseline, and bound its advantage by a total variation distance;
- derive the loss-threshold membership attack from the generalization gap and LiRA from the Neyman–Pearson lemma, and evaluate both by the TPR at a low FPR;
- separate attribute inference from what the population already reveals, and say why masking confidences does not stop it;
- explain how a property of the training population can leak when no individual record does;
- define verbatim, discoverable and extractable memorization, and compute a canary's exposure;
- recover an input exactly from the gradient of a fully connected layer, and say why averaging a batch does not remove the leak;
- invert a hashed identifier by enumeration, compute the fraction of a population made unique by a set of quasi-identifiers, and run a Netflix-style de-anonymization;
- say what k-anonymity, l-diversity and t-closeness each guarantee, and break each one with homogeneity, skewness and composition attacks;
- prove that answers with error $o(\sqrt{n})$ to random subset sums allow almost all of a dataset to be reconstructed, and predict how many queries an attack on a deployed query system needs.

Each of these is a result derived in one of the chapters that follow.

9. Threat models and privacy games

9.1. Why this matters

A hospital trains a model on patient records and offers it to doctors through a web service. Is the model "private"? The question has no answer until you say **against whom**. Can the attacker only send inputs and read predicted labels, or does it hold the weights? Does it know the other patients in the training set, or only what the population looks like? Does it follow the rules of the service, or does it also slip crafted records into the training data? And what does it want: to learn that one person was a patient, to learn their diagnosis, or to rebuild the whole table? A **threat model** answers these questions. Without one, "the model leaks" and "the model is safe" are both untestable claims.

Once the threat model is fixed, an attack can be written down as a **game**, the way cryptographers write down attacks on encryption. A **challenger** runs the training pipeline with some hidden **secret**, such as whether one patient's record was used. It hands the **adversary** what the threat model allows it to see, and the adversary guesses the secret. An attack is good if it guesses better than someone who never saw the model.

That is the one idea of this chapter: **an attack is a guess about a hidden secret, made from a view that the threat model fixes.** When the secret is a single bit, such as "was this patient in the training set?", the game is a hypothesis test, so everything in Hypothesis testing carries over. The attack's **advantage** is its true positive rate (TPR) minus its false positive rate (FPR). No attack can push it above the total variation (TV) distance between what the adversary sees in the two worlds, and one curve bounds the attack's whole error trade-off.

The chapter builds this up in four steps. It first lists what a threat model has to specify, and proves the one ordering that always holds: more access never makes the adversary weaker. It then writes the attacks of this part as games, each with its own baseline. Next it turns the hypothesis-testing results into ceilings on any attack, and explains why the low false-positive end of the curve is where privacy is really lost. Finally it shows how far apart the average-case and worst-case versions of the same game can be. Every later chapter of this part is an instance of these games: membership inference, attribute inference, dataset properties and reconstruction. Table 9.1 lists the results and where they are used.

Table 9.1.: The results of this chapter and where each is used.

Result	Where it is used
Threat-model taxonomy: access, behaviour, trust, side information	Stating what an attack assumes, before reading any number it reports

Result	Where it is used
More access never lowers the best advantage	Comparing label-only, black-box and white-box attacks
Privacy games: membership, attribute, reconstruction, distinguishing	A precise definition of every attack in this part
Baselines and the Bayes-optimal guess	Telling an attack apart from a good guess about the population
Advantage $\leq$ TV; attack's error curve below the trade-off curve	The ceiling every attack runs into; the target defences aim at
TPR at a low FPR, precision	How attacks are evaluated in practice
Average case $\leq$ worst case	Why a defence must hold for every record and every dataset

What this chapter assumes. The hypothesis-testing vocabulary (type I and II errors, the Neyman–Pearson lemma, the trade-off function $T(P, Q)$, receiver operating characteristic (ROC) curves) is in Hypothesis testing. The total variation distance and the hockey-stick divergence E_γ are in Divergences. Security games and advantage, in their cryptographic form, are in Cryptography basics. No privacy definition is introduced here: this part only attacks. The definition that defends against these games comes in Part 3.

Conventions. D is a dataset of records drawn from a population, the data distribution $\mathcal{D}$. A training algorithm $\mathcal{T}$ maps D to a model $\theta = \mathcal{T}(D)$, possibly at random. In a two-world game a hidden bit b selects the world: $b = 1$ is the world in which the target's record is used ("member", the alternative hypothesis), and $b = 0$ the world in which it is not (the null). Everything the adversary gets to look at, including what it knew beforehand, is its **view** V. P and Q are the distributions of V when $b = 0$ and $b = 1$. An attack outputs a guess b', 1 for "member" and 0 for "not a member". Two numbers describe how it behaves. Its **true positive rate** is the fraction of members it correctly flags, and its **false positive rate** is the fraction of non-members it wrongly flags:

$$\text{TPR} = \Pr[b' = 1 \mid b = 1], \qquad \text{FPR} = \Pr[b' = 1 \mid b = 0]. \tag{9.1}$$

9.2. Toolkit: three facts every derivation uses

9.2.1. Fact 1 — A game with a hidden bit is a hypothesis test

The challenger flips the hidden bit before anything else happens: $b = 1$ with probability π_1 and $b = 0$ with probability $\pi_0 = 1 - \pi_1$. The adversary then sees its view and announces b'. It wins when its guess matches the hidden bit, whichever value the bit has: $b' = b$ means "$b' = 1$ and $b = 1$, or $b' = 0$ and $b = 0$". So $\Pr[b' = b]$ is the probability that the guess is correct, taken over the challenger's coin flip and everything else that is random in the game. It is not the probability that b is 1, which is just π_1. The probability of a correct guess is

$$\Pr[b' = b] = \pi_1 \,\mathrm{TPR} + \pi_0 \,(1 - \mathrm{FPR}). \tag{9.2}$$

Derivation. The idea is to split the games by which world the challenger chose, count the wins in each world, and add.

1. **Split the win into the two worlds.** There are exactly two ways to win: the bit is 1 and the attack says 1, or the bit is 0 and the attack says 0. In a single game the bit has one value, either 1 or 0, so a game can win in one of these ways or the other, never both. Events that cannot happen together are called **disjoint**, and the probability that one of two disjoint events happens is the sum of their probabilities. Counting games shows why: if you count the games won with $b = 1$ and the games won with $b = 0$, every won game is counted exactly once, because no game belongs to both groups. (For events that can overlap you would have to subtract the overlap, which here is empty.) So

$$\Pr[b' = b] = \Pr[b = 1 \text{ and } b' = 1] + \Pr[b = 0 \text{ and } b' = 0]. \tag{9.3}$$

2. **Write each joint probability as "prior times conditional".** For any two events, $\Pr[A \text{ and } B] = \Pr[A]\Pr[B \mid A]$. So $\Pr[b = 1 \text{ and } b' = 1] = \Pr[b = 1]\Pr[b' = 1 \mid b = 1] = \pi_1 \,\mathrm{TPR}$, by the definition of the TPR.
3. **Do the same in the other world.** $\Pr[b = 0 \text{ and } b' = 0] = \pi_0 \Pr[b' = 0 \mid b = 0]$. When the bit is 0 the attack says either 0 or 1, so $\Pr[b' = 0 \mid b = 0] = 1 - \Pr[b' = 1 \mid b = 0] = 1 - \mathrm{FPR}$.
4. **Add the two worlds.** This gives Equation 9.2.

A concrete count. Play 1,000 games with an attack whose TPR is 0.6 and FPR is 0.2. Table 9.2 counts the wins for a fair bit, $\pi_1 = \frac{1}{2}$, and for a bit that is 1 only one time in ten, $\pi_1 = 0.1$.

Table 9.2.: Expected wins in 1,000 games of an attack with TPR 0.6 and FPR 0.2. The win rate in each world is fixed by the attack; the prior decides how many games are played in each world.

Prior π_1	Games with $b = 1$	Wins there ($b' = 1$)	Games with $b = 0$	Wins there ($b' = 0$)	Wins in total
$\frac{1}{2}$	500	$0.6 \times 500 = 300$	500	$0.8 \times 500 = 400$	700, so $\Pr[b' = b] = 0.7$
0.1	100	$0.6 \times 100 = 60$	900	$0.8 \times 900 = 720$	780, so $\Pr[b' = b] = 0.78$

The formula gives the same numbers: $\frac{1}{2}(0.6) + \frac{1}{2}(0.8) = 0.7$ and $0.1(0.6) + 0.9(0.8) = 0.78$. The second row is a warning. The attack wins more often there, but only because most games are played in the world where saying 0 is easy. Always saying 0, with no attack at all, would win 900 of those games. Accuracy alone cannot tell a good attack from a good guess about the prior, which is why every game below is scored against a baseline.

Most evaluations use a **fair bit**, $\pi_1 = \frac{1}{2}$: half the targets are members and half are not, so that neither answer is right more often by default. In that game an adversary who never looks at its

view, and so has nothing to go on, wins exactly half the games, whatever it answers; a coin flip, "always say member" and "always say non-member" all score $\frac{1}{2}$. That is the sense of "coin flip" below: not a model of any attack, but the score of knowing nothing in a fair game. With a fair bit, Equation 9.2 becomes $\frac{1}{2}\mathrm{TPR} + \frac{1}{2}(1 - \mathrm{FPR}) = \frac{1}{2} + \frac{1}{2}(\mathrm{TPR} - \mathrm{FPR})$: the know-nothing score, plus half of the difference between the two rates. That difference is the **advantage**,

$$\mathrm{Adv} = \mathrm{TPR} - \mathrm{FPR} = 2\Pr[b' = b] - 1, \tag{9.4}$$

and it measures how much better the attack does than an adversary who ignores its view. The second equality is the fair-bit formula solved for TPR−FPR: from $\Pr[b' = b] = \frac{1}{2} + \frac{1}{2}(\mathrm{TPR} - \mathrm{FPR})$, subtract $\frac{1}{2}$ and multiply by 2.

Why does this number measure the gain over knowing nothing? Look at what it is: $\mathrm{TPR} - \mathrm{FPR}$ is how much more often the attack says "member" when the target is a member than when it is not. Three cases show what that means.

1. **An attack that ignores its view scores 0.** A coin flip, or "always say member", does not look at anything that differs between the two worlds, so it says 1 with the same probability in both. Its TPR equals its FPR, its advantage is 0, and by the fair-bit formula it wins with probability exactly $\frac{1}{2}$.
2. **A perfect attack scores 1.** It says 1 every time the target is a member and never otherwise: $\mathrm{TPR} = 1$, $\mathrm{FPR} = 0$, advantage 1, and it wins every game.
3. **Every attack in between is scored by its extra wins.** Rearranged, Equation 9.4 says $\mathrm{Adv} = 2(\Pr[b' = b] - \frac{1}{2})$: the amount by which the attack's win probability exceeds the know-nothing score $\frac{1}{2}$, doubled so that a perfect attack scores 1. An attack can only win more than half the time if its answer depends on which world it is in, and the advantage measures exactly how much it does.

A negative advantage means the attack says "member" more often for non-members; flipping its answers turns it into an attack with the same advantage, positive. In the first row of Table 9.2 the advantage is $0.6 - 0.2 = 0.4 = 2(0.7) - 1$: the attack wins 0.2 more often than a coin flip, and 0.2 doubled is 0.4. Unlike the win rate, the advantage does not depend on the prior, because TPR and FPR are each measured inside one world. That matters because real targets are rarely half members. With an unequal prior the know-nothing score is no longer $\frac{1}{2}$ but the larger of π_0 and π_1, which is 0.9 in the second row of Table 9.2, where always saying 0 wins 900 games of 1,000. The advantage needs no adjustment: an attack that ignores its view still has $\mathrm{TPR} = \mathrm{FPR}$ and advantage 0, at any prior. Every two-world game in this part is scored by its advantage, and the best possible guess with an unequal prior (Equation 9.10) starts from Equation 9.2. The same fact, in the language of security games, is Fact 1 of Cryptography basics.

9.2.2. Fact 2 — Processing the view cannot help the adversary

If the adversary throws information away, or adds noise of its own, it cannot do better. Formally, let $V' = g(V, R)$ for any function g and any randomness R independent of b. Then every attack that sees V' has the same TPR and FPR as some attack that sees V, so the best advantage from V', and the best TPR at every FPR, are at most those from V.

The reason is that whoever holds V can always produce V' themselves. Given an attack $\mathcal{A}'$ on V', build an attack $\mathcal{A}$ on V that draws R, computes $g(V, R)$ and runs $\mathcal{A}'$ on the result. In each world $\mathcal{A}$'s output has the same distribution as $\mathcal{A}'$'s, so it has the same TPR and FPR. For instance, if a service returns a confidence score s and you only look at whether $s > 0.5$, you can do no better than someone who looks at s itself, because they could apply the same cut-off.

This is the data processing inequality of Divergences, seen from the attacker's side. It is what orders the access levels of a threat model.

9.2.3. Fact 3 — Mixing hides, and knowing the mixture index undoes it

This fact compares adversaries who know different amounts, so it needs a number for "the best any attack can do against views P and Q". That number is the **total variation distance**. For views with probabilities $p(x)$ and $q(x)$, it is half the total absolute difference between the two probability tables,

$$\mathrm{TV}(P, Q) = \tfrac{1}{2} \sum_x |p(x) - q(x)|. \tag{9.5}$$

It is the best possible advantage for a simple reason. An attack that says "member" on a set A of views has $\mathrm{TPR} = Q(A)$ and $\mathrm{FPR} = P(A)$, so its advantage is $Q(A) - P(A) = \sum_{x \in A} (q(x) - p(x))$. That sum is largest when A contains exactly the views where $q(x) > p(x)$, the views that are more likely in the member world, and its largest value is the total excess of q over p, which is half the total absolute difference. Section 9.5 returns to this with the full error curve.

Now the fact itself. Often the adversary's view depends on something it does not know, such as the other records in the dataset. Not knowing it works like extra noise: the adversary sees an average of several possible situations, and averaging two distributions can only blur the difference between them. Knowing it removes that noise, and being allowed to choose it lets the adversary pick the situation where the difference is largest.

In symbols, call the unknown Ω, with weights w_ω, and let P_ω and Q_ω be the views in the two worlds when $\Omega = \omega$. An adversary who does not see Ω faces the averages $\bar{P} = \sum_\omega w_\omega P_\omega$ and $\bar{Q} = \sum_\omega w_\omega Q_\omega$. An adversary who sees it faces the pair (Ω, V). Their best advantages are ordered, from not knowing, to knowing, to choosing:

$$\mathrm{TV}(\bar{P}, \bar{Q}) \;\le\; \sum_\omega w_\omega \,\mathrm{TV}(P_\omega, Q_\omega) \;=\; \mathrm{TV}((\Omega, V)_{b=0}, (\Omega, V)_{b=1}) \;\le\; \max_\omega \mathrm{TV}(P_\omega, Q_\omega). \tag{9.6}$$

Each step has a short proof. The first inequality is the triangle inequality, $|u + v| \le |u| + |v|$, which says that differences can cancel when they are added up before taking absolute values, but not after: $\mathrm{TV}(\bar{P}, \bar{Q}) = \frac{1}{2} \sum_x \left| \sum_\omega w_\omega (p_\omega(x) - q_\omega(x)) \right| \le \frac{1}{2} \sum_x \sum_\omega w_\omega |p_\omega(x) - q_\omega(x)|$, and swapping the sums gives the middle term. The equality holds because the pair (Ω, V) has probability $w_\omega p_\omega(x)$ in world 0 and $w_\omega q_\omega(x)$ in world 1, so half the L^1 distance between the two worlds is exactly $\sum_\omega w_\omega \mathrm{TV}(P_\omega, Q_\omega)$. The last inequality says that an average is at most its largest term.

A tiny case shows how much the unknown can hide. Let there be one other record, with a bit $\omega \in \{0, 1\}$ that is 0 or 1 with probability $\frac{1}{2}$ each, and let the mechanism release the exact count $\omega + b$. An adversary who knows ω subtracts it and reads off b, so for each ω the TV is 1. An adversary who does not know it sees counts 0 or 1 in world 0 and 1 or 2 in world 1, each with

probability $\frac{1}{2}$. A count of 1 could come from either world, and the TV drops to $\frac{1}{2}$ (Exercise 7 in the exercise book). This fact is what separates the average-case and worst-case games, and it is how the chapter prices side information.

9.3. Threat models

9.3.1. Context

Papers on privacy attacks report numbers such as "membership advantage 0.2" or "90% of records reconstructed". Those numbers mean nothing until you know what the attacker was assumed to see, know and do. A threat model fixes these assumptions. This section lists what a threat model has to specify, and proves the one ordering that always holds among the choices: an adversary with more access is never weaker.

9.3.2. Statement

A threat model answers five questions.

1. **Goal: what is the secret?** Whether a given record was in the training data (membership), the value of a sensitive field of a known record (attribute), the records themselves (reconstruction), or a statistic of the dataset as a whole (property).
2. **Access: what does the adversary observe?** From least to most: only the model's decisions on inputs it chooses, such as a predicted class or an "anomaly" flag (**label-only**); the model's scores on those inputs, such as confidences, losses or log-probabilities (**black-box**); the parameters θ themselves (**white-box**); or everything the training process exposed along the way, such as intermediate models and per-step gradients (the **transcript**).
3. **Behaviour: does it follow the rules?** An **honest-but-curious** (semi-honest) adversary follows the protocol and only analyses what it legitimately sees. A **malicious** (active) adversary may deviate: choose its queries adaptively, insert crafted records into the training data (**poisoning**), or, if it runs part of the system, send tampered models to the other participants.
4. **Trust: who sees the raw data?** In the **central** model a trusted curator holds the data, and the adversary sees only what is released. In the **local** model nobody is trusted: each person's data leave their device already protected, and the adversary may be the collector itself. Distributed settings, where many parties each hold a slice, sit in between.
5. **Side information: what does it know already?** The population distribution, a public dataset drawn from it, some or all of the other records, the target's non-sensitive fields.

Of these, access is the one with a natural order, and the reason is Fact 2. Each level of access lets the adversary compute the level below it: from the weights it can compute any score, and from a score it can compute the label. So whatever an attack does with less access, an attack with more access can do too, and the best attack can only get better as access grows. Write $\mathrm{Adv}^*(V) = \max_{\mathcal{A}} \mathrm{Adv}(\mathcal{A})$ for the best advantage of any attack whose input is the view V. For the same model and the same side information S,

$$\mathrm{Adv}^*(\text{labels}, S) \le \mathrm{Adv}^*(\text{scores}, S) \le \mathrm{Adv}^*(\theta, S) \le \mathrm{Adv}^*(\text{transcript}, S), \tag{9.7}$$

and the same chain holds for the best TPR at every fixed FPR. In the same way, more side information never lowers the best advantage, $\mathrm{Adv}^*(V) \leq \mathrm{Adv}^*(V, S)$, and neither does allowing malicious behaviour.

9.3.3. Derivation

1. **Each view can be computed from the next one.** A label is a function of the scores: the class with the largest score, or "score above a cut-off". A score on a query x is a function of θ and x, and the adversary chose x itself. The final θ is the last entry of the transcript.
2. **So Fact 2 applies at each link.** Each view on the left of Equation 9.7 is $g(V, R)$ for the view V to its right. Its achievable $(\mathrm{FPR}, \mathrm{TPR})$ pairs are therefore a subset of those to its right, and a maximum over a smaller set is smaller.
3. **Side information works the same way.** V is what you get from (V, S) by forgetting S, so Fact 2 applies again.
4. **Behaviour is a larger set of strategies.** An honest-but-curious adversary is a malicious one that chooses not to deviate, and a maximum over more strategies is at least as large.

9.3.4. Interpretation

The chain compares the *best* attacks at each level, not the attacks people actually run. A particular white-box attack can do worse than a well-designed black-box one, and the example below shows the gap inside a single access level can be larger than the gap between levels.

The access levels map directly onto deployments. Label-only and black-box access describe a model behind an application programming interface (API), such as a cloud prediction service or a chatbot. White-box access describes released weights, and also every participant who receives the global model in federated learning. The transcript describes a federated-learning server that sees each client's updates, the setting of Gradient inversion. Table 9.3 places four common deployments on all the axes. The same trained model can sit in several rows at once, and its risk is set by the weakest one.

Table 9.3.: Four deployments read as threat models.

Deployment	Access	Behaviour	Trust	Typical side information
Prediction service that returns the top class	label-only	honest-but-curious user, adaptive queries	central	public data from the same population
Service that returns confidences or log-probabilities	black-box	honest-but-curious user, adaptive queries	central	public data; the target's record
Model weights published for download	white-box	anyone; can run any computation	central	public data; possibly some training records

Deployment	Access	Behaviour	Trust	Typical side information
Federated training with a coordinating server	transcript (per-client updates)	server may be malicious	distributed	the global model at every round

Trust works differently from the other axes: it decides *who* the adversary is, not how strong it is. In the central model the threat is whoever sees the released model, and the curator is outside the threat model. In the local model the curator is inside it, so protection has to be applied before data leave the user. Part 3 compares the two.

Side information is the hardest axis to bound, because the defender usually does not know what the adversary knows. That is why the strongest assumption, "the adversary knows every record except the target's", is the one a guarantee should survive (Section 9.6).

9.3.5. Example: a centroid anomaly detector at four access levels

A security team fits the simplest anomaly detector there is: the mean $\theta = \frac{1}{n}\sum_i x_i$ of $n = 100$ records $x_i \sim \mathcal{N}(0, I_d)$ with $d = 50$ features. A point x gets the anomaly score $\|x - \theta\|^2$ and is flagged when the score exceeds $\tau = d$. The adversary holds a target z and plays the membership game: if $b = 1$, z is one of the n records; if $b = 0$, it is a fresh draw from the population. Here is what the adversary can do at each level of access.

With the weights (**white-box**), the adversary knows θ. The best thing it can do with θ is to ask how much more likely this exact θ is in the member world than in the non-member world. That ratio of the two probability densities is the **likelihood ratio**, and the Neyman–Pearson lemma of Hypothesis testing says that, for any target false positive rate, no attack catches more members than one that says "member" when the likelihood ratio is above a threshold. Intuitively, the views that are most typical of members relative to non-members are the ones to flag first.

Here the two densities are Gaussians. If z was used, $\theta = (z + W)/n$, where $W \sim \mathcal{N}(0, (n-1)I_d)$ is the sum of the other records, so θ is pulled a little towards z. If it was not, $\theta \sim \mathcal{N}(0, I_d/n)$. Expanding the squares in the two Gaussian densities (Section G.6 in the appendices does it step by step) gives the log of the likelihood ratio,

$$\ln \frac{q(\theta \mid z)}{p(\theta \mid z)} = \frac{n}{2(n-1)}\left(2\langle z, \theta\rangle - \|\theta\|^2\right) - \frac{\|z\|^2}{2(n-1)} + \text{const}, \tag{9.8}$$

and the best white-box attack thresholds it. The bracket $2\langle z, \theta\rangle - \|\theta\|^2$ is the part that depends on θ: it grows when θ points towards z, which is exactly what training on z does.

With only the score (**black-box**), the adversary gets $\|z - \theta\|^2 = \|z\|^2 - (2\langle z, \theta\rangle - \|\theta\|^2)$. It knows z, so the **calibrated score** $\|z\|^2 - \|z - \theta\|^2$ gives back exactly the bracket that the white-box likelihood ratio needs, and the remaining term $-\|z\|^2/(2(n-1))$ it can compute itself. The calibrated score drops that term, which only shifts the threshold from one target to the next, so it is almost, not exactly, the likelihood-ratio test: in Table 9.4 the two agree to four decimals. In

this model the score carries everything about θ that matters for the decision (it is a **sufficient statistic**: the likelihood ratio can be computed from it alone), so white-box access adds nothing. A simpler black-box attack ignores $\|z\|^2$ and says "member" when the raw score is low. That attack is confused by targets that are simply far from the mean: they have a high score whether or not they were used, so it mixes a target's typicality with its membership. With only the flag (**label-only**), the adversary says "member" when z is not flagged.

The script plays 100,000 games in each world and reports the best advantage over thresholds of each score (Table 9.4).

Table 9.4.: Membership advantage against the centroid detector with $n = 100$ and $d = 50$, from 100,000 games per world.

View	Attack	Best advantage TPR − FPR
White-box	likelihood ratio of θ	0.2789
Black-box	calibrated score $\|z\|^2 - \|z - \theta\|^2$	0.2789
Black-box	raw loss $-\|z - \theta\|^2$	0.0407
Label-only	not flagged, $\tau = d$	0.0400

The chain Equation 9.7 holds: $0.0400 \leq 0.2789 \leq 0.2789$. But the large gap is *inside* the black-box level, between two attacks on the same view. Calibrating each target against its own typicality multiplies the advantage by about seven. That is the idea behind the per-example attacks of Membership inference. Sablayrolles et al. (2019) give a general version: if training draws the parameters with a probability that decreases exponentially in the training loss, the Bayes-optimal membership attack depends on the parameters, to a good approximation, only through the target's loss, calibrated for each target. White-box access then adds little, as here, where the dependence is exact (Section G.6 in the appendices derives both).

Figure 9.1 shows the calibrated scores in the two worlds, and the advantage at each level as the dimension grows. With more parameters per record, a single record moves the model in more directions at once, and the best advantage climbs from 0.0326 at $d = 1$ to 0.7407 at $d = 500$ (100,000 games per world).

9.3.6. Check yourself

- A service adds a little random noise to every confidence score it returns. Can that make some attack stronger? *(No. The noisy score is $g(\text{score}, R)$ with R independent of b, so by Fact 2 every attack on it is matched by an attack on the clean score. Noise can only lower the best advantage, though it may not lower it by much.)*
- Why can a black-box attack beat a white-box attack in practice, despite Equation 9.7? *(The chain compares the best attack at each level. A particular white-box attack can be badly designed, just as the raw-loss attack is far worse than the calibrated one in Table 9.4.)*

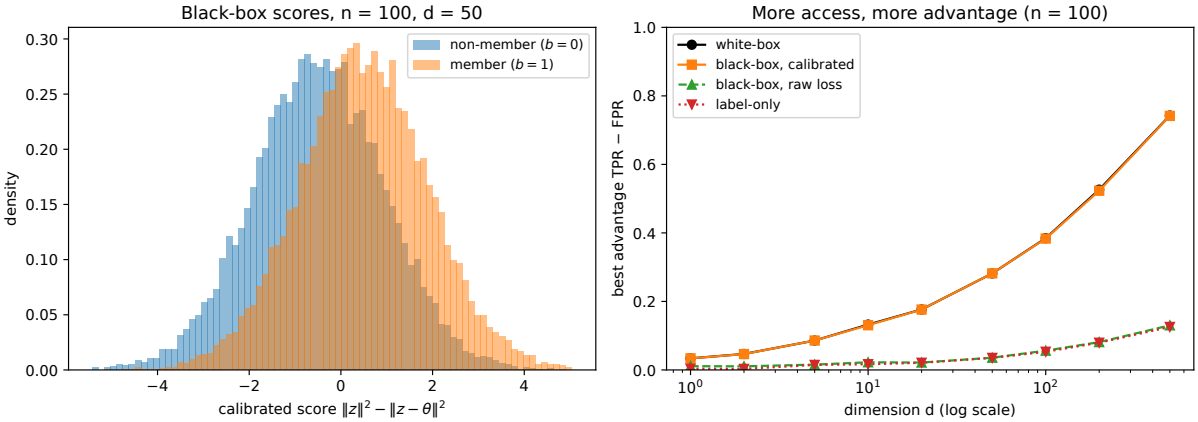

Figure 9.1.: Left: the calibrated black-box score $\|z\|^2 - \|z-\theta\|^2$ for members and non-members of the centroid detector, $n = 100$, $d = 50$. Right: the best advantage at each access level against the dimension d, from 20,000 games per world and point. White-box and calibrated black-box coincide; raw loss and label-only are far below.

9.4. Privacy games

9.4.1. Context

The same name, such as "membership inference", is used for attacks with different assumptions and different ways of scoring success. Salem et al. ("SoK: Let the Privacy Games Begin!", 2023) collect the attacks in the literature and write each one as a game between a challenger and an adversary. A game pins down three things: how the secret and the data are drawn, what the adversary sees, and how its guess is scored against a baseline. This section defines the games used in the rest of the part, and works out the best possible guess when the secret is a bit.

9.4.2. Statement

Every game in this part has the same four steps. The challenger draws a secret s from a known distribution, together with a dataset D whose distribution may depend on s. It trains $\theta = \mathcal{T}(D)$ and gives the adversary the view V that the threat model allows, along with the side information S. The adversary outputs a guess s' and earns a **gain** $g(s, s')$, usually $\mathbf{1}[s' = s]$. Finally, the attack is compared with a **baseline**: the best expected gain of a guess made from S alone, without looking at V. Figure 9.2 draws the membership game, and Table 9.5 lists the others.

Table 9.5.: The privacy games of this part. The first three are average-case: data come from the population. The distinguishing game is worst-case: the adversary picks the data.

Game	Secret s	Data in the two worlds	Gain	Baseline
Membership	bit b	$b = 1$: target z drawn from D; $b = 0$: z fresh from $\mathcal{D}$	$\mathbf{1}[b' = b]$	$\frac{1}{2}$
Attribute	sensitive field a of a known member $z = (u, a)$	$z \in D$; adversary knows u	$\mathbf{1}[a' = a]$	best guess of a from u and $\mathcal{D}$; or the same attack on non-members
Reconstruction	the records of D (or one column)	D drawn from $\mathcal{D}$	fraction of entries recovered	guessing from $\mathcal{D}$
Distinguishing	bit b	adversary chooses D_0, D_1 differing in one record; challenger trains on D_b	$\mathbf{1}[b' = b]$	$\frac{1}{2}$
Property	bit b	D drawn from $\mathcal{D}_{t_b}$, populations differing in a statistic t	$\mathbf{1}[b' = b]$	$\frac{1}{2}$

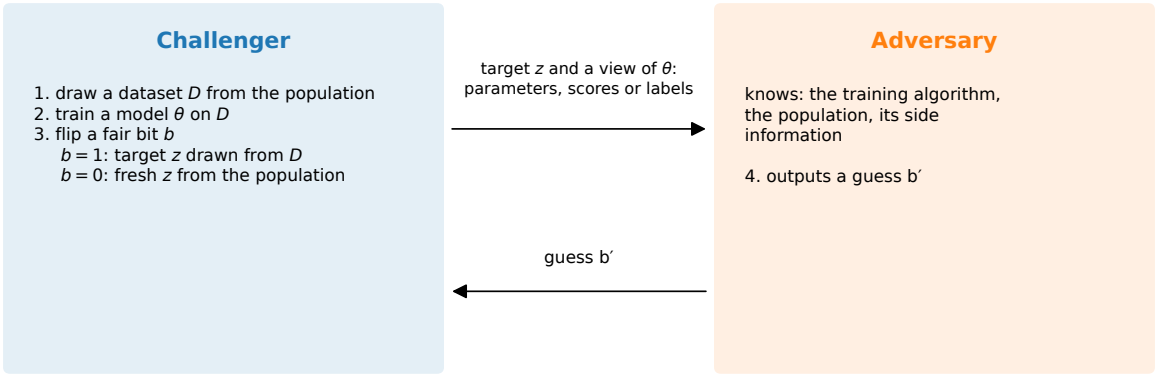

Figure 9.2.: The membership game. The challenger trains on a dataset, flips a bit that decides whether the target was in it, and shows the adversary the target and a view of the model. The adversary's guess is scored by its advantage.

When the secret is a bit that is not equally likely to be 0 or 1, the best possible guess has a closed form, and the idea behind it is simple. Say the bit is 1 only rarely, with prior $\pi_1 < \frac{1}{2}$. Then the safe default is to guess 0, which already wins with probability π_0. The view should overturn that

default only where it is strong enough evidence for 1 to outweigh the prior: where a view is more than $\gamma = \pi_0/\pi_1$ times as likely when the bit is 1 as when it is 0. With $\pi_1 = 0.1$ that is 9 times as likely. The best attack's gain over the default is the probability mass on those strongly convincing views.

The quantity that measures this mass is the **hockey-stick divergence**. With p and q the probabilities of a view when the bit is 0 and 1,

$$E_\gamma(Q\|P) = \sum_x \max\left(q(x) - \gamma p(x),\, 0\right), \tag{9.9}$$

the total by which q exceeds γ times p, counted only on the views where it does. At $\gamma = 1$ it is the total variation distance of Fact 3. The best attack wins with probability

$$\max_{\mathcal{A}} \Pr[b' = b] = \pi_0 + \pi_1\, E_\gamma(Q\|P), \qquad \gamma = \frac{\pi_0}{\pi_1}. \tag{9.10}$$

The first term is the baseline of always guessing 0; the second is everything the view adds.

9.4.3. Derivation

The Bayes-optimal guess (Equation 9.10).

1. **Write an attack as a set.** A deterministic attack says 1 on some set A of views. By Equation 9.2 it wins with probability $\pi_1 Q(A) + \pi_0(1 - P(A))$.
2. **Pull out the baseline.** This equals $\pi_0 + \pi_1(Q(A) - \gamma P(A))$ with $\gamma = \pi_0/\pi_1$.
3. **Choose the best set.** $Q(A) - \gamma P(A) = \sum_{x\in A}(q(x) - \gamma p(x))$ is a sum over the views in A. To make it as large as possible, put a view in A exactly when its term is positive, that is when $q(x) > \gamma p(x)$. The maximum is then the sum of the positive terms, which is $E_\gamma(Q\|P)$. In words: say 1 when the likelihood ratio q/p exceeds the prior odds γ against the bit being 1. A randomized attack says 1 on view x with some probability $\phi(x)$ and gets $\sum_x \phi(x)(q(x) - \gamma p(x))$, which is also largest with $\phi = 1$ on the positive terms and 0 elsewhere, so randomizing does not help.
4. **Check the fair case.** With $\pi_1 = \frac{1}{2}$, $\gamma = 1$ and $E_1 = \mathrm{TV}$, so the best attack wins with probability $\frac{1}{2} + \frac{1}{2}\mathrm{TV}$, matching Fact 1 with the best advantage TV of Fact 3.

Reconstruction from one exact count. The secret is m uniform bits $x_1, \ldots, x_m$, and the release is their sum K.

1. **What the count says about each bit.** Given $K = k$, every arrangement of k ones among m places is equally likely, so each bit is 1 with probability k/m.
2. **The best guess for each bit.** Guess 1 when $k/m > \frac{1}{2}$ and 0 otherwise. Every bit gets the same guess, the majority value, and the expected number right is $\max(k, m-k)$.
3. **Average over the count.** With $K \sim \mathrm{Bin}(m, \frac{1}{2})$, the expected fraction recovered is $\mathbb{E}[\max(K, m-K)]/m = \frac{1}{2} + \mathbb{E}|K - \frac{m}{2}|/m$.
4. **How large the gain is.** The count is a sum of m fair bits, each with variance $\frac{1}{4}$, so by the central limit theorem $K - \frac{m}{2}$ is approximately normal with mean 0 and variance $m/4$. The average distance of a normal variable from its mean is its standard deviation times $\sqrt{2/\pi}$ (integrate $|x|$ against the normal density), here $\frac{\sqrt{m}}{2}\sqrt{2/\pi}$. Dividing by m, the

fraction recovered is approximately $\frac{1}{2} + \frac{1}{\sqrt{2\pi m}}$. Section E.2 in the appendices computes it exactly, as $\frac{1}{2} + \frac{1}{2}\binom{2j}{j}4^{-j}$ with $j = \lfloor m/2 \rfloor$, and proves the approximation without the central limit theorem.

9.4.4. Interpretation

The baseline is part of the game, not an afterthought. A model that lets an attacker guess a rare diagnosis "with 90% accuracy" reveals nothing if 90% of people do not have that diagnosis. Accuracy only means something next to the baseline of Equation 9.10.

Attribute inference needs particular care, because it has two possible baselines that answer different questions. Comparing with a guess from the population asks "does the model help?". Comparing members with non-members asks "does the model help *because this person was in the training data*?". Only the second is a breach of that person's privacy; the first may be ordinary statistics that any study of the population would reveal. Attribute inference and model inversion develops this.

The games also differ in where the data come from. In the membership, attribute and reconstruction games the data are drawn from the population, so the score is an average over datasets and targets. In the distinguishing game the adversary chooses both datasets, so the score is a worst case. Section 9.6 shows that the first is never larger than the second, and how far apart they can be. Finally, games and threat models combine freely: every row of Table 9.5 can be played at every access level, so "label-only membership" and "white-box reconstruction" are both well defined.

9.4.5. Example: one noisy count, three games

A data team publishes how many people in a dataset have a sensitive condition, with Gaussian noise added: $Y = \sum_{x \in D} x + \sigma Z$, with bits $x \in \{0, 1\}$, $Z \sim \mathcal{N}(0, 1)$ and $\sigma = 1$. Suppose the adversary knows every record except the target's, so the rest of the count is a known number c. The same release can be attacked in three games.

In the **membership** game, the target has the condition. Without the target, $Y \sim \mathcal{N}(c, 1)$; with it, $Y \sim \mathcal{N}(c + 1, 1)$: the same bell curve, shifted right by one. The best attack says "member" on the views more likely in the member world, which are the counts to the right of the point where the two curves cross, $c + \frac{1}{2}$. Write Φ for the standard normal cumulative distribution function (CDF), so $\Phi(t)$ is the probability that a standard normal variable is below t. A member's count lands above $c + \frac{1}{2}$ with probability $\Phi(\frac{1}{2})$, its TPR, and a non-member's with probability $1 - \Phi(\frac{1}{2})$, its FPR. The advantage is $2\Phi(\frac{1}{2}) - 1$, and by Fact 1 the attack wins with probability $\frac{1}{2} + \frac{1}{2}(2\Phi(\frac{1}{2}) - 1) = \Phi(\frac{1}{2}) = 0.6915$.

In the **attribute** game with a fair prior, the target is known to be in D and its bit is the secret. The view has the same two distributions, so the best guess is again right with probability 0.6915 (0.6925 in 200,000 simulated games). Now make the condition rare, with prior $\pi_1 = 0.1$. Always guessing "no" already wins with probability 0.9, and by Equation 9.10 the release should overturn that only where the count is at least $\gamma = 9$ times as likely with the condition as without. For two unit-variance normals one apart, the likelihood ratio at y is $e^{(y-c)-1/2}$, which exceeds 9 when $y > c + \frac{1}{2} + \ln 9$. On those counts, Q puts mass $\Phi(\frac{1}{2} - \ln 9)$ and P puts mass $\Phi(-\frac{1}{2} - \ln 9)$, so

$E_9 = \Phi(\frac{1}{2} - \ln 9) - 9\Phi(-\frac{1}{2} - \ln 9) = 0.0134$. The best accuracy is $0.9 + 0.1 \times 0.0134 = 0.9013$ (simulated: 0.9028). The same release that lifts a fair guess from 0.5 to 0.69 lifts this one by about a tenth of a percentage point, because the likelihood ratio is rarely large enough to overturn 9-to-1 odds.

In the **reconstruction** game, release the exact count of m uniform bits instead. The best reconstruction recovers a fraction 0.6230 of the bits for $m = 10$ (0.6236 in simulation), 0.5398 for $m = 100$ and 0.5126 for $m = 1000$. The approximation $\frac{1}{2} + 1/\sqrt{2\pi m}$ gives 0.6262, 0.5399 and 0.5126. One aggregate reveals little about each record, and less as m grows. Many aggregates are a different matter: Reconstruction attacks shows how a few times as many noisy subset counts as there are bits give away almost every bit.

9.4.6. Check yourself

- In the distinguishing game the adversary picks D_0 and D_1. Why does that make its best advantage at least the best advantage in the membership game, for the same mechanism? *(It can pick the pair that is hardest to hide, for example the dataset and target on which the mechanism leaks the most. The membership game averages over pairs drawn from the population, and a maximum is at least an average, as Section 9.6 makes precise.)*
- An attribute attack is right 75% of the time on members and 75% of the time on non-members. Is it a privacy attack on the members? *(No. It does equally well on people who were never in the data, so it is inferring the attribute from the population, not from the person's participation.)*

9.5. Advantage, total variation and the trade-off curve

9.5.1. Context

A two-world game is a test of $H_0 : V \sim P$ ("not a member") against $H_1 : V \sim Q$ ("member"). So everything Hypothesis testing proved about tests becomes a statement about attacks. This section draws out three: a ceiling on the advantage, a ceiling on the whole ROC curve, and a warning about which point of that curve to report.

9.5.2. Statement

Fact 3 already showed that no attack's advantage exceeds the total variation distance between the two worlds' views. The first bound restates that. The second goes further: it bounds the attack's TPR at *every* false positive rate, not just at the one point where TPR − FPR is largest. The bound comes from the **trade-off function** $T(P, Q)$: for each false positive rate α, $T(P, Q)(\alpha)$ is the smallest fraction of members that any attack with false positive rate α must miss. An attack can catch at most the rest. For every attack in a two-world game,

$$\text{Adv} = \text{TPR} - \text{FPR} \le \text{TV}(P, Q), \qquad \Pr[b' = b] \le \tfrac{1}{2} + \tfrac{1}{2}\text{TV}(P, Q), \tag{9.11}$$

$$\mathrm{TPR} \le 1 - T(P, Q)(\mathrm{FPR}). \tag{9.12}$$

Both bounds are attained by likelihood-ratio attacks, which flag the views that are most typical of members relative to non-members first.

The third quantity answers the question a person who is flagged cares about: given that the attack says "member", how likely is that to be true? Of all the targets the attack flags, some are members (a fraction π_1 of targets are members, and it flags a fraction TPR of them) and some are non-members (a fraction π_0, of which it flags FPR). The **precision** is the members' share of the flagged:

$$\Pr[b = 1 \mid b' = 1] = \frac{\pi_1 \,\mathrm{TPR}}{\pi_1 \,\mathrm{TPR} + \pi_0 \,\mathrm{FPR}}. \tag{9.13}$$

9.5.3. Derivation

1. **The attack is a test.** It says "member", rejecting H_0, with probability $\phi(V)$. Its type I error is the FPR and its type II error is $1 - \mathrm{TPR}$.
2. **The advantage ceiling** (Equation 9.11). The advantage of an attack that says "member" with probability $\phi(x)$ on view x is $\sum_x \phi(x)(q(x) - p(x))$. It is largest when $\phi = 1$ exactly where $q > p$, that is, where the likelihood ratio q/p is above 1, and that largest value is $\mathrm{TV}(P, Q)$, as in Fact 3. The winning probability follows from Fact 1.
3. **The curve ceiling** (Equation 9.12). The fraction of members an attack misses is $1 - \mathrm{TPR}$. By the definition of the trade-off function, no attack with false positive rate FPR misses fewer than $T(P, Q)(\mathrm{FPR})$, so $1 - \mathrm{TPR} \ge T(P, Q)(\mathrm{FPR})$. Which attack attains it? The Neyman–Pearson lemma answers: with a budget of false positives to spend, spend it on the views where members are most over-represented, that is, flag views in decreasing order of the likelihood ratio q/p until the false positive rate reaches the budget. Each view flagged that way buys the most members per false positive.
4. **Precision** (Equation 9.13). The precision is a conditional probability, so it is the probability that a target is a member *and* flagged, divided by the probability that it is flagged. The first is $\pi_1 \mathrm{TPR}$, as in step 2 of Fact 1. A target is flagged either as a member, $\pi_1 \mathrm{TPR}$, or as a non-member, $\pi_0 \mathrm{FPR}$, and these are disjoint, so the second is their sum.

9.5.4. Interpretation

The advantage is only one point of the ROC curve, the plot of an attack's TPR against its FPR as its threshold varies. Because the advantage is $\mathrm{TPR} - \mathrm{FPR}$, it is the height of that curve above the diagonal, and TV is the largest such height, reached at the likelihood-ratio threshold 1, and it says nothing about what happens at the low false-positive end. Yet that end is where privacy breaks. An attack that flags 1% of members with no false alarms has an advantage of only about 0.01, yet it identifies those members with certainty. An attack with advantage 0.1, right on 55% of members and wrong on 45% of non-members, identifies nobody with confidence. Carlini et al. (2022) argue from this that membership attacks should be reported by their TPR at a low FPR, such as 10^{-3}, on ROC curves with log axes. The rest of this part does so.

Precision tells the same story from the attacker's side. If only one target in a hundred is a member, even a good attack produces mostly false alarms (Jayaraman et al. 2021). A low FPR is what keeps precision high when members are rare.

The two ceilings depend only on P and Q, so they bound every attack, including ones nobody has invented yet. That is what makes them the right target for a defence: a mechanism whose trade-off curve $T(P, Q)$ stays close to the diagonal for every target defeats every attack at once.

9.5.5. Example: the noisy count, worst case

Take the noisy count of the previous example, $\sigma = 1$, with the other $m = 100$ bits known (the script fixes them at 50 ones). Then $P = \mathcal{N}(50, 1)$, $Q = \mathcal{N}(51, 1)$, and as computed there the best attack says "member" when $Y > 50.5$, the point where the two curves cross, with advantage $\mathrm{TV} = 2\Phi(\frac{1}{2}) - 1 = 0.3829$. Over 200,000 games in each world it scores TPR $= 0.6901$ and FPR $= 0.3092$: advantage 0.3809 and winning probability 0.6905, against the ceilings 0.3829 and 0.6915.

Now hold the false positive rate at 10^{-3}. The attack still flags large counts, but it has to move its threshold τ up until only one non-member in a thousand exceeds it: $\Pr[\mathcal{N}(50, 1) > \tau] = 10^{-3}$, so $\tau = 50 + \Phi^{-1}(0.999) = 50 + 3.0902 = 53.09$, where Φ^{-1} is the inverse of Φ. A member's count, centred one higher, exceeds τ with probability $1 - \Phi(\tau - 51) = 1 - \Phi(3.0902 - 1) = 0.0183$. That is the TPR, and by the Neyman–Pearson argument above it is the best possible at this FPR (simulated: 0.0184, at an FPR of 0.00109). The attack now catches fewer than 2% of members, but when it fires it is right with precision $0.0183/(0.0183 + 0.001) = 0.948$ at a fair prior. If only one target in a hundred is a member, the precision drops to 0.156.

The black curve in Figure 9.3 is this ROC curve on log axes. The green one is the same game when the adversary does not know the other records, which is the subject of the next section.

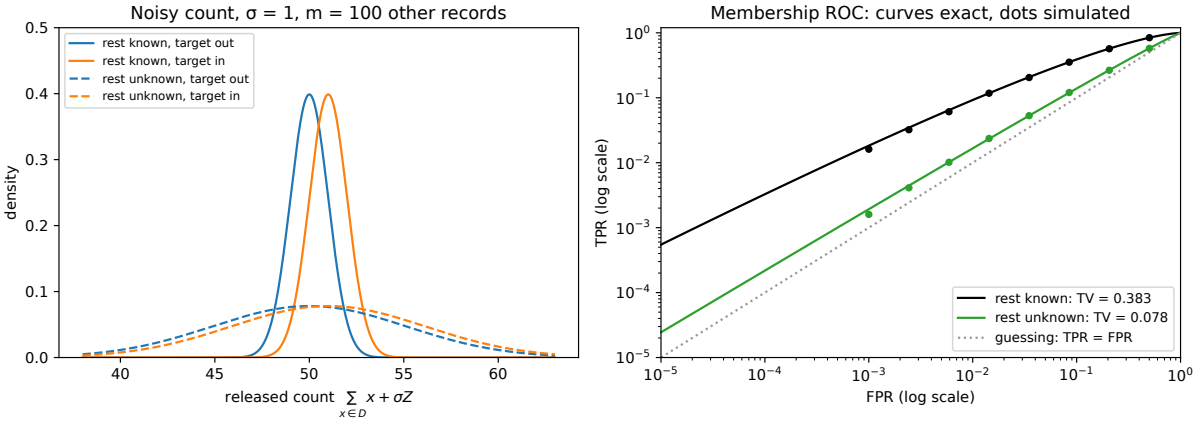

Figure 9.3.: Left: the released count in the two worlds when the other 100 records are known (solid) and unknown (dashed). Right: the membership ROC curves of the best attacks on log axes, exact (lines) and from 100,000 simulated games per world (dots). The dotted diagonal is random guessing.

9.5.6. Check yourself

- Attack A has TPR 0.5 at FPR 0.3; attack B has TPR 0.02 at FPR 10^{-4}. Which has the larger advantage, and which is the bigger privacy threat? *(A has advantage 0.2, B about 0.02. B is the bigger threat to the people it flags: its precision at a fair prior is* $0.02/(0.02 + 0.0001) = 0.995$*, against* $0.5/0.8 = 0.625$ *for A.)*
- Why can no attack, however clever, beat Equation 9.12? *(The bound is a property of the two view distributions. Any attack is a test of P against Q, and the Neyman–Pearson lemma says no test with that FPR has more power than the likelihood-ratio test.)*

9.6. Average case and worst case

9.6.1. Context

A membership game can be scored in two ways. In the **average case**, the data and the target come from the population, the adversary knows only the population, and the advantage is an average over all of that randomness. In the **worst case**, the adversary knows, or even picks, the rest of the data and the target, and the advantage is the maximum over those choices. Evaluations of real models usually measure the first; privacy guarantees have to control the second. This section shows how far apart the two can be.

9.6.2. Statement

The comparison is Fact 3 again, with the unknown being the rest of the game. Let ω collect everything that the average-case game draws at random and that a worst-case adversary is allowed to fix: the other records, and the target. An average-case adversary does not know ω, so it sees an average over its possible values, which blurs the two worlds together. An adversary who knows ω sees each situation sharply, and one who chooses ω picks the sharpest. Let P_ω, Q_ω be the views given ω, and $\bar{P}, \bar{Q}$ their averages. Then, by Fact 3,

$$\underbrace{\mathrm{TV}(\bar{P}, \bar{Q})}_{\text{adversary does not know } \omega} \;\le\; \underbrace{\mathbb{E}_\omega \,\mathrm{TV}(P_\omega, Q_\omega)}_{\text{adversary knows } \omega} \;\le\; \underbrace{\max_\omega \,\mathrm{TV}(P_\omega, Q_\omega)}_{\text{adversary chooses } \omega}. \tag{9.14}$$

Both gaps can be as large as possible: there are mechanisms for which the left side is close to 0 and the right side is 1.

9.6.3. Derivation

1. **Three adversaries, three views.** An adversary that does not know ω sees V, distributed as the average $\bar{P}$ or $\bar{Q}$, so its best advantage is $\mathrm{TV}(\bar{P}, \bar{Q})$ by Equation 9.11. One that knows ω sees the pair (ω, V), and by Fact 3 its best advantage is $\mathbb{E}_\omega \mathrm{TV}(P_\omega, Q_\omega)$. One that chooses ω picks the most revealing value, which gives the maximum.
2. **The inequalities** are the two inequalities of Equation 9.6.

3. **The gaps can be extreme.** For the left gap, release the exact count, with the target's bit 1 and m other bits the adversary does not know. An adversary who knew the others would read b off the count, so the middle term is 1. One who does not know them sees the count K in world 0 and $K+1$ in world 1, where $K \sim \mathrm{Bin}(m, \frac{1}{2})$ is the unknown sum of the others. The two distributions are the same list of binomial weights $w_k = \Pr[K = k]$, the second shifted one place to the right. Their total variation is the total excess of the shifted list over the original, counted where it is positive. The binomial weights rise up to the middle value $\lfloor m/2 \rfloor$ and fall after it (Section E.2 in the appendices proves it), so the shifted list is the larger one exactly to the right of the middle, and there its excess at k is $w_{k-1} - w_k$. Adding these differences from the middle to the end, every weight cancels except the first, so the total is the largest weight, $\binom{m}{\lfloor m/2 \rfloor} 2^{-m}$. For large m the binomial is close to a normal curve with standard deviation $\sqrt{m}/2$, whose peak height is $1/(\sqrt{2\pi} \cdot \sqrt{m}/2) = \sqrt{2/(\pi m)}$ (Exercise 2 in the exercise book works this out). It tends to 0 as m grows. For the right gap, release one record of D chosen at random, worked out in the example below.

9.6.4. Interpretation

Averaging over datasets hides the target in a crowd, but only from an adversary who does not know the crowd. In the noisy count, the unknown other records act as extra noise with variance $m/4$. A defence that relies on that noise fails against an adversary who knows the other records, or who planted them, and inserting records the adversary controls is exactly what a malicious adversary of Section 9.3 can do.

Averaging over targets hides the worst-treated person. If a mechanism exposes one person in a thousand completely and everyone else not at all, its average advantage is about 0.001. Privacy is a promise to each person, so the number that matters is the advantage against that one person. Outliers and duplicated records are the usual victims, as Membership inference and Memorization and training-data extraction show.

Average-case numbers are still useful. They measure the risk that a typical record faces from a realistic attacker, and they are what an audit can estimate from data. But they are lower bounds on the worst case, never upper bounds. An audit narrows the gap by playing the adversary that chooses the target: it plants **canaries**, records built to be as exposed as possible, and measures the attack on those (Memorization and training-data extraction).

This is where the part is heading. A guarantee that holds for every pair of neighbouring datasets bounds the right-hand side of Equation 9.14, and therefore every membership-style game in this part at once, every game whose two worlds differ in one record. A game whose two worlds differ in many records, such as the property games of Property inference, is bounded only through a weaker guarantee for groups of records, which degrades with the size of the group. That is how the definition in Part 3 is designed.

9.6.5. Example: the noisy count and the random-record release

The noisy count. Keep $\sigma = 1$ and the target's bit 1, but now let the $m = 100$ other bits be fresh $\mathrm{Bern}(\frac{1}{2})$ draws that the adversary does not see. The count is then $K + b + Z$ with $K \sim \mathrm{Bin}(100, \frac{1}{2})$. In the two worlds the count has the same distribution, shifted by 1, and its

likelihood ratio increases with the observed count. The reason is that the binomial weights are log-concave and that normal noise makes a larger observation favour a larger centre. The density itself need not be log-concave, and for smaller noise it is not; Section F.6 in the appendices derives the increasing ratio step by step. So the best attack is still a threshold, and by symmetry the two densities cross at $m/2 + \frac{1}{2} = 50.5$. Table 9.6 compares the adversaries of Equation 9.14, and adds the case where the target's own bit is random.

Table 9.6.: Membership advantage on a noisy count with 100 other records, for adversaries with different knowledge.

Adversary	Best advantage (exact)	Simulated (200,000 games per world)
Knows the other records ($\sigma = 1$)	0.3829	0.3809
Does not know them, target's bit 1	0.0779	0.0751
Does not know them, target's bit random	0.0390	0.0398
Knows the other records, exact count ($\sigma = 0$)	1	—
Does not know them, exact count ($\sigma = 0$)	0.0796	—

Not knowing the crowd cuts the advantage by a factor of five. A normal approximation explains the number: treating K as $\mathcal{N}(50, 25)$ makes the two worlds Gaussians with shift 1 and standard deviation $\sqrt{25+1}$, which gives $2\Phi(1/(2\sqrt{26})) - 1 = 0.0781$. When the target's own bit is random, the count does not depend on b for the half of targets whose bit is 0, and the advantage halves to $0.0779/2 = 0.0390$. At an FPR of 10^{-3} the average-case attack has TPR 0.0019 (simulated 0.0016), against 0.0183 for the adversary who knows the rest; these are the green and black curves of Figure 9.3. Figure 9.4 shows the average-case advantage falling as the crowd grows, while the worst case does not move.

The random-record release. A mechanism publishes one record of D, chosen uniformly among $n = 1000$ records that are all different. The attack says "member" if the published record is z. If z is in D, it is published with probability $1/n$, so TPR $= 0.001$; if not, it is never published, so FPR $= 0$. The script measures TPR $= 0.00098$ and FPR $= 0$ over 200,000 games per world. By the average-case measure, an advantage of $1/n = 0.001$, the mechanism looks almost perfectly safe. Yet every run exposes one person completely, and when the attack fires its precision is 1. Against the target that is published, the advantage is 1. Only the right side of Equation 9.14, which fixes the dataset and asks about the worst target, reveals the problem.

9.6.6. Check yourself

- A team audits its model by running a membership attack on 10,000 random training and held-out examples and reports advantage 0.01. What can you conclude about the worst-case risk? *(Only that it is at least 0.01. The audit averages over targets and datasets. A small group of outliers could be exposed far more, and the average would barely show it.)*

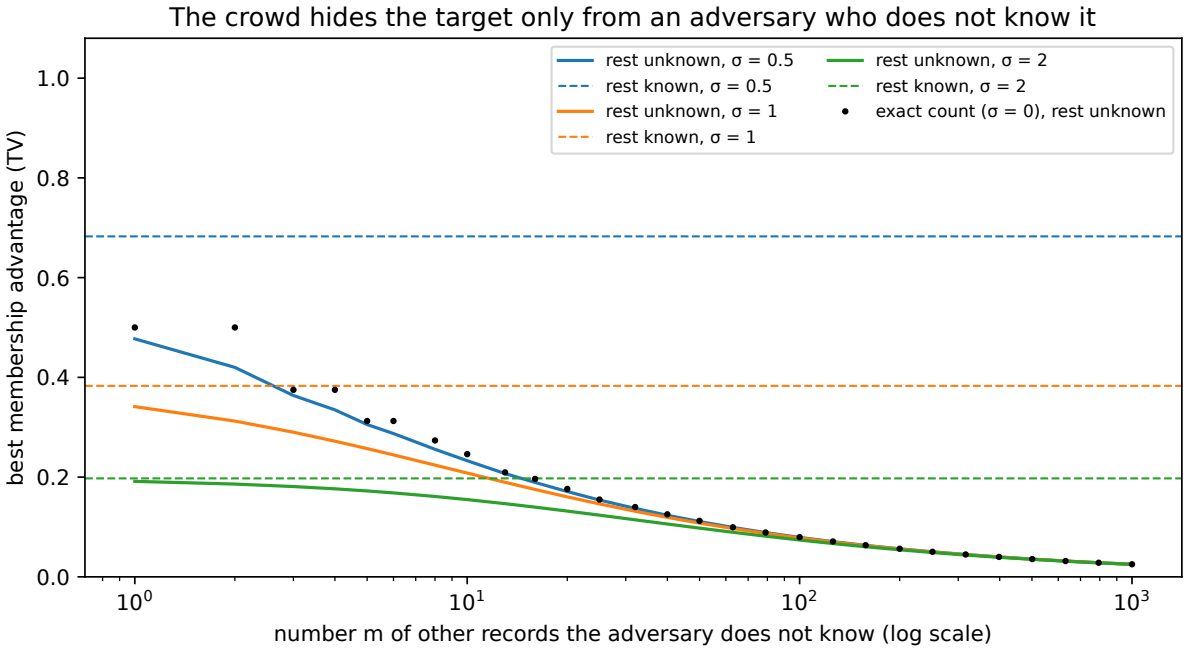

Figure 9.4.: Best membership advantage on the noisy count against the number m of other records the adversary does not know, for three noise levels (solid), and the same mechanism against an adversary who knows them (dashed). Dots: the exact count, $\sigma = 0$, whose worst case is 1.

- In the noisy count with unknown others, how could a malicious adversary recover the worst-case advantage? *(By controlling the other records, for example by flooding the dataset with records whose bits it knows. Then the rest of the count is known, and the advantage goes back to the 0.3829 of the first row of Table 9.6.)*

9.7. Code: check every number by computation and simulation

The script code/threat_models.py computes every number in this chapter and draws every figure. Exact values come from closed forms (normal tails via `math.erfc`, binomial weights) and are checked against games played by simulation. From the repository root:

```
uv run python code/part02-attacks/threat_models.py
```

Output (seed 0), summarized in Table 9.7:

Table 9.7.: The script's output with the default seed.

Experiment	Result
Centroid detector, $n = 100$, $d = 50$	Best advantage: white-box 0.2789; calibrated black-box 0.2789; raw loss 0.0407; label-only 0.0400
Noisy count, rest known, $\sigma = 1$	TV 0.3829; simulated TPR 0.6901, FPR 0.3092, advantage 0.3809, winning probability 0.6905
Same, at FPR 10^{-3}	TPR 0.0183 (simulated 0.0184); precision 0.948 at prior $\frac{1}{2}$, 0.156 at prior 0.01
Noisy count, 100 unknown others	TV 0.0779 (normal approximation 0.0781; simulated 0.0751); TPR at FPR 10^{-3} 0.0019 (simulated 0.0016)
Same, random target bit	Advantage 0.0390 (simulated 0.0398)
Exact count, 100 unknown others	TV 0.0796; $\sqrt{2/(\pi m)} = 0.0798$
Attribute from the noisy count	Prior $\frac{1}{2}$: 0.6915 (simulated 0.6925). Prior 0.1: baseline 0.9, best 0.9013, $E_9 = 0.0134$ (simulated 0.9028)
Reconstruction from one exact count	$m = 10$: 0.6230 (simulated 0.6236); $m = 100$: 0.5398; $m = 1000$: 0.5126
Random-record release, $n = 1000$	Simulated TPR 0.00098, FPR 0; $1/n = 0.001$

tests/test_threat_models.py checks that the output still matches.

Four things stand out. First, the ceilings are reached: every simulated likelihood-ratio membership attack lands within 0.003 of its TV ceiling, within two standard errors for 200,000 games per world, and the small differences in either direction are sampling error. Second, access is not the only lever: in the centroid example the biggest gap is between two attacks on the same black-box view, not between access levels. Third, knowledge changes everything: the same noisy count has advantage 0.38 against an adversary who knows the other records and 0.08 against one who does not, and the exact count goes from 1 to 0.08. Fourth, one number is not enough: advantage, TPR at a low FPR, precision and accuracy against a baseline each answer a different question, and they can disagree by orders of magnitude.

9.9. Cheat sheet

P and Q are the adversary's view without and with the target ($b = 0$ and $b = 1$); π_1 is the prior of $b = 1$. Table 9.8 collects the results.

Table 9.8.: The results of this chapter.

Result	Statement	Where
Winning and advantage	$\Pr[b' = b] = \pi_1\mathrm{TPR} + \pi_0(1 - \mathrm{FPR})$; fair prior: $\frac{1}{2} + \frac{1}{2}\mathrm{Adv}$, $\mathrm{Adv} = \mathrm{TPR} - \mathrm{FPR}$	Equation 9.2, Equation 9.4
Access chain	labels $\leq$ scores $\leq$ parameters $\leq$ transcript, for the best attack	Equation 9.7
Ceiling on advantage	$\mathrm{Adv} \leq \mathrm{TV}(P, Q)$	Equation 9.11
Ceiling on the ROC curve	$\mathrm{TPR} \leq 1 - T(P, Q)(\mathrm{FPR})$	Equation 9.12
Bayes-optimal guess	$\max \Pr[b' = b] = \pi_0 + \pi_1 E_{\pi_0/\pi_1}(Q\|P)$ for $\pi_1 \leq \frac{1}{2}$	Equation 9.10
Precision	$\pi_1\mathrm{TPR}/(\pi_1\mathrm{TPR} + \pi_0\mathrm{FPR})$	Equation 9.13
Average against worst case	$\mathrm{TV}(\bar{P}, \bar{Q}) \leq \mathbb{E}_\omega \mathrm{TV}(P_\omega, Q_\omega) \leq \max_\omega \mathrm{TV}(P_\omega, Q_\omega)$	Equation 9.14
Noisy count, shift 1, noise σ	Rest known: $2\Phi(\frac{1}{2\sigma}) - 1$. m unknown others: $\approx 2\Phi(1/(2\sqrt{m/4 + \sigma^2})) - 1$	Table 9.6

Rules of thumb

- Before reading an attack's number, read its threat model: access, behaviour, trust, side information, and the game.
- Compare every attack with its baseline. Accuracy near the prior is no attack.
- Report TPR at a low FPR, with the ROC curve on log axes; advantage and accuracy hide the cases that matter.
- An average-case number is a lower bound on the worst case. A defence has to hold for the worst record, the worst dataset and the best-informed adversary.
- A better attack on the same view can matter more than more access: calibrate scores per target.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

10. Membership inference

10.1. Why this matters

A hospital trains a model to predict a disease and publishes it. You hold one patient's record. **Was that record in the training set?** If it was, you have learned that the patient was treated at that hospital for that disease, and the model never output a diagnosis. This is **membership inference**, the simplest question an attacker can ask about a trained model and the one asked most often. A membership inference attack is also the standard way to measure how much a model leaks: if an attacker cannot even tell whether a record was used, it can do little else with it. The reverse does not hold. A model that leaks membership may leak more, and the later chapters of this part show how.

An attack is scored by two rates. Its **true positive rate (TPR)** is the fraction of members it flags as members, and its **false positive rate (FPR)** is the fraction of non-members it wrongly flags. A useful attack flags many members while flagging few non-members. With these two numbers in hand, the chapter answers four questions, each building on the one before.

The first is why a model leaks membership at all. The answer is that it fits its training data better than other data, so its loss on a record it trained on is usually lower than on a fresh one. The simplest attack says "member" when the loss is low, and its advantage, the TPR minus the FPR, turns out to equal the generalization gap: the difference between the model's average loss on fresh data and on its training data. The second question is how an attacker can learn what members look like when it cannot see the training data. It trains **shadow models** of its own, on data where it knows who is a member, and watches how they behave. The third is what the best attack is. It is a likelihood-ratio test run separately for each record: the **likelihood ratio attack (LiRA)** estimates, for each record, how the model's output on that record is distributed when the record was trained on and when it was not, and asks which of the two the observed output fits better. The fourth is how an attack should be scored and who is at risk. Attacks should be compared by their TPR at a low FPR, because only there does a "member" verdict carry confidence, and the people an attack identifies at that end are almost all outliers.

10.1.1. The one idea: membership inference is a test about one record

Fix a target record z. Train a model on a dataset that contains z, and look at the model's output on z. Train it again on a dataset that does not, and look again. The two outputs will not repeat exactly if you retrain, because training is random: the rest of the data, the initialization and the order of the examples all change. So each case gives a *distribution* of outputs, the **IN** distribution and the **OUT** distribution of z. The attacker sees one output and must say which distribution it came from.

That is a test between two fully specified hypotheses, and the **Neyman–Pearson lemma** says how to do it best. Compute the **likelihood ratio**, the density of the observed output under IN divided by its density under OUT, and say "member" when it is above a threshold. For any allowed FPR, no test flags more members. The reason is a budgeting argument. Each possible output costs its OUT probability in false positives if you call it "member", and earns its IN probability in true positives. With a fixed false-positive budget, you earn the most by calling "member" on the outputs with the best ratio of earnings to cost first, and that ratio is the likelihood ratio.

The IN and OUT distributions differ from record to record. A typical record is predicted well whether or not it was in the training set, so its two distributions nearly coincide. An atypical record is predicted badly unless the model saw it, so its two distributions are far apart. Every result in this chapter follows from taking that seriously. The loss attack uses one threshold for every record, so it confuses "easy record" with "member". Shadow models are how the attacker estimates the two distributions, record by record. LiRA fits them per record, and once you account for the record's identity it is the Neyman–Pearson test for the whole game. And the low-FPR end of the curve is made of the records whose two distributions are far apart, which are the outliers.

Table 10.1 lists the results and where each is used.

Table 10.1.: The results of this chapter and where each is used.

Result	Where it is used
Loss attack: advantage = generalization gap $/B$	Why overfit models leak; a lower bound on leakage from train and test error alone
Shadow models	Every practical attack that needs to know what members look like
Shadow attack model estimates the membership posterior	Why an attack model trained on shadows is optimal among attacks that ignore the record's identity
LiRA (online and offline) as a per-example likelihood-ratio test	The strongest black-box attack; the attack used to audit trained models
One threshold on the per-example likelihood ratio is optimal	Why calibrating per example beats any global threshold
TPR at a low FPR on log-scaled receiver operating characteristic (ROC) curves	Reporting any privacy attack honestly
Per-example separation and self-influence	Predicting which records are exposed; why outliers are

10.1.2. The running example

Every number in this chapter comes from one experiment, small enough to run in seconds and rich enough to show every effect. It has a **pool** of 1,000 labelled points in $\mathbb{R}^{100}$, of two kinds, built so that some points are easy to predict and a few are not.

The 950 **typical points** have features $x \sim \mathcal{N}(0, I/100)$: each of the 100 coordinates is normal with variance $1/100$, so the squared length $\|x\|^2$ is a sum of 100 terms that average $1/100$

each, and $\|x\| \approx 1$. Each gets a label $y = \pm 1$ that follows its first coordinate with some noise: $\Pr[y = 1 \mid x] = \sigma(30x_1)$, where $\sigma(t) = 1/(1 + e^{-t})$ is the logistic function, which turns any real number into a probability. The 50 **outliers** have the same kind of x scaled by 5, so they are five times longer, and a label drawn by a fair coin. Nothing else in the data predicts an outlier's label, so a model can only get it right by fitting that point itself.

Each **model** is L_2-regularized logistic regression: it chooses the weight vector θ that minimizes the average logistic loss on its training points plus a penalty $\frac{\lambda}{2}\|\theta\|^2$ that keeps the weights small, with $\lambda = 10^{-3}$. Each model trains on a random half of the pool ($n = 500$). Models come in complementary pairs: one trains on a random half, the next on the other half, so every point is a member of exactly half the models. The attacker targets 128 such models. It also trains 64 **shadow models** of its own in the same way. The attacker knows the pool and the training recipe but not which half any target model used. Every target model can be asked about all 1,000 pool points, and each (target model, point) pair is one game: 500 of the points are members of that model and 500 are not. Over 128 target models, that is $128 \times 500 = 64{,}000$ member pairs and 64,000 non-member pairs.

This is the setup of Carlini et al. (2022), scaled down from an image classifier to a linear model. Section 10.8 describes the full-size pipeline.

What this chapter assumes. The membership game, the advantage $\mathrm{Adv} = \mathrm{TPR} - \mathrm{FPR}$ and its ceiling, and the difference between average-case and worst-case games are in Threat models and privacy games. The Neyman–Pearson lemma, trade-off curves, ROC curves, the Bayesian view and confidence intervals for rates are in Hypothesis testing. The generalization gap and the self-influence of a training example are in Algorithmic stability and generalization. Each is restated below where it is used.

Conventions. As in Threat models and privacy games, $b = 1$ is the world in which the target is a member (the alternative hypothesis) and $b = 0$ the world in which it is not (the null). A model is its weight vector θ. A record is $z = (x, y)$, a feature vector and its label. An attack outputs a score and says "member" when the score exceeds a threshold. Its TPR is the fraction of members it flags and its FPR the fraction of non-members it flags. Logarithms are natural.

10.2. Toolkit: three facts every derivation uses

10.2.1. Fact 1 — The membership game and its advantage

Membership inference is scored as a game, so that "the attack works" has a precise meaning. The challenger draws a training set and flips a fair coin to get a hidden bit b. The coin decides the target z: if $b = 1$, z is a member of the training set; if $b = 0$, it is a fresh record from the same population. The challenger trains θ and gives the adversary z and query access to θ. The adversary guesses b', 1 for "member" and 0 for "not a member".

The coin is fair so that neither answer is right more often by default: an adversary that ignores the model and always says "member", or flips a coin of its own, wins exactly half the games. Any win rate above $\frac{1}{2}$ must come from what the model reveals. $\Pr[b' = b]$ is the probability that the guess is correct, whichever value the bit has; it is not the probability that b is 1.

To compute it, split the games by the value of the bit. Half the games have $b = 1$, and the adversary wins those when it says "member", which it does with probability TPR. The other half have $b = 0$, and it wins those when it says "not a member", with probability $1 - \text{FPR}$. Adding the two halves gives $\frac{1}{2}\text{TPR} + \frac{1}{2}(1 - \text{FPR})$, which rearranges to

$$\Pr[b' = b] = \tfrac{1}{2} + \tfrac{1}{2}\text{Adv}, \qquad \text{Adv} = \text{TPR} - \text{FPR}. \tag{10.1}$$

The **advantage** is how much more often the attack says "member" to members than to non-members. An attack that ignores the model says "member" equally often in both worlds and scores 0; a perfect attack scores 1. This is Fact 1 of Threat models and privacy games.

In the running example, "pick a target model and a pool point" is this game with the pool as the population: the point is a member of that model's training set with probability $\frac{1}{2}$, because each model trains on half the pool. The loss attack, the shadow attack and the comparison of attacks by advantage all use this fact.

10.2.2. Fact 2 — The best test of two Gaussians, at any FPR

Most of the chapter reduces to one test: an observation X is a standard normal variable in one world and the same bell curve shifted right by s in the other. Which world produced it? Write $H_0 : X \sim \mathcal{N}(0, 1)$ and $H_1 : X \sim \mathcal{N}(s, 1)$, with $s > 0$. The number s is the **separation**: the distance between the two means in units of the standard deviation. A large s means the two bell curves barely overlap.

By the Neyman–Pearson lemma, the best test thresholds the likelihood ratio. Here the log of the ratio of the two normal densities is

$$\ln \frac{e^{-(X-s)^2/2}}{e^{-X^2/2}} = \frac{X^2 - (X-s)^2}{2} = sX - \frac{s^2}{2}, \tag{10.2}$$

which grows with X. So "the likelihood ratio is large" is the same as "X is large", and the best test says "H_1" when X exceeds some cut-off.

The cut-off is set by the FPR you allow. Write Φ for the standard normal cumulative distribution function: $\Phi(t)$ is the probability that a standard normal variable is below t, and Φ^{-1} is its inverse. To flag a fraction α of H_0 draws, the cut-off must be the point that a standard normal exceeds with probability α, which is $\Phi^{-1}(1-\alpha)$. Under H_1, $X - s$ is standard normal, so X passes the cut-off with probability $1 - \Phi\big(\Phi^{-1}(1-\alpha) - s\big)$. That is the TPR:

$$\text{TPR}(\alpha) = 1 - \Phi\big(\Phi^{-1}(1-\alpha) - s\big). \tag{10.3}$$

This is the Gaussian trade-off curve of Hypothesis testing, written as TPR against FPR: the most members any test can catch, at each FPR.

To get a feel for it, take $\alpha = 10^{-3}$, so the cut-off is $\Phi^{-1}(1-\alpha) = 3.0902$: a standard normal exceeds 3.0902 one time in a thousand. With a separation of 0.5, a member's X must still clear $3.0902 - 0.5 = 2.59$ standard deviations above its own mean, so $\text{TPR} = 1 - \Phi(2.59) = 0.0048$, barely five times the chance rate of 0.001. With a separation of 4, the cut-off sits $3.0902 - 4 = -0.91$ standard deviations from the member mean, below it, so most members pass: $1 - \Phi(-0.91) = 0.8185$. LiRA's Gaussian fits, the two-type example and the exposure of outliers all use this formula.

10.2.3. Fact 3 — For logistic regression, the logit of the confidence is the margin

An attack has to pick some number from the model's output to look at. Three natural choices are the **confidence** p_y, the probability the model gives to the true label; the **loss** $\ell = -\ln p_y$; and the **logit of the confidence**, $\phi = \ln \frac{p_y}{1-p_y}$, the log of the odds the model gives to the true label. For logistic regression the last one is especially simple. The model gives the true label y the probability $p_y = \sigma(y\langle\theta, x\rangle)$, and the logit undoes the logistic function, $\ln \frac{\sigma(t)}{1-\sigma(t)} = \ln \frac{1/(1+e^{-t})}{e^{-t}/(1+e^{-t})} = t$. So ϕ is the **margin** $y\langle\theta, x\rangle$, how far the point lies on the correct side of the decision boundary, and the loss is a function of it:

$$\phi = \ln \frac{p_y}{1-p_y} = y\langle\theta, x\rangle, \qquad \ell = -\ln p_y = \ln\left(1 + e^{-\phi}\right). \tag{10.4}$$

The second formula is $-\ln \sigma(\phi)$ written out, since $1/\sigma(\phi) = 1 + e^{-\phi}$.

The three numbers behave differently at the confident end. A model that gives the true label probability 0.9 has $\phi = \ln(0.9/0.1) = \ln 9 = 2.197$ and loss $\ln(1/0.9) = 0.105$. Probability 0.99 gives $\phi = 4.595$; 0.999 gives 6.907. The probability crowds against 1, while ϕ keeps spreading the values out.

Yet as decision rules they are interchangeable. The confidence and ϕ rise together, and the loss falls as they rise, so each is a monotone function of the others. **A threshold on one is a threshold on the others,** and all three give the same ROC curve. They differ only when a statistic is *combined* across records, for example averaged or fitted with a Gaussian, which is where LiRA's choice of ϕ matters.

10.3. The loss attack and the generalization gap

10.3.1. Context

A model is fitted to its training data, so it usually has a lower loss on a training point than on a fresh one. Yeom et al. (2018) turned this into an attack: **say "member" when the loss is low**. The attack needs no shadow models and no knowledge of the population beyond the loss threshold. They also showed that its advantage is exactly the generalization gap: overfitting and membership leakage are, for this attack, the same number.

10.3.2. Statement

The cleanest version of the attack turns the loss directly into a probability of saying "member": the lower the loss, the more likely the verdict "member". For that to be a probability, the loss must have a known range, so let it take values in $[0, B]$. The **bounded-loss attack** says "member" with probability $1 - \ell(\theta; z)/B$: always at loss 0, never at loss B, and in proportion in between. In the membership game of Fact 1, its advantage is the expected loss on non-members minus the expected loss on members, divided by B. That difference is the **generalization gap**: the

model's expected loss on fresh data, its **population risk** $\mathcal{L}_{\mathcal{D}}(\theta_D)$, minus its average loss on its own training set D, its **empirical risk** $\mathcal{L}(\theta_D; D)$. So

$$\text{Adv} = \frac{\mathbb{E}[\ell(\theta; z) \mid b = 0] - \mathbb{E}[\ell(\theta; z) \mid b = 1]}{B} = \frac{\mathbb{E}_D[\mathcal{L}_{\mathcal{D}}(\theta_D) - \mathcal{L}(\theta_D; D)]}{B}, \tag{10.5}$$

the expected generalization gap divided by B. For the 0-1 loss ($B = 1$), which is 0 on a correct prediction and 1 on a wrong one, the attack is deterministic, "member if and only if the model classifies z correctly", and its advantage is the test error minus the training error.

10.3.3. Derivation

The plan is to compute the attack's TPR and FPR as average losses, subtract them as Fact 1 says, and then recognize the two averages as test loss and training loss.

1. **TPR.** Given $b = 1$, the attack says "member" with probability $1 - \ell/B$ for whatever loss the target has. Averaging over targets and training runs, $\text{TPR} = \mathbb{E}[1 - \ell/B \mid b = 1] = 1 - \mathbb{E}[\ell \mid b = 1]/B$.
2. **FPR.** The same calculation with $b = 0$ gives $\text{FPR} = 1 - \mathbb{E}[\ell \mid b = 0]/B$.
3. **Subtract.** By Fact 1 the advantage is TPR − FPR. The 1s cancel and $\text{Adv} = (\mathbb{E}[\ell \mid b = 0] - \mathbb{E}[\ell \mid b = 1])/B$.
4. **Identify the two averages.** When $b = 1$, z is a uniformly chosen training point, so its expected loss is the expected training loss, $\mathbb{E}[\ell \mid b = 1] = \mathbb{E}_D[\mathcal{L}(\theta_D; D)]$. When $b = 0$, z is a fresh draw independent of D, so its expected loss is the expected test loss, $\mathbb{E}[\ell \mid b = 0] = \mathbb{E}_D[\mathcal{L}_{\mathcal{D}}(\theta_D)]$. Their difference is the expected gap of Algorithmic stability and generalization.
5. **The 0-1 loss.** With $\ell \in \{0, 1\}$ and $B = 1$, "member with probability $1 - \ell$" says "member" with probability 1 when $\ell = 0$ and 0 when $\ell = 1$, that is, exactly when z is classified correctly. The members it flags are the training points the model gets right, so TPR = 1 − train error; the non-members it flags are the fresh points it gets right, so FPR = 1 − test error; and Adv = test error − train error.

10.3.4. Interpretation

The first lesson is that **overfitting implies leakage.** Any model with a generalization gap leaks membership through its loss, by at least the gap divided by the loss range. You can read this off from training and test error alone, without running any attack.

The gap also has a finer structure. The stability chapter shows that the expected gap equals the average **self-influence** of the training examples: how much each example's own loss rises when it is taken out of training and replaced by a fresh record. The reason is that a training point's loss and a fresh point's loss differ exactly by whether the model saw that point. So the loss attack's advantage is the average, over records, of how much each record is memorized. An average hides who is memorized, and Section 10.7 measures it record by record.

The converse fails: **a small gap does not mean a private model.** The loss attack is one attack. It is the best attack that sees only the loss and ignores *which* record it is looking at, but

a record-aware attack can beat it by a wide margin, as the rest of this chapter shows. Yeom et al. also construct models that leak membership with no generalization gap at all.

Finally, the randomized rule is convenient for the proof, but an attacker would rather use a plain threshold. Yeom et al. also propose a deterministic version: say "member" when the loss is below the expected training loss τ. That needs only τ, which an attacker can estimate from shadow models or a reported training loss.

10.3.5. Example: the running example

Over the 128 target models, the training error is 0.1495 and the test error is 0.2663. "Member if correctly classified" flags the members it gets right, so $\text{TPR} = 1 - 0.1495 = 0.8505$, and the non-members it gets right, so $\text{FPR} = 1 - 0.2663 = 0.7337$. Its advantage is $0.8505 - 0.7337 = 0.1168$, exactly the gap $0.2663 - 0.1495$.

The logistic loss is unbounded, so the bounded-loss attack needs it clipped: replace any loss above $B = 2$ by 2. The mean clipped loss is 0.4158 on members and 0.5433 on non-members. Equation 10.5 predicts an advantage of $(0.5433 - 0.4158)/2 = 0.0638$. Drawing the attack's coins gives 0.0639. With Yeom's threshold, the mean training loss $\tau = 0.4159$, the deterministic attack has $\text{TPR} = 0.5936$, $\text{FPR} = 0.4834$ and advantage 0.1102.

By Fact 1, an advantage between 0.0638 and 0.1168 means winning between $\frac{1}{2} + \frac{1}{2}(0.0638) = 0.532$ and $\frac{1}{2} + \frac{1}{2}(0.1168) = 0.558$ of games: the three attacks win between 53% and 56% of games. None identifies anyone with confidence: an FPR near one half means that half of the non-members are flagged too. Figure 10.1 shows why. The two distributions of ϕ (equivalently, of the loss, by Fact 3) are shifted but almost entirely overlap.

10.3.6. Check yourself

- A model has training accuracy 99% and test accuracy 70%. What advantage does "member if correctly classified" reach? *(The test error minus the training error,* $0.30 - 0.01 = 0.29$*. It wins the membership game with probability* $\frac{1}{2} + \frac{1}{2} \times 0.29 = 0.645$*.)*
- Why does the bounded-loss attack need a randomized decision rather than a threshold? *(Randomizing with probability* $1 - \ell/B$ *makes the probability of saying "member" linear in the loss, so its expectation is the expected loss. A threshold gives an advantage that depends on the whole distribution of the loss, not only its mean.)*

10.4. Shadow models

10.4.1. Context

An attacker who wants a better rule than "low loss means member" has to know what members' outputs look like, and it has no labelled examples: it does not know who is in the target's training set. Shokri et al. (2017) solved this with **shadow models**. The attacker trains models of its own that imitate the target: same architecture, same training recipe, data from the same distribution. For its own models it *knows* who was a member. It collects the shadow models' outputs on

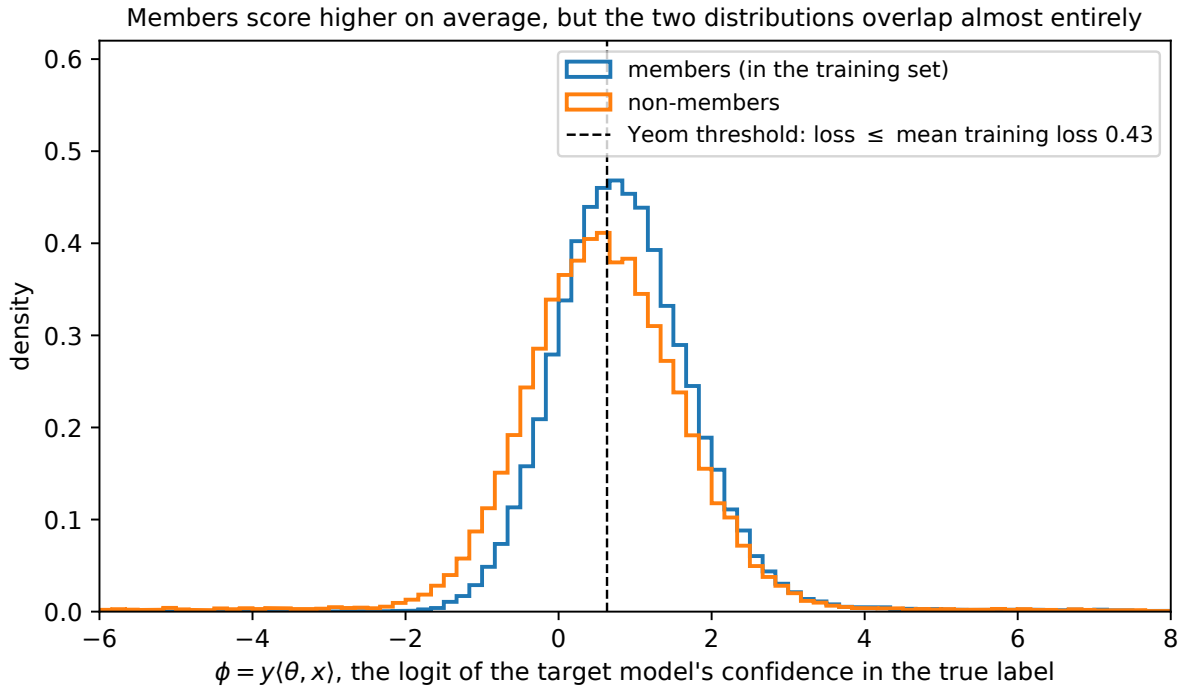

Figure 10.1.: Distribution of ϕ, the logit of the target model's confidence in the true label, over member pairs and non-member pairs of the 128 target models. The dashed line is Yeom's threshold: the attack says "member" to its right, where the loss is below the mean training loss.

members and non-members, labels them "in" and "out", and trains an **attack model**, a classifier from outputs to membership. Shokri et al. train one attack model per class, with the prediction vector as input.

10.4.2. Statement

The claim is that, with enough shadow data, the attack model learns the best rule available from the output alone. Suppose each shadow model is trained exactly as the target is. Let o be the output the attacker sees (here $o = (y, \phi)$, the class and the logit of the confidence). Train the attack model $h(o) \in (0, 1)$, a predicted probability of "in", by minimizing the cross-entropy, the usual classification loss $-\ln h$ on "in" pairs and $-\ln(1-h)$ on "out" pairs, over the shadow pairs (o, m), with $m = 1$ for "in".

As the number of shadow pairs grows, h tends to the **posterior probability of membership**, the probability that the record is a member given that the output is o. With a fair prior, the posterior odds equal the likelihood ratio, so the posterior is an increasing function of it:

$$h(o) \to \Pr[b = 1 \mid o], \qquad \frac{\Pr[b = 1 \mid o]}{\Pr[b = 0 \mid o]} = \frac{q(o)}{p(o)}, \tag{10.6}$$

where q and p are the densities of o for members and for non-members, *pooled over all records*. So thresholding the attack model is the Neyman–Pearson test for the observation o, and no attack that sees only o has a higher TPR at any FPR.

10.4.3. Derivation

The argument has four links: the shadow data look like the real game, cross-entropy training recovers the posterior, the posterior is a monotone function of the likelihood ratio, and thresholding the likelihood ratio is optimal.

1. **The shadow pairs have the right distribution.** A shadow model is trained like the target, on data from the same population, and each record is in or out with probability $\frac{1}{2}$. So a shadow pair (o, m) has the same joint distribution as a pair (target output, membership bit) in the game. Learning from shadow pairs is learning about the real game.
2. **Cross-entropy is minimized by the true posterior.** Fix one output o and let $\rho = \Pr[m = 1 \mid o]$ be the true fraction of "in" among pairs with that output. If the attack model predicts h there, its expected loss is $-\rho \ln h - (1-\rho)\ln(1-h)$. Its derivative in h is $-\rho/h + (1-\rho)/(1-h)$, which is zero at $h = \rho$, and the function is convex, so that zero is the minimum. Since this holds separately at every o, the minimizer over all functions of o is $h(o) = \rho(o)$. With enough shadow data and a flexible enough attack model, training finds it.
3. **Bayes' rule.** Posterior odds equal prior odds times the likelihood ratio (Hypothesis testing): $\Pr[b = 1 \mid o] / \Pr[b = 0 \mid o] = \frac{\Pr[b=1]}{\Pr[b=0]} \frac{q(o)}{p(o)}$, because the joint probability of a world and an output is the prior of the world times the density of the output in that world. With prior odds 1, $\Pr[b = 1 \mid o] / \Pr[b = 0 \mid o] = q(o)/p(o)$. The posterior h and the odds $h/(1-h)$ rise together, since $h \mapsto h/(1-h)$ is increasing.
4. **Neyman–Pearson.** So a threshold on $h(o)$ is a threshold on $q(o)/p(o)$. By the Neyman–Pearson lemma, a likelihood-ratio threshold has the highest TPR at its FPR among all tests that see o.

10.4.4. Interpretation

The attack model is **optimal for the wrong question.** The densities q and p in step 4 are *pooled over records*: the attack model sees (y, ϕ), not which record produced it. So it is the best attack among those that treat all records alike. If $q(o)/p(o)$ is increasing in ϕ within each class, which is what you expect when members tend to have higher ϕ, the attack is a threshold on ϕ per class, which is the loss attack with a class-dependent threshold. It cannot know that $\phi = 2$ is a high value for one record and a low value for another.

What shadow models really buy, then, is **calibration**. They let the attacker choose a threshold that gives a target FPR on the real model, without any member of the real training set: the attacker picks the threshold at which the desired fraction of its own shadow non-members pass, and trusts that the real non-members behave the same way. That is the job they keep in LiRA.

The imitation can also be crude. Salem et al. (2019) found that one shadow model is often enough, and that shadow data from a different distribution still works, because what the attack model learns (lower loss means member) transfers across tasks.

10.4.5. Example: the attack model on the running example

For each class, the attack model is a logistic regression of "in" on $(1, \phi)$, trained on the roughly 32,000 shadow pairs of that class (64 shadow models times the pool points with that label). Both slopes are positive (0.238 for $y = -1$, 0.158 for $y = +1$), so within each class the predicted probability of "in" rises with ϕ, and a threshold on it is a threshold on ϕ. It is a per-class threshold on the loss. Its performance across all thresholds is summarized by the **area under the curve (AUC)**, the area under its ROC curve, which equals the probability that a random member gets a higher score than a random non-member. Its AUC is 0.577, the same as the loss attack's, and so is its TPR at every FPR to within sampling noise (Table 10.4).

Calibration works. Setting the attack model's threshold on the shadow models so that their FPR is 1% gives, on the 128 target models it never saw, an FPR of 0.0095 and a TPR of 0.0098. The attacker hits the FPR it aimed for. At that FPR the TPR is no better than chance, since 0.0098 is about the 0.0095 fraction of non-members flagged, because a global threshold on ϕ has nothing to work with at the low end.

10.4.6. Check yourself

- The attacker's shadow data come from a different hospital than the target's. Which step of the derivation fails, and is the attack useless? *(Step 1: the shadow pairs no longer have the target's joint distribution, so the attack model estimates the wrong posterior. It is not useless. Calibration is off, but "lower loss means member" usually still holds.)*
- Why does feeding the attack model a richer input, the whole prediction vector instead of ϕ, not help in the running example? *(For a binary linear model the prediction vector is $(\sigma(\langle\theta, x\rangle), 1 - \sigma(\langle\theta, x\rangle))$, and with the label it determines exactly ϕ and y, and ϕ and y determine it back. Each view can be computed from the other, so by Fact 2 of Threat models and privacy games, which says that processing a view cannot help, they give the same best attack.)*

10.5. LiRA: a likelihood-ratio test per example

10.5.1. Context

The pooled attacks of the last two sections compare a record's output with everyone else's. The right comparison is with the *same record's* output under models that did and did not train on it. Carlini et al. (2022) built the **likelihood ratio attack** (LiRA) on that idea. For a target record z, the attacker uses shadow models to estimate two distributions of ϕ_z, the logit of the confidence on z: the IN distribution $\tilde{Q}_z$ (models trained with z) and the OUT distribution $\tilde{P}_z$ (models trained without z). It then computes the likelihood ratio of the observed ϕ_z and thresholds it.

10.5.2. Statement

The attacker needs densities to form a likelihood ratio, and it only has a few dozen shadow values of ϕ_z per record. So it summarizes each set by a bell curve: it fits a Gaussian to each distribution, $\tilde{Q}_z = \mathcal{N}(\mu_{\text{in},z}, \sigma^2_{\text{in},z})$ and $\tilde{P}_z = \mathcal{N}(\mu_{\text{out},z}, \sigma^2_{\text{out},z})$, from the shadow models that did and did not train on z. Here μ and σ are the mean and standard deviation of ϕ_z over those models.

Online LiRA asks how much more likely the target model's ϕ_z is under the IN fit than under the OUT fit. Its score is the natural log of that ratio, where $\mathcal{N}(\phi; \mu, \sigma^2)$ denotes the normal density at ϕ:

$$\ln \Lambda_z(\phi_z) = \ln \mathcal{N}(\phi_z;\, \mu_{\text{in},z}, \sigma^2_{\text{in},z}) - \ln \mathcal{N}(\phi_z;\, \mu_{\text{out},z}, \sigma^2_{\text{out},z}) \tag{10.7}$$

It says "member" when $\ln \Lambda_z$ exceeds a threshold τ that is **the same for every record**.

Offline LiRA uses only OUT models, which can be trained before the target record is known. It cannot compute an IN density, so it asks only how far above its usual OUT value the observed ϕ_z lies, measured in OUT standard deviations:

$$\frac{\phi_z - \mu_{\text{out},z}}{\sigma_{\text{out},z}}, \tag{10.8}$$

again with one threshold for all records. When the Gaussian fits are exact, online LiRA is the Neyman–Pearson test for the membership game: no attack that sees z and ϕ_z has a higher TPR at any FPR.

10.5.3. Derivation

Why one threshold on the per-example ratio is optimal. The adversary does not see ϕ_z alone; it also knows which record it is testing. So the observation is the pair (record, output), and the Neyman–Pearson lemma should be applied to the pair. The point of the steps below is that the record part of the pair carries no evidence and drops out of the ratio, leaving each record's own ratio.

1. **The view is a pair.** In the membership game the adversary sees the target record z and the output ϕ_z. The density of the pair is the probability of drawing that record times the density of the output given the record. Write it as $g(z)\, q_z(\phi)$ when $b = 1$ and $g(z)\, p_z(\phi)$ when $b = 0$, where q_z and p_z are the IN and OUT densities of ϕ_z.

2. **The record's own distribution is the same in both worlds.** The challenger picks z from the same pool whether or not it ends up in the training set, so g is the same factor in both. (In the running example every point is in the pool and is a member with probability $\frac{1}{2}$.)
3. **The likelihood ratio of the pair** is $\frac{g(z)\,q_z(\phi)}{g(z)\,p_z(\phi)} = \frac{q_z(\phi)}{p_z(\phi)} = \Lambda_z(\phi)$. The factor $g(z)$ cancels.
4. **Neyman–Pearson.** The best test of the pair thresholds its likelihood ratio, $\Lambda_z(\phi)$, at a single value. Different records are compared through their ratios, never through their raw ϕ.

This is the mixture argument of Fact 3 in Threat models and privacy games. An attacker that does not know which record it is testing sees an average over records of their IN and OUT distributions, and averaging blurs the differences, as when a large shift for a hard record is diluted among the small shifts of easy ones. An attacker that knows the record can undo that mixing: its best advantage rises from the total variation distance of the pooled distributions (the best advantage of any test between two distributions) to the average of the per-record ones.

Why Gaussian fits on ϕ. The fits are only as good as the bell-curve shape they assume, so it matters that ϕ, rather than the loss or the confidence, is close to Gaussian.

5. **ϕ is linear in the weights.** By Fact 3, $\phi_z = y\langle\theta, x\rangle$, a fixed linear function of θ for a fixed record. The regularized logistic-regression estimate θ solves the equation "average gradient over the training points plus $\lambda\theta$ equals zero". Because that is an average of many independent terms, the central limit theorem makes θ approximately Gaussian over the randomness of the training set (statisticians call such an estimate an M-estimator, and Section G.5 in the appendices proves this), and any fixed linear function of a Gaussian vector is Gaussian too. For a deep network the same scaling turns the confidence p_y, which piles up against 1, into a quantity whose distribution over retrainings Carlini et al. found close to Gaussian.
6. **Estimate the parameters from shadows.** In the running example every point is in exactly 32 of the 64 shadow models, because the shadows come in complementary pairs. The sample means and standard deviations over the 32 IN and the 32 OUT values give $\mu_{\text{in},z}, \sigma_{\text{in},z}, \mu_{\text{out},z}, \sigma_{\text{out},z}$.

Offline as a one-sided test. Offline LiRA is a weaker test, and the last two steps say what it tests and when it loses nothing.

7. **Without IN models**, the attacker cannot write down q_z. It can still test "ϕ_z is from $\tilde{P}_z$" against "ϕ_z is larger than that", because training on z raises ϕ_z: the model moves to fit z, which increases its margin on z. The standardized score Equation 10.8 is the natural statistic, and $1 - \Phi$ of it is a one-sided p-value: the probability that a non-member's output would lie at least this far above its OUT mean.
8. **When it loses nothing.** Suppose the two fits have the same width, $\sigma_{\text{in},z} = \sigma_{\text{out},z} = \sigma_z$. Measure everything in units of σ_z from the OUT mean: the offline score is $t_z = (\phi_z - \mu_{\text{out},z})/\sigma_z$, and the IN mean sits at $s_z = (\mu_{\text{in},z} - \mu_{\text{out},z})/\sigma_z$. Then t_z is standard normal under OUT and normal with mean s_z under IN, which is exactly the setting of Fact 2, and Equation 10.7 becomes $\ln \Lambda_z = s_z t_z - s_z^2/2$. For one record, s_z is a fixed positive number, so both scores rank outputs the same way. Across records, they differ: online LiRA multiplies t_z by s_z, so it turns a given t_z into strong evidence when s_z is large and weak evidence when s_z is small; offline LiRA treats every t_z the same.

10.5.4. Example: two kinds of record, in closed form

A population with two kinds of record shows how much the per-record comparison matters, with numbers you can check by hand. Take unit variances everywhere (Table 10.2). A typical record is predicted confidently whether or not the model trained on it, so its OUT and IN means are both high and close together. An atypical record has a negative ϕ (it is misclassified) unless the model trained on it.

Table 10.2.: Two kinds of record. A typical record is predicted confidently whether or not it was trained on; an atypical one is predicted wrongly unless it was. The last column is Equation 10.3.

Kind	Share	OUT: $\phi \sim$	IN: $\phi \sim$	Separation s	Best TPR at FPR 10^{-3}, this kind alone
Typical	95%	$\mathcal{N}(3,1)$	$\mathcal{N}(3.5,1)$	0.5	0.0048
Atypical	5%	$\mathcal{N}(-2,1)$	$\mathcal{N}(2,1)$	4	0.8185

The separations are the gaps between the means, $3.5-3=0.5$ and $2-(-2)=4$, and the last column is the Fact 2 calculation done above for exactly these two separations. Now run three attacks, each set to a pooled FPR of 10^{-3}: over all non-members together, one in a thousand is flagged.

One threshold on ϕ is the loss attack. The OUT values of typical records are high, and they make up 95% of non-members, so the threshold must sit high to let through only 0.1% of non-members: at $\phi = 6.075$, typical non-members pass with probability $1-\Phi(6.075-3) = 1-\Phi(3.075)$, about 0.00105, and times their share of 0.95 that is the whole budget of 10^{-3}. Atypical non-members, centred at -2, essentially never pass. An atypical member scores around 2 and almost never passes. Only typical members, whose IN mean is 3.5, occasionally do, and the pooled TPR is 0.0048.

One threshold on the z-score is offline LiRA. Each record is standardized against its own OUT distribution, so every record gets FPR 10^{-3}, at $t_z \geq 3.0902$. Each kind then gets its own best TPR from the table, and the pooled TPR is their weighted average, $0.95 \times 0.0048 + 0.05 \times 0.8185 = 0.0455$.

One threshold on $\ln\Lambda$ is online LiRA. The threshold is $\ln\Lambda \geq 1.497$. With equal variances $\ln\Lambda = st - s^2/2$ (step 8), so for typical records the threshold is $t \geq (1.497+0.125)/0.5 = 3.244$, which lets through an FPR of only 5.90×10^{-4}; for atypical records it is $t \geq (1.497+8)/4 = 2.374$, which lets through FPR 0.0088. The pooled FPR is $0.95\times5.90\times10^{-4} + 0.05\times0.0088 = 10^{-3}$. The pooled TPR is 0.0503, the best possible at that FPR by the derivation above.

The global threshold is ten times worse than either per-example test. The likelihood ratio does better still than the z-score because it moves FPR budget from records where it buys little to records where it buys a lot. A typical record's extra false positives buy almost no true positives, since its two curves overlap; an atypical record's buy many, since its IN curve lies far to the right. The likelihood ratio makes that trade automatically.

Figure 10.2 shows the IN and OUT distributions for two real points of the running example: a typical point and an outlier.

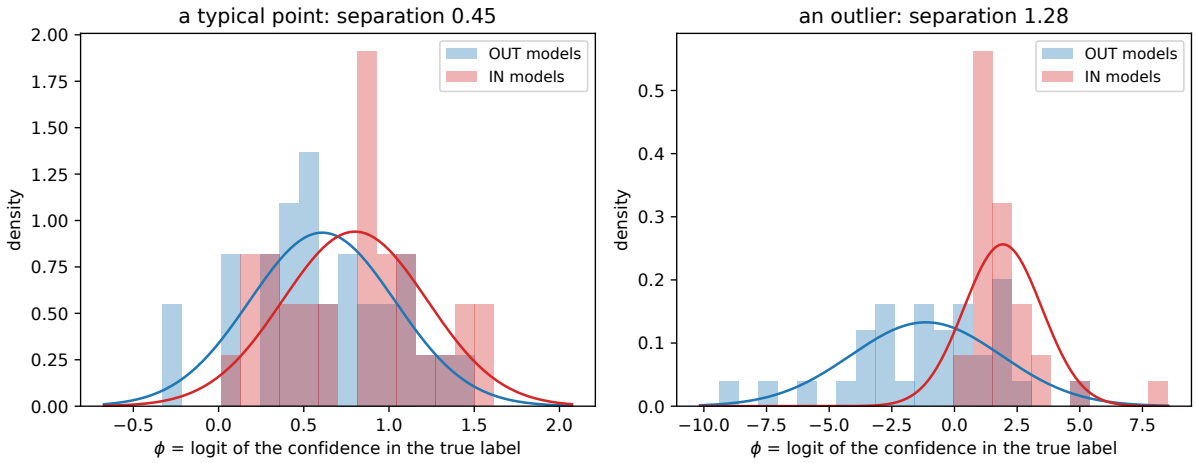

Figure 10.2.: The logit ϕ of one point over the 64 shadow models, split into the 32 that trained on it (IN) and the 32 that did not (OUT), with the fitted Gaussians. Left: a typical point, whose two distributions overlap. Right: an outlier, which the models predict wrongly unless they trained on it.

10.5.5. Interpretation

Online against offline. Online LiRA needs models trained *with* each target record, so to attack a new record you must train new shadow models. Offline LiRA's OUT models can be trained once, before the targets are known, and reused for every query. That is why it matters in practice, at some cost in power.

Per-example or global variance. Each per-example variance is estimated from half the shadow models, and with few shadow models those estimates are noisy. Noise in the variance is most harmful exactly where it counts. A record whose spread happens to be underestimated has its OUT curve drawn too narrow, so an ordinary output looks far out in the tail, its likelihood ratio is inflated, and it becomes a false positive at the strict thresholds that define the low-FPR end. Carlini et al. recommend one **global variance**, shared by all records, when shadow models are few: it averages over every record, so it is estimated from far more values and is stable. Figure 10.3 shows the effect on the running example.

More queries. For image models, Carlini et al. query each target on several augmented copies (flips, shifts) and fit a multivariate Gaussian. More observations of the same record give more evidence.

10.5.6. Check yourself

- The IN and OUT distributions of a record are identical. What is its likelihood ratio, and can LiRA ever flag it? *(The ratio is 1,* $\ln \Lambda = 0$*, for every output. With a positive threshold it is never flagged, which is right: no test can tell member from non-member for that record.)*

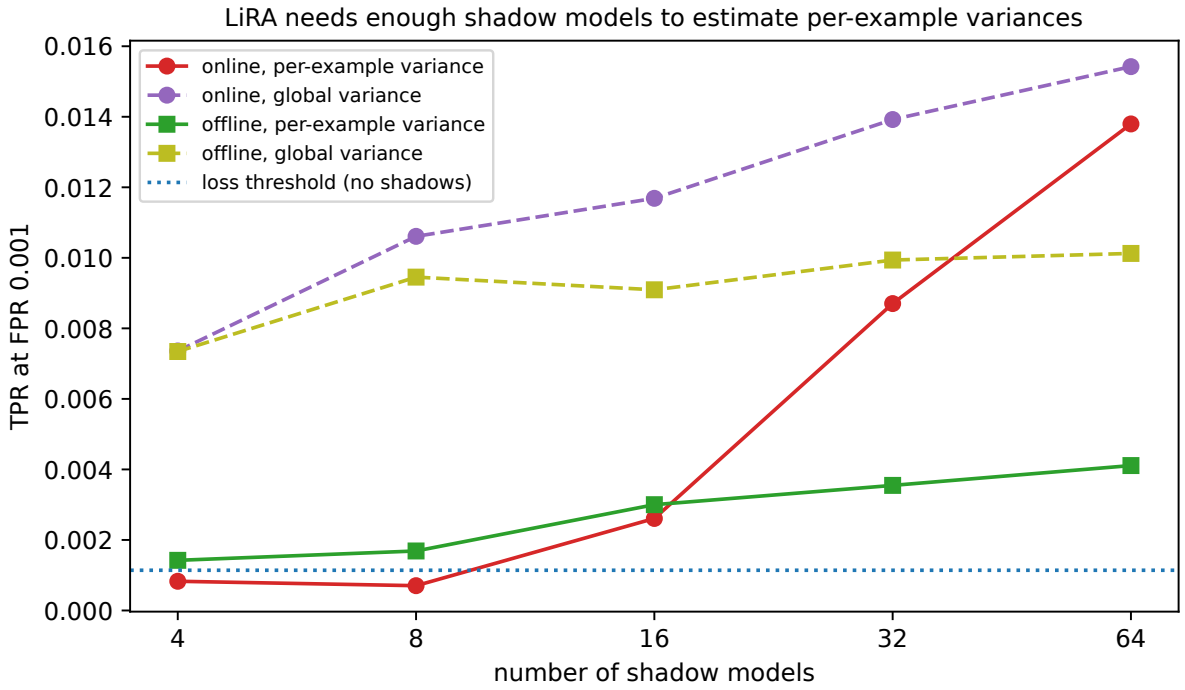

Figure 10.3.: TPR at FPR 10^{-3} of four LiRA variants on the 128 target models, as the attacker uses the first 4, 8, 16, 32 or 64 of its shadow models. With a global variance the attack is strong even with few shadow models; with per-example variances it needs many. The dotted line is the loss attack, which needs no shadow models.

- Why does the derivation need the target record to be drawn the same way in both worlds (step 2)? *(Otherwise the factor $g(z)$ does not cancel, and the record's identity is itself evidence. If, say, members were drawn from one hospital and non-members from another, the record alone would reveal b.)*

10.6. Evaluating attacks: TPR at a low FPR

10.6.1. Context

Two numbers dominate older papers on membership inference: the attack's **accuracy** (equivalently its advantage, by Fact 1) and its **AUC**, the probability that a random member scores higher than a random non-member. Both average over all members and non-members. A privacy breach is not an average. It happens when an attacker can say *with confidence* that a particular person was in the data. That means a low FPR, because at a low FPR almost every "member" verdict is right. Carlini et al. (2022) argued that attacks should be reported by their TPR at a fixed low FPR, such as 10^{-3}, and by the full ROC curve on log axes. The ROC curve plots TPR against FPR as the threshold sweeps from strict to lenient.

10.6.2. Statement

Two attacks can have the same AUC and nearly the same accuracy, yet TPRs at FPR 10^{-3} that differ by a factor of 38. The two attacks below are built to show how. Both concern a population of members and non-members; r is a fraction of members, and α is the FPR at which a TPR is read off.

Attack A exposes a few members completely and learns nothing about anyone else. It recognizes a fraction r of members with certainty and gives every other record, member or not, the same random score. Its AUC is $\frac{1}{2} + \frac{r}{2}$, its best advantage is r, and $\mathrm{TPR}(\alpha) = r + (1-r)\alpha$.

Attack B learns a little about everyone. It gives members a score $\mathcal{N}(\mu, 1)$ and non-members $\mathcal{N}(0, 1)$, with the shift μ chosen so that its AUC is the same as A's: $\Phi(\mu/\sqrt{2}) = \frac{1}{2} + \frac{r}{2}$. Its best advantage is $2\Phi(\mu/2) - 1$ and its TPR is Equation 10.3 with $s = \mu$.

10.6.3. Derivation

1. **AUC of A.** The AUC is the probability that a random member outscores a random non-member, with ties counted as one half (Hypothesis testing). Split on whether the member is one of the recognized ones. With probability r it is, and it wins. Otherwise both scores have the same distribution, so neither is more likely to be higher and the member wins with probability $\frac{1}{2}$. Total: $r + (1-r)\frac{1}{2} = \frac{1}{2} + \frac{r}{2}$.
2. **TPR of A.** At any threshold with FPR α, the recognized members always pass, and the others have the same score distribution as non-members, so they pass with the same probability α. So $\mathrm{TPR} = r + (1-r)\alpha$, and $\mathrm{TPR} - \mathrm{FPR} = r + (1-r)\alpha - \alpha = r(1-\alpha)$, at most r.

3. **AUC of B.** A member outscores a non-member when the difference of their scores is positive. That difference is a member's $\mathcal{N}(\mu, 1)$ minus an independent $\mathcal{N}(0, 1)$, so it is normal with mean μ and variance $1 + 1 = 2$. It is positive with probability $\Phi(\mu/\sqrt{2})$, the chance that a normal variable lies less than $\mu/\sqrt{2}$ of its standard deviations below its mean.
4. **Advantage of B.** The best advantage of a test between two distributions is their **total variation distance**: the most that the probability of any set of scores can differ between the two, reached by the set where one density exceeds the other. For two unit-variance Gaussians at distance μ the densities cross halfway, at $\mu/2$, so the best test says "member" above $\mu/2$. Its TPR is $\Pr[\mathcal{N}(\mu, 1) > \mu/2] = \Phi(\mu/2)$, its FPR is $\Pr[\mathcal{N}(0, 1) > \mu/2] = 1 - \Phi(\mu/2)$, and its advantage is the difference, $2\Phi(\mu/2) - 1$ (both facts are in Hypothesis testing).

With $r = 0.05$ (Table 10.3), both AUCs are $\frac{1}{2} + \frac{0.05}{2} = 0.5250$, and solving $\Phi(\mu/\sqrt{2}) = 0.5250$ gives $\mu = 0.0887$. A's best advantage is $r = 0.0500$ and B's is $2\Phi(0.0887/2) - 1 = 0.0354$. At FPR 10^{-3}, A has TPR $0.05 + 0.95 \times 10^{-3} = 0.05095$, while B has $1 - \Phi(3.0902 - 0.0887) = 0.00134$, a factor of 38.

Table 10.3.: Two attacks with the same AUC. Only the TPR at a low FPR tells them apart.

	AUC	Best advantage	TPR at FPR 10^{-3}
A: 5% of members exposed	0.5250	0.0500	0.05095
B: every member shifted by $\mu = 0.0887$	0.5250	0.0354	0.00134

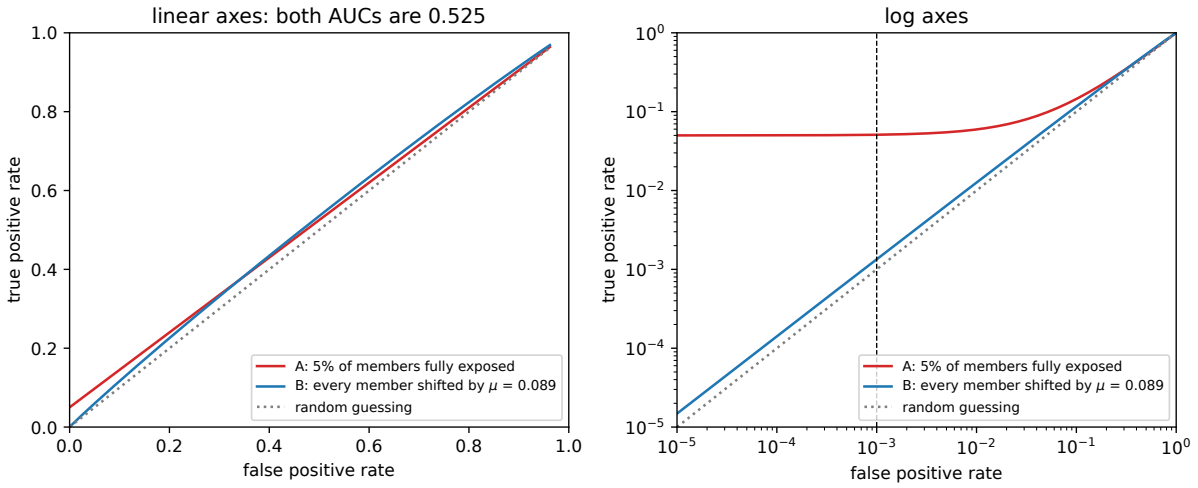

Figure 10.4.: ROC curves of attacks A and B. Left, linear axes: the two curves are indistinguishable from each other and from the diagonal. Right, log axes: A identifies 5% of members at every FPR, B is barely above chance. The dashed line marks FPR 10^{-3}.

10.6.4. Interpretation

Who is exposed matters more than how many. Attack A is a severe breach for one person in twenty, and B is a negligible one for everyone. AUC cannot tell them apart, and their best

advantages differ by only $0.0500 - 0.0354$, about 0.015. Only the low-FPR end of the ROC curve shows the difference.

Log axes are how you see that end. On linear axes, everything below FPR 0.01 is squeezed into one pixel column (Figure 10.4). On log axes, chance is the diagonal TPR = FPR at every scale, and an attack that is useful at low FPR stands out as a curve that flattens above it.

Measuring a low FPR takes many non-members. An FPR is estimated by counting false positives, and a count of k events has a relative error of about $1/\sqrt{k}$, so the estimate is only as good as the number of false positives behind it (Hypothesis testing). To see k false positives at FPR α you need about k/α non-members. That is why the running example evaluates many target models: 64,000 non-member pairs give about $64{,}000 \times 10^{-3} = 64$ false positives at 10^{-3}.

Precision is the fraction of "member" verdicts that are right. At a fair prior, members and non-members are equally many, so the right verdicts are proportional to TPR and the wrong ones to FPR, and the precision is TPR/(TPR + FPR). At TPR 0.05 and FPR 10^{-3} that is $0.05/0.051 = 0.98$. Real targets are rarely members with probability one half. Threat models and privacy games shows how the prior changes this.

10.6.5. Example: the five attacks on the running example

Table 10.4 scores every attack on the 128 target models, and Figure 10.5 draws their ROC curves on log axes. "Best advantage" is the largest TPR − FPR over all thresholds.

Table 10.4.: Every attack on the running example: 128 target models, 64 shadow models, 64,000 member and 64,000 non-member pairs.

Attack	AUC	Best advantage	TPR at FPR 10^{-3}	TPR at FPR 10^{-2}
Loss threshold (Yeom)	0.577	0.122	0.0009	0.0103
Shadow attack model (Shokri)	0.577	0.121	0.0008	0.0104
LiRA offline	0.632	0.189	0.0030	0.0273
LiRA online	0.629	0.175	0.0149	0.0386
LiRA online, global variance	0.623	0.169	0.0177	0.0396

By AUC the attacks are close, 0.577 against about 0.63, and by best advantage offline LiRA is even the strongest. At FPR 10^{-3} they are not close at all. The loss and shadow attacks are at chance: their TPRs of 0.0009 and 0.0008 are no higher than the FPR of 0.001, which is what a coin weighted to say "member" one time in a thousand would score. Online LiRA reaches 0.0149, 17.0 times the loss attack. It finds 952 of the 64,000 members, and 952/64,000 is the 0.0149.

How precise are those numbers? The **Clopper–Pearson interval** is an exact 95% confidence interval for a proportion estimated from a count: the range of true rates under which the observed

count would not be unusually high or low. For the TPR it is $[0.0140, 0.0158]$. The FPR is measured from 64 false positives among 64,000 non-members, with interval $[0.00077, 0.00128]$: the FPR itself is only known to lie between 0.77 and 1.28 times its nominal value. That is the $1/\sqrt{k}$ rule at work: 64 counts give a relative standard error of about $1/\sqrt{64}$, an eighth, and a 95% interval reaches about two standard errors to each side.

One caveat: **the threshold was chosen on the same data** that measure the rates, as is usual in this literature. A real attacker would set it on its shadow models, as the shadow-attack example did.

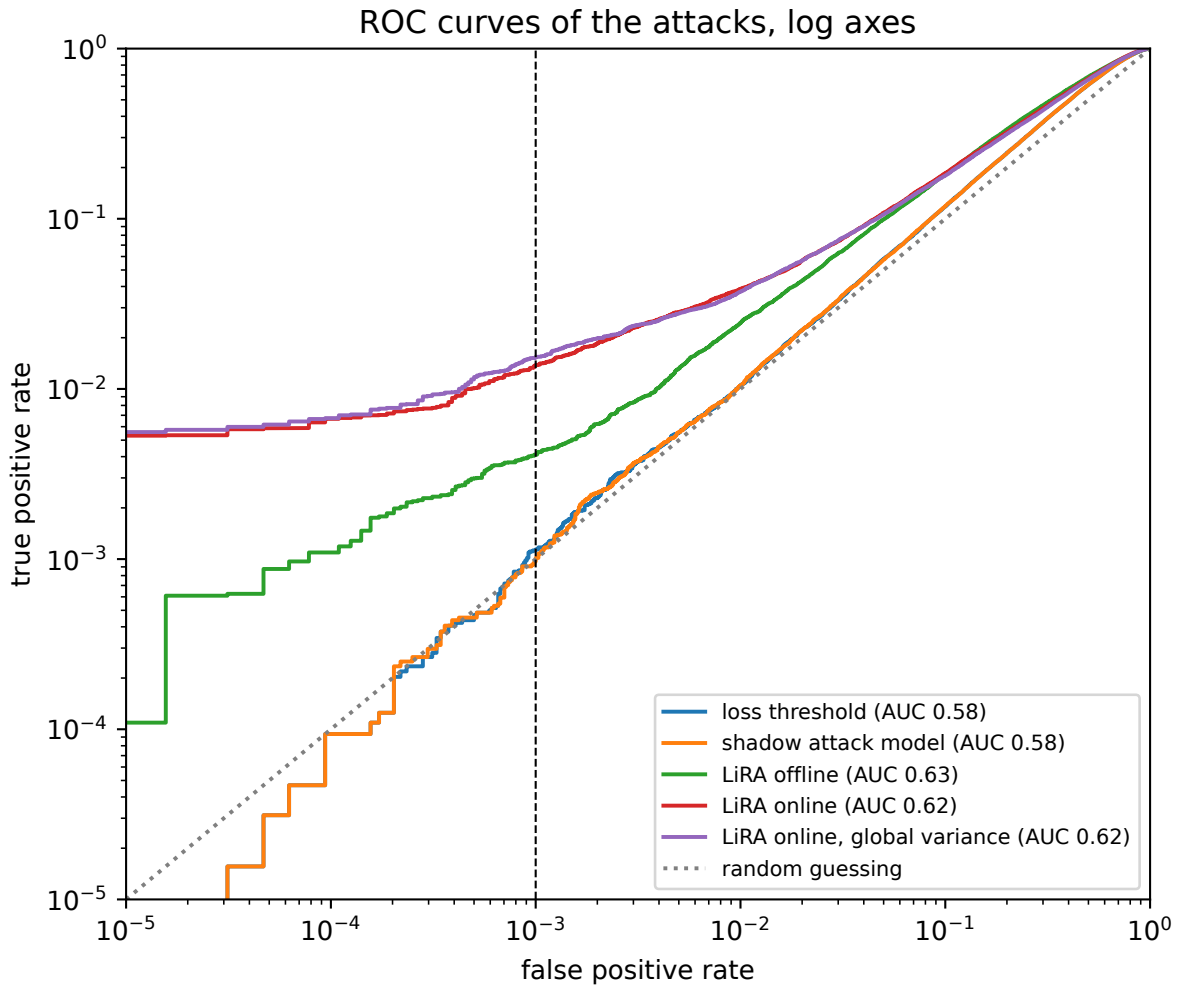

Figure 10.5.: ROC curves of the five attacks on log axes, over the 128 target models. The loss threshold and the shadow attack model follow the diagonal below FPR 0.01; online LiRA stays far above it down to the smallest FPR the 64,000 non-member pairs can measure, $1/64{,}000 \approx 1.6 \times 10^{-5}$. The dashed line marks FPR 10^{-3}.

10.6.6. Check yourself

- An attack has AUC 0.9 and TPR 10^{-3} at FPR 10^{-3}. Is it a privacy threat? *(Not to anyone in particular. It ranks members above non-members on average, but it cannot pick out any member with confidence: at FPR 10^{-3} it is at chance.)*
- With 5,000 non-members, can you report a TPR at FPR 10^{-4}? *(No. The threshold would have to admit $5{,}000 \times 10^{-4}$, that is half a false positive, so it can only admit none. With zero false positives among 5,000, the rule of three only bounds the FPR by about $3/5{,}000 = 6 \times 10^{-4}$. The rule comes from asking which rates make zero events in n trials still 5% likely: $(1-p)^n \approx e^{-pn} = 0.05$ gives $p = \ln 20/n \approx 3/n$.)*

10.7. Why outliers are most exposed

10.7.1. Context

Table 10.2 already shows the pattern: the low-FPR end of the ROC curve is made of records with a large separation between their IN and OUT distributions. Which records are those? The ones the model cannot predict without having seen them: rare, atypical or mislabelled records. This section measures that on the running example and connects it to self-influence, the amount by which training on a record changes the model's fit to that record.

10.7.2. Statement

For one record, the best test is the two-Gaussian test of Fact 2, so the best TPR is set by that record's own separation. For a record z with Gaussian IN and OUT distributions of a common width σ_z, the best TPR of any test on z alone at FPR α is

$$\mathrm{TPR}_z(\alpha) = 1 - \Phi(\Phi^{-1}(1-\alpha) - s_z), \qquad s_z = \frac{\mu_{\mathrm{in},z} - \mu_{\mathrm{out},z}}{\sigma_z}, \tag{10.9}$$

and the numerator $\mu_{\mathrm{in},z} - \mu_{\mathrm{out},z}$ is the **self-influence** of z measured in ϕ: the average amount by which training on z raises the model's logit on z.

10.7.3. Derivation

1. **Per-example test.** For a fixed record, standardize the output: subtract $\mu_{\mathrm{out},z}$ and divide by σ_z. The result is standard normal under OUT and normal with mean s_z and variance 1 under IN, which is the setting of Fact 2 with $s = s_z$. Fact 2 gives Equation 10.9.
2. **Self-influence.** The stability chapter defines the self-influence of a training example z_i as $\ell(\theta_{D^{(i)}}; z_i) - \ell(\theta_D; z_i)$: the loss of the model trained on $D^{(i)}$, the training set with z_i replaced by a fresh record, minus the loss of the model trained on D itself. It is how much z_i's loss rises when z_i is left out, and its average over records is the expected generalization gap. Measure the same thing with ϕ instead of ℓ, with the sign flipped because ϕ rises where the loss falls, and average over the training randomness. Models trained with z give ϕ_z the mean $\mu_{\mathrm{in},z}$ and models trained without it give $\mu_{\mathrm{out},z}$, so it is $\mathbb{E}[\phi_z \mid z \in D] - \mathbb{E}[\phi_z \mid z \notin D] = \mu_{\mathrm{in},z} - \mu_{\mathrm{out},z}$.

3. **Who has large self-influence.** If the rest of the data already predict z's label, $\mu_{\text{out},z}$ is high and training on z adds little. If they predict the opposite label, $\mu_{\text{out},z}$ is low and the model must move toward z to fit it. How far it can move is limited by the regularization. The stability bound for regularized empirical risk minimization in Algorithmic stability and generalization says that one example can move the weights by at most $2L/(\lambda n)$, where L bounds the length of one example's loss gradient. For logistic regression that gradient has length at most $\|x\|$, so a longer x can pull harder. The effect on $\phi_z = y\langle\theta, x_z\rangle$ of a move in θ is the move times up to $\|x_z\|$ again. So a long x_z both pulls the weights harder and turns that pull into a larger change in its own margin. Points with an unpredictable label and a large norm, the outliers of the running example, have both. Section G.5 in the appendices turns this into a formula: to first order, training on z raises ϕ_z by $\frac{1}{n}\sigma(-\phi_z)\, x_z^\top H^{-1} x_z$, where H is the Hessian of the training objective. The formula is accurate for typical points and overstates the effect for the outliers.

10.7.4. Interpretation

Leakage is concentrated. The loss attack's advantage is the *average* self-influence (Section 10.3). The low-FPR end of the ROC curve is governed by the *largest* ones, because a strict threshold is passed only by the records with the largest separations. A model can have a small generalization gap and still expose a few records completely.

Memorizing outliers can be what makes a model accurate. Feldman (2020) shows that on long-tailed data, where many subpopulations are rare, a rare subpopulation seen only once in training must be memorized for good test accuracy, because the next example from it will look like that one. The records a model needs to memorize are the ones it exposes.

Removing the outliers does not fix it. Carlini et al. (2022b), "The Privacy Onion Effect", removed the most exposed records and retrained: the next layer of records became exposed. Exposure is relative to the rest of the dataset, since a record's OUT distribution depends on what the other records predict about it. Exercise 6 in the exercise book reproduces this on the running example.

Average-case evaluation understates the risk to individuals. This is the average-case versus worst-case gap of Threat models and privacy games, seen from the data: a score averaged over records drawn from the population is never more than the score on the worst record, and can be far less. A guarantee that protects every record, the subject of Part 3, has to bound the self-influence of the worst record, not the average.

10.7.5. Example: outliers in the running example

Table 10.5 splits the running example by kind of point.

Table 10.5.: The running example, split into typical points and outliers. Separations and self-influences are estimated from the 64 shadow models; TPR and FPR are measured on the 128 target models.

	Typical points (950)	Outliers (50)
Mean separation s_z	0.461	1.539
Mean loss self-influence, $\mathbb{E}[\ell \mid \text{out}] - \mathbb{E}[\ell \mid \text{in}]$	0.0897	2.0999
Mean of Equation 10.9 at $\alpha = 10^{-3}$	0.0074	0.2145
Online LiRA at pooled FPR 10^{-3}: TPR	0.0020	0.2597
Online LiRA at pooled FPR 10^{-3}: FPR	0.00086	0.00375

Outliers carry the gap. The mean loss self-influence over all points weights the two kinds by their shares: $0.95 \times 0.0897 + 0.05 \times 2.0999 = 0.1902$. The outliers' part of that is $0.05 \times 2.0999 \approx 0.105$, a share of 0.552 of the total, from 5% of the points.

Outliers are the true positives. At FPR 10^{-3}, online LiRA flags 26% of outlier members and 0.2% of typical members. Each target model has about 25 outlier members and 475 typical members, so it finds about $0.2597 \times 25 \approx 6.5$ outliers for every $0.0020 \times 475 \approx 0.95$ typical points. So roughly $6.5/(6.5 + 0.95)$, about seven in eight, of the members it finds are outliers; counting the actual flags on the 128 target models gives a share of 0.873, from 5% of the pool.

The likelihood ratio moves FPR budget to them, exactly as in the two-type example: typical points get an FPR of 0.00086, outliers 0.00375, and the weighted average $0.95 \times 0.00086 + 0.05 \times 0.00375$ is the pooled 10^{-3}.

Not every outlier is exposed. Figure 10.6 plots each point's separation against $\mu_{\text{out},z}$. An outlier's label is a coin flip, so about half the time it happens to agree with the trend in the first coordinate. Those outliers are predicted correctly without being seen ($\mu_{\text{out},z} \gg 0$) and are no more exposed than typical points. The exposed ones are those the model gets wrong unless it trains on them.

10.7.6. Check yourself

- Two records have the same loss under the target model. Can one be far more exposed than the other? *(Yes. Exposure depends on the separation between the record's own IN and OUT distributions, not on the observed loss. A low loss is normal for an easy record and strong evidence for a hard one.)*
- A team deletes the 50 outliers from the pool and retrains. Will the typical points be as safe as before? *(Not necessarily. Some typical points now become the least predictable records, and their self-influence rises. This is the onion effect; Exercise 6 in the exercise book measures it.)*

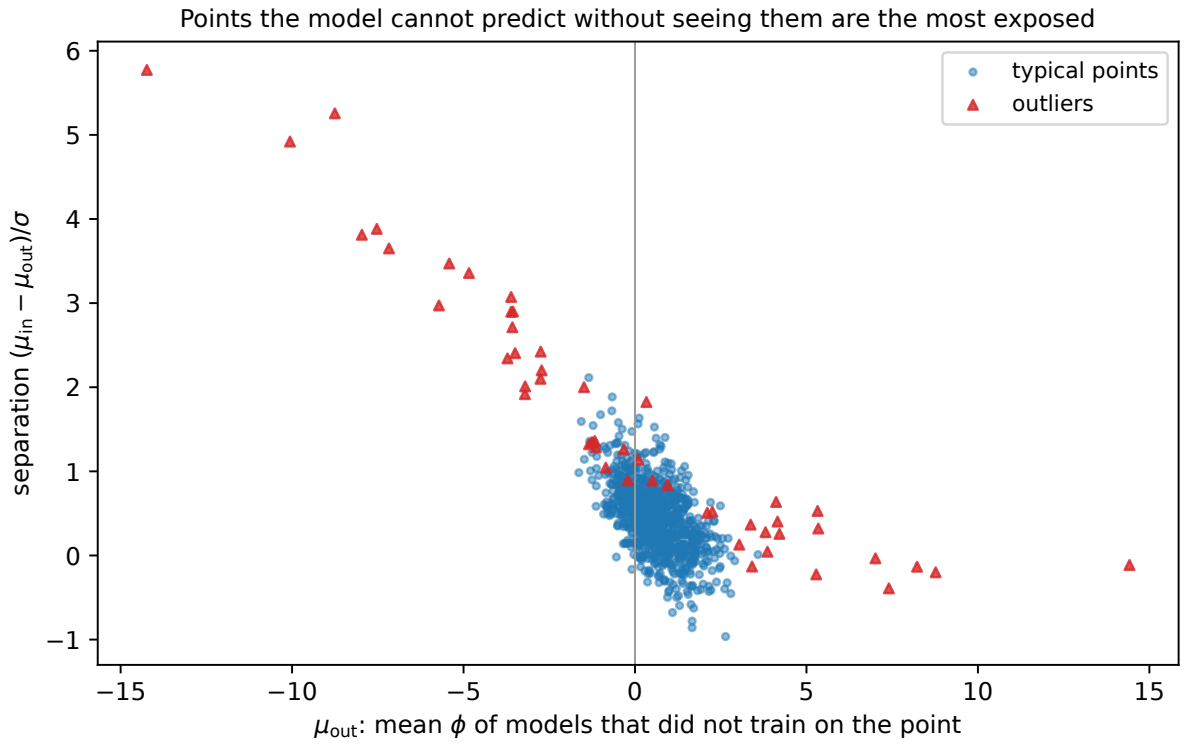

Figure 10.6.: Each pool point's separation $(\mu_{\text{in}} - \mu_{\text{out}})/\sigma$ against μ_{out}, the mean ϕ of the shadow models that did not train on it. Outliers (triangles) whose label the rest of the data contradict have the largest separations.

10.8. The full-size pipeline: LiRA on CIFAR-10

10.8.1. Context

The usual full-scale experiment trains an image classifier on CIFAR-10, a standard benchmark of small colour images in ten classes, runs LiRA with 16 shadow models, and reports the TPR at FPR 0.1%; the same pipeline later audits private training. That takes hours of GPU time, so this book does not run it. The running example is the same protocol with logistic regression in place of a ResNet, a deep convolutional network for images. This section lists what changes at full size.

10.8.2. Statement: the protocol

The protocol is the running example's, step for step. The steps are a recipe to follow in order, so they are listed.

1. **Data split.** Take the 50,000 CIFAR-10 training images as the pool. For each of $N+1$ models, choose a random half of the pool, so that each image is in about half of the models. One model plays the target, the others the shadows. Rotating which model is the target gives many target models and many (model, image) pairs to evaluate, as in the running example.
2. **Training.** Train every model with the same recipe: architecture (Carlini et al. use wide ResNets), optimizer, number of epochs, data augmentation. Imitating the target's recipe is what makes the shadow models valid (Step 1 of the shadow-model derivation: the shadow pairs must have the same distribution as the real ones).
3. **Statistic.** For each model and image, compute the logits on the image and on a few augmented copies (horizontal flips and small shifts). Convert each to $\phi = \ln \frac{p_y}{1-p_y}$, computed stably from the logits as $\phi = f_y - \ln \sum_{y' \neq y} e^{f_{y'}}$, where f are the logits. This follows from the softmax $p_y = e^{f_y} / \sum_{y'} e^{f_{y'}}$: the ratio $p_y/(1-p_y)$ is e^{f_y} over the sum of the other classes' $e^{f_{y'}}$, and the log of it never forms $1-p_y$, which rounds to 0 for a confident model.
4. **Fits.** For each image, fit IN and OUT Gaussians over the shadow models (a mean vector over the augmentations, and per-example or global variances).
5. **Scores.** For each target model and image, compute the online likelihood ratio Equation 10.7, or the offline z-score Equation 10.8.
6. **Evaluation.** Pool all (target model, image) pairs, sweep one threshold, and plot the ROC curve on log axes. Report the TPR at FPR 10^{-3}, with the number of non-member pairs it rests on.

10.8.3. Interpretation

With 16 shadow models, use a global variance. Each image is then in about 8 shadows and out of about 8. Per-example variances from 8 values are too noisy for the low-FPR end, as Figure 10.3 shows for 16 shadow models in the running example.

What to expect. Carlini et al. report that online LiRA is about ten times more powerful than earlier attacks at low FPR on CIFAR-10, and that the loss attack is close to chance there, which

is what Table 10.4 shows in miniature. The exact TPR depends on the model, its training length and the augmentations.

Why it is reused later. The auditing part of the book uses the same pipeline to measure privacy leakage empirically. A privately trained model takes the place of the target, and inserted canaries play the members. Canaries are records chosen to be as exposed as possible, such as mislabelled or out-of-distribution images, so that the attack sees the worst case rather than the average.

10.8.4. Check yourself

- Why must the shadow models use the same data augmentation as the target? *(Augmentation changes how strongly the model fits each image, so it changes μ_{in} and the variances. Shadow models with a different recipe estimate the wrong IN and OUT distributions.)*
- With 25,000 non-member images per target and one target model, how many false positives does FPR 10^{-3} allow? *(25. Rotating over several target models multiplies the count and tightens the interval.)*

10.9. Code: run every attack on the running example

The script code/membership_inference.py builds the pool, trains the 128 target and 64 shadow models, runs every attack, and prints every number in this chapter. It also computes the closed-form examples. Each attack is a small typed function of the margins ϕ and the shadow models' fits, and the figures loop over those functions. It runs in about ten seconds. From the repository root:

```
uv run python code/part02-attacks/membership_inference.py
```

Output (seed 0), summarized in Table 10.6:

Table 10.6.: The script's output with the default seed.

Experiment	Result
Setup	Pool 1,000 points in $\mathbb{R}^{100}$, 50 outliers, $\lambda = 10^{-3}$; 128 target models, 64 shadow models; 64,000 member and 64,000 non-member pairs
Generalization gap	Train error 0.1495, test error 0.2663; "correct means member": TPR 0.8505, FPR 0.7337, advantage 0.1168
Bounded loss, $B = 2$	Clipped loss: members 0.4158, non-members 0.5433; gap/B 0.0638; simulated advantage 0.0639
Yeom threshold	$\tau = 0.4159$: TPR 0.5936, FPR 0.4834, advantage 0.1102

Experiment	Result
Shadow attack model	Slopes 0.238 and 0.158; threshold set on shadows for FPR 1%: target FPR 0.0095, TPR 0.0098
Attacks	Table 10.4
LiRA online at FPR 10^{-3}	952 true positives of 64,000, interval $[0.0140, 0.0158]$; 64 false positives of 64,000, interval $[0.00077, 0.00128]$; 17.0 times the loss attack
Two kinds of record	Global threshold at $\phi = 6.075$: TPR 0.0048. z-score: 0.0455. Likelihood ratio, $\ln \Lambda \geq 1.497$: 0.0503, with FPRs 5.90×10^{-4} and 0.0088
Same AUC	A: AUC 0.5250, advantage 0.0500, TPR 0.05095. B: $\mu = 0.0887$, advantage 0.0354, TPR 0.00134
Outliers	Table 10.5; mean loss self-influence 0.1902, outliers' share 0.552; outliers' share of true positives 0.873
Shadow models, TPR at 10^{-3} for 4, 8, 16, 32, 64	Online, per-example variance: 0.0015, 0.0009, 0.0023, 0.0086, 0.0149. Online, global: 0.0092, 0.0127, 0.0151, 0.0171, 0.0177. Offline, per-example: 0.0018, 0.0023, 0.0029, 0.0035, 0.0030. Offline, global: 0.0098, 0.0111, 0.0112, 0.0114, 0.0118

tests/test_membership_inference.py checks that the output still matches.

What to take from it

Start with the loss attack, where theory and experiment meet exactly. **Yeom's identity is exact:** the 0-1 attack's advantage equals the error gap to four decimals, and the simulated bounded-loss attack matches gap/B to within sampling noise.

That identity measures an average, and the average is misleading where it matters. **Pooled attacks are at chance at the low-FPR end.** The loss threshold and the shadow attack model have AUC 0.577 and best advantage above 0.12, yet their TPR at FPR 10^{-3} is below 10^{-3}.

The fix is not a better statistic. **Per-example calibration is the whole gain:** LiRA uses the same statistic ϕ as the loss attack. It only compares each record with itself, and that multiplies the TPR at FPR 10^{-3} by 17.

How well it compares each record with itself depends on the shadow models. **The variance estimate decides the low end.** With 16 shadow models, online LiRA with per-example variances barely beats chance (0.0023), while with a global variance it reaches 0.0151. Per-example variances only catch up at 64 shadow models.

Finally, the gain is not spread evenly over the records. **The exposed are the outliers:** 5% of the pool provides 87% of the true positives at FPR 10^{-3}.

10.11. Cheat sheet

$\phi = \ln \frac{p_y}{1-p_y}$ is the logit of the confidence in the true label ($y\langle\theta, x\rangle$ for logistic regression). IN and OUT are the distributions of ϕ_z over models trained with and without z. Table 10.7 collects the results.

Table 10.7.: Every result in this chapter.

Result	Formula	Note
Advantage	$\mathrm{Adv} = \mathrm{TPR} - \mathrm{FPR} = 2\Pr[b' = b] - 1$	Fair prior
Loss attack (Yeom)	$\mathrm{Adv} = \mathbb{E}[\mathrm{gap}]/B$; 0-1 loss: test error − train error	Average-case; ignores which record it is
Shadow attack model	$h(o) \to \Pr[b = 1 \mid o]$, increasing in pooled $q(o)/p(o)$	Best among record-blind attacks; calibrates thresholds
LiRA online	$\ln \Lambda_z = \ln \mathcal{N}(\phi; \mu_{\text{in}}, \sigma^2_{\text{in}}) - \ln \mathcal{N}(\phi; \mu_{\text{out}}, \sigma^2_{\text{out}})$, one threshold for all z	Neyman–Pearson for the game when the fits are right
LiRA offline	$(\phi - \mu_{\text{out}})/\sigma_{\text{out}}$	OUT models only, reusable across targets
Equal variances	$\ln \Lambda_z = s_z t_z - s_z^2/2$	Online and offline rank one record alike, records differently
Per-example best TPR	$1 - \Phi(\Phi^{-1}(1-\alpha) - s_z)$, $s_z = (\mu_{\text{in}} - \mu_{\text{out}})/\sigma$	$\mu_{\text{in}} - \mu_{\text{out}}$ is the self-influence in ϕ
Same AUC, A vs B	A: $\mathrm{TPR} = r + (1-r)\alpha$; B: $\Phi(\mu/\sqrt{2}) = \frac{1}{2} + \frac{r}{2}$	AUC hides who is exposed

Rules of thumb

- Report the full ROC curve on log axes and the TPR at FPR 10^{-3} or lower, with the number of non-members behind it. Never report accuracy or AUC alone.
- A global threshold on loss or confidence is near chance at low FPR. Calibrate per example.
- With fewer than about 64 shadow models, use a global variance in LiRA.
- The records an attack exposes are the ones the rest of the data cannot predict: outliers, rare subgroups, mislabelled points.
- Overfitting implies membership leakage; no overfitting does not imply its absence.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

11. Attribute inference and model inversion

11.1. Why this matters

A hospital trains a model that predicts whether a patient will develop a lung disease from their age band and whether they smoke, and puts it behind an interface that anyone can query. An insurer knows your age and, from a claim, that you have the disease. Can it use the model to find out whether you smoke?

It can make a better guess than it could without the model. But that is not yet a privacy failure. If smokers get the disease more often, the insurer learns something about every person with the disease, whether or not their record was used for training. A published study saying "smoking causes this disease" would let it make the same guess. The question that matters for *you* is different: **does the model reveal more about your attribute because your record was in its training data?**

That question needs a baseline, and this chapter builds it and measures attacks against it. The attacks have a name. **Attribute inference** asks an adversary to recover one sensitive field of a record, such as smoking status, a genotype or an income band, from the other fields of the record and access to a model. **Model inversion** is the classic way to do it: you query the model once for each candidate value of the sensitive field, and keep the value whose prediction best explains the label you already know. In the insurer's case, you ask the model "how likely is the disease for a smoker of this age?" and "for a non-smoker of this age?", and lean towards whichever answer makes the known diagnosis less surprising.

11.1.1. The one idea: compare with the guesser who never sees the model

Imagine a second insurer who has no access to the model but knows the population perfectly: how common smoking is, how it relates to age and how it relates to the disease. For each combination of the fields it can see, it picks the value of the sensitive field that is most probable in the population. That guess is called the maximum a posteriori (MAP) guess, "a posteriori" because it is made after seeing the other fields, and its success rate is the **imputation baseline**. No model is involved in computing it. (Information theory calls this success rate the posterior vulnerability.)

The chapter rests on one claim about this baseline. **For a record that was not in the training set, no attack can beat the imputation baseline. For a record that was, an attack can.** The reason is that a model trained without your record was built from other people's data only, so it cannot carry any information about you specifically; at most it teaches the adversary about the population, and the baseline already assumes the population is known perfectly. So everything an attack achieves up to the baseline is population inference. What it achieves on training records beyond what it achieves on fresh ones is the leak about individuals. Measuring that leak means comparing people who were in the training set with people who were not, so

attribute inference turns out to be a membership question in disguise, which ties this chapter to Membership inference.

Table 11.1 lists the results and where each is used.

Table 11.1.: The results of this chapter and where each is used.

Result	Where it is used
The attribute inference game and its advantage	Measuring an attack as a difference between training and fresh records (Threat models)
Attribute advantage is a membership advantage	Turning any attribute attack into a membership test; bounding it by total variation
The non-member ceiling: imputation is the best possible on fresh records	Separating population inference from individual leakage
MAP model inversion; it equals imputation for a calibrated model	Reading an inversion attack as Bayes' rule with the model as likelihood
Overfitting lets members beat the baseline	Why the leak shrinks with the training-set size
Masking the confidences cannot help the best attacker	What rounding or label-only outputs do, and what they don't

What you need. Everything this chapter borrows is restated where it is used, so the links below are pointers for more detail. The MAP guess, vulnerability and min-entropy leakage are in Information theory. Bayes' rule, true and false positive rates, and the fact that the best advantage of a test is the total variation distance are in Hypothesis testing. Games and the vocabulary of adversaries are in Threat models, and the loss-threshold attack and the generalization gap are in Membership inference.

Notation. A record is $z = (s, x, y)$: a sensitive attribute s that takes a few values (smoker or not), public features x (the age band), and a label y (the disease). Records come from a population distribution $\mathcal{D}$, and $p(s, x, y)$ is the probability of a record (or its density, when x is continuous). A training set $D \sim \mathcal{D}^n$ is n records drawn independently from $\mathcal{D}$, and a training algorithm $\mathcal{T}$ turns it into a model $\theta = \mathcal{T}(D)$. The model's **confidence** in label y at input (x, s) is $f_y(x, s)$, the probability the model assigns to y.

The chapter keeps returning to one number: how often the best possible guess of s is right when the guesser sees x and y and knows the population. For each pair (x, y), the best guess is the value of s with the largest probability $p(s, x, y)$, and it is right on exactly that much probability. Adding over all pairs gives the success rate, written

$$V(S \mid X, Y) = \sum_{x,y} \max_s p(s, x, y). \tag{11.1}$$

For continuous x, read it as $\mathbb{E}\big[\max_s p(s \mid X, Y)\big]$: the average, over records, of the probability of the most likely value of s given that record's x and y. The capital letters S, X and Y stand for the random sensitive attribute, features and label of a record drawn from $\mathcal{D}$.

11.2. Toolkit: three facts every derivation uses

11.2.1. Fact 1 — The MAP guess is the best guess

Suppose you must guess s after seeing some observation o. For each value of o, whatever you answer is right exactly when the true s is your answer, so the best you can do is answer the value of s that is most probable together with that o. That answer is the **MAP guess**, $\arg\max_s p(s \mid o)$, and its success probability is the sum of the largest probabilities, one per observation:

$$V(S \mid O) = \sum_o \max_s p(s, o) = \mathbb{E}_O\Big[\max_s p(s \mid O)\Big]. \tag{11.2}$$

The second form is the same sum written as an average: $p(s, o) = p(o)\, p(s \mid o)$, and $p(o)$ does not depend on s, so it comes out of the maximum. V stands for **vulnerability**, the name Information theory gives this success rate.

The proof is the counting argument made precise. A deterministic guessing rule g maps each observation o to a guess $g(o)$. It is right when o occurs and $s = g(o)$, which has probability $p(g(o), o)$, so its success is $\sum_o p(g(o), o)$, one term per value of o. Each term is at most $\max_s p(s, o)$, and equals it when $g(o)$ is the MAP guess. A randomized rule picks among deterministic rules at random, so its success is an average of their successes, and an average is never above the best one.

For a concrete case, take no observation at all and a prior of 0.3 that a person smokes. The rule "always say non-smoker" is right 70% of the time and "always say smoker" 30%, so the best guess is "non-smoker", with $V(S) = 0.7$.

11.2.2. Fact 2 — An independent observation is useless

If an extra observation U has nothing to do with s and o, seeing it cannot change which value of s is most likely, so it cannot raise the best success. In symbols: if U is independent of (S, O), then $V(S \mid O, U) = V(S \mid O)$.

Independence means the probabilities multiply, $p(s, o, u) = p(s, o)\, p(u)$. Put that into Fact 1 with the observation (o, u):

$$V(S \mid O, U) = \sum_{o,u} \max_s p(s, o)\, p(u) = \sum_u p(u) \sum_o \max_s p(s, o) = V(S \mid O). \tag{11.3}$$

The middle step pulls $p(u)$ out of the maximum, which is allowed because $p(u) \geq 0$ does not depend on s; the last step uses that the $p(u)$ add up to 1. For instance, a coin flip you see before guessing does not change which smoking status is more likely, so it cannot change your success. This fact is what gives the non-member ceiling: a model trained without you is, as far as your record goes, such an independent observation.

11.2.3. Fact 3 — Processing an observation cannot help the best guesser

If you only see a transformed version $g(O)$ of the observation, you have at most the information in O itself, so you cannot do better: for any function g, $V(S \mid g(O)) \leq V(S \mid O)$.

The reason is that whoever sees o can compute $g(o)$ and then guess. A rule h that guesses from $g(o)$ is therefore also a rule on o, namely "apply g, then h", written $h \circ g$. So every rule on $g(O)$ is among the rules on O, and by Fact 1 none of those beats $V(S \mid O)$. For example, rounding a confidence of 0.62 to 0.6 can only merge observations that a guesser could have told apart; it never separates two that were the same. This is the guessing version of the data-processing inequality of Divergences, and the chapter uses it for confidence masking.

11.3. The attribute inference game

11.3.1. Context

"The attack recovered 78% of smoking statuses" sounds alarming, but it means nothing until you know two other numbers: how often the attribute could be guessed without the model, and how often the attack succeeds on people who were not in the training set. Yeom et al. (2018) made this precise with a game in the style of Threat models: a challenger sets up a hidden situation, the adversary gets a fixed view of it, and its guess is scored. Here the challenger flips a coin to decide whether the target record comes from the training set or fresh from the population. The coin is not a model of anything an attacker does; it is just a way to run both situations, member and non-member, under one set of rules, so that the attack's success in one can be compared with its success in the other.

11.3.2. Statement

The game (Yeom et al. 2018) is played for a training algorithm, a population $\mathcal{D}$, a training-set size n and an adversary $\mathcal{A}$. It has three steps.

1. The challenger draws a training set $D \sim \mathcal{D}^n$ and trains a model $\theta = \mathcal{T}(D)$ on it.
2. It draws a hidden bit $b \in \{0, 1\}$, each value with probability $\frac{1}{2}$. If $b = 1$, it picks the target $z = (s, x, y)$ uniformly from D, so the target is a **member** of the training set. If $b = 0$, it draws $z \sim \mathcal{D}$ afresh, so the target is a **non-member**.
3. The adversary receives the target's public fields and label (x, y), but not s, and access to θ. It may also know some or all of $\mathcal{D}$: that is its auxiliary knowledge. It outputs a guess $\hat{s}$ of the sensitive attribute.

The score should measure how much better the attack does on people who were in the training data than on people who were not, because that difference is what the model knows about its training records beyond the population. So the **attribute advantage** is the success rate on members minus the success rate on non-members,

$$\mathrm{Adv}^{\mathrm{attr}}(\mathcal{A}) = \Pr[\hat{s} = s \mid b = 1] - \Pr[\hat{s} = s \mid b = 0]. \tag{11.4}$$

Here $\Pr[\hat{s} = s \mid b = 1]$ is the probability that the guess equals the target's true attribute, over everything random in the game, given that the target is a member.

Attribute advantage is membership advantage. Any attribute attack can be turned into a membership attack, by a simple observation: if the attribute attack is right more often on members, then "the attribute attack was right" is itself evidence of membership. Build the membership adversary $\mathcal{B}$ that receives the whole record $z = (s, x, y)$ and θ, runs $\mathcal{A}$ on (x, y) and θ, and says "member" exactly when $\hat{s} = s$. A membership attack is described by two rates: its true positive rate (TPR), the probability that it says "member" for a member, and its false positive rate (FPR), the probability that it says "member" for a non-member. Its advantage is their difference. For $\mathcal{B}$ these are

$$\mathrm{TPR}_{\mathcal{B}} = \Pr[\hat{s} = s \mid b = 1], \qquad \mathrm{FPR}_{\mathcal{B}} = \Pr[\hat{s} = s \mid b = 0], \qquad \mathrm{TPR}_{\mathcal{B}} - \mathrm{FPR}_{\mathcal{B}} = \mathrm{Adv}^{\mathrm{attr}}(\mathcal{A}). \tag{11.5}$$

Membership attacks have a ceiling: no attack can tell two distributions apart better than their **total variation distance**, which is half the total absolute difference between their probabilities, $\mathrm{TV}(P, Q) = \frac{1}{2}\sum_v |p(v) - q(v)|$. Because $\mathcal{B}$ is a membership attack, its ceiling is also a ceiling on every attribute attack:

$$\mathrm{Adv}^{\mathrm{attr}}(\mathcal{A}) \le \mathrm{TV}(P_{\mathrm{in}}, P_{\mathrm{out}}), \tag{11.6}$$

where P_{in} and P_{out} are the distributions of the pair (z, θ), the target record together with the model, when z is a member and when it is not.

11.3.3. Derivation

1. **The membership test fires when the attribute guess is right.** $\mathcal{B}$ is given s, so it can check whether $\hat{s} = s$, and it says "member" on exactly that event.
2. **Read off its rates.** Its TPR is the probability that it says "member" when $b = 1$, and it says "member" exactly when the guess is right, so the TPR is $\Pr[\hat{s} = s \mid b = 1]$. In the same way its FPR, the probability of "member" when $b = 0$, is $\Pr[\hat{s} = s \mid b = 0]$.
3. **Subtract.** TPR − FPR is the right-hand side of Equation 11.4 term by term.
4. **Bound by total variation.** Why can no test beat the total variation distance? A test that says "member" on a set A of views $v = (z, \theta)$ has $\mathrm{TPR} = P_{\mathrm{in}}(A)$ and $\mathrm{FPR} = P_{\mathrm{out}}(A)$, so its advantage is $\sum_{v \in A} (p_{\mathrm{in}}(v) - p_{\mathrm{out}}(v))$. That sum is largest when A contains exactly the views with a positive term, those more likely for members, and its largest value is the total excess of p_{in} over p_{out}. Since both distributions add up to 1, the total excess one way equals the total excess the other way, so it is half the total absolute difference, $\mathrm{TV}(P_{\mathrm{in}}, P_{\mathrm{out}})$. A randomized test averages such sets and does no better. (Hypothesis testing proves this in general.) Applied to $\mathcal{B}$, this gives Equation 11.6.

11.3.4. Interpretation

The subtraction in Equation 11.4 is what makes the advantage a measure of privacy. Any success that comes from knowing the population, for example "people with the disease tend to smoke", is the same for members and non-members, so it appears in both terms and cancels. What is left is what the model knows about its own training records.

The reduction also says which leak implies which. If a model reveals nothing about membership, in the sense that P_{in} and P_{out} are equal and their total variation is 0, then Equation 11.6 forces the attribute advantage of every adversary to 0. The converse fails. A membership leak does not have to come with an attribute leak: if s is irrelevant to the label, a model can memorize who was in its training set without its predictions depending on s at all, and then no attribute attack gains anything on members.

Because the advantage is a difference, it is not enough to report it alone. Report the success on members and on non-members, as a membership attack reports its TPR and FPR. The advantage by itself hides how much of the success is population inference, which is the part common to both.

Finally, the membership test $\mathcal{B}$ that the reduction produces is a weak one. It outputs a single bit, so when it says "member" the only evidence it carries is how much more often that happens for members than for non-members, the ratio TPR/FPR. An attack that is right on most people of the population, members or not, has an FPR close to its TPR and a ratio close to 1, so at a low FPR it is much weaker than the dedicated attacks of Membership inference (Exercise 3 in the exercise book).

11.3.5. Example: one model, 200 times

The toy experiment of this chapter (Section 11.7) has a binary sensitive attribute with prior $\Pr[s = 1] = 0.3$, ten public features and a binary label. A logistic regression with one weight vector per value of s is trained on $n = 100$ records, and this is repeated 200 times. Each time, the MAP inversion attack of Section 11.5 guesses s for the 100 members and for 100 fresh records. It is right on 0.7832 of members and 0.7262 of non-members, and the attribute advantage is the difference (computed before rounding the two rates),

$$\text{Adv}^{\text{attr}} = 0.7832 - 0.7262 = 0.0569, \tag{11.7}$$

with a standard error of 0.0045 over the 200 models. Read as a membership test, the same attack has TPR 0.7832 at FPR 0.7262. Its likelihood ratio when it fires is $0.7832/0.7262 = 1.08$: being right is barely more likely for a member than for a non-member. Its balanced accuracy, the average of its accuracy on members (the TPR) and on non-members ($1 - \text{FPR}$), is $\frac{1}{2}(\text{TPR} + 1 - \text{FPR}) = \frac{1}{2} + \frac{1}{2} \times 0.0569 = 0.5285$, hardly better than the $\frac{1}{2}$ of a coin flip. Most of its 78% success would be there even if the person had never been in the training data.

11.3.6. Check yourself

- An attack guesses the right attribute for 90% of members and 90% of non-members. What is its attribute advantage, and does it leak anything about individuals? *(Zero, since $0.9 - 0.9 = 0$. It is doing population inference: whatever it learned applies equally to people outside the training set.)*
- Why does the membership adversary $\mathcal{B}$ need the sensitive attribute s of the target, while $\mathcal{A}$ does not get it? *(The membership game hands the adversary the whole record and asks only whether it was used. $\mathcal{B}$ uses s to check whether $\mathcal{A}$'s guess was right.)*

11.4. The imputation baseline

11.4.1. Context

The game removes population inference by subtracting it. It is just as useful to measure it directly, because it tells you how much of an attack's success any model trained on the same population would give, or any published statistics about it. The measure is the success of the best guess of s from (x, y) when the population law is known. Statisticians call filling in a missing field from the others **imputation**, so this is the imputation baseline. Jayaraman & Evans (2022) found that many published attribute inference attacks do no better than imputation from similar data, and argued that this baseline is the one an attack must beat.

11.4.2. Statement

On a non-member, the model was trained without the target, so it is an independent observation (Fact 2) and the best any adversary can do is the best guess from (x, y) alone (Fact 1). That gives the **non-member ceiling**: for every adversary in the game,

$$\Pr[\hat{s} = s \mid b = 0] \le V(S \mid X, Y) = \sum_{x,y} \max_{s} p(s, x, y). \tag{11.8}$$

The second result is about attacks that never look at the model. A training record, picked at random from a training set drawn from the population, looks exactly like a fresh draw if you ignore the model, so such attacks cannot tell the two worlds apart. **Model-free attacks have zero advantage:** if $\hat{s}$ depends on (x, y) only, not on θ, then $\Pr[\hat{s} = s \mid b = 1] = \Pr[\hat{s} = s \mid b = 0]$, and the Bayes imputation guess $\arg\max_s p(s \mid x, y)$, the MAP guess under the true population, attains the bound Equation 11.8 in both worlds.

11.4.3. Derivation

The ceiling.

1. **A non-member is independent of the model.** When $b = 0$, z is drawn afresh, separately from D. The model depends only on D and the randomness of training, so θ is independent of $z = (s, x, y)$.
2. **So the model is a useless observation for the guess.** Fact 2 says that adding an observation independent of (s, x, y) does not change the best success: $V(S \mid X, Y, \theta) = V(S \mid X, Y)$.
3. **No guessing rule beats the MAP guess.** The adversary's rule is a function of (x, y, θ), possibly randomized. By Fact 1 its success is at most the best success from that observation, $V(S \mid X, Y, \theta)$, which step 2 showed is $V(S \mid X, Y)$.

Model-free attacks.

1. **A member is a population record.** D consists of n independent draws from $\mathcal{D}$, and the target is one of them chosen uniformly at random. Whichever one is chosen, it was drawn from $\mathcal{D}$, so on its own (ignoring the model) the target has distribution $\mathcal{D}$, the same as a fresh draw.

2. **A rule that ignores θ sees the same distribution in both worlds.** Its success is $\Pr[g(X,Y) = S]$ for a record drawn from $\mathcal{D}$ either way, so the two terms of Equation 11.4 are equal and the advantage is 0.
3. **Imputation attains the ceiling.** With g the MAP guess under $\mathcal{D}$, Fact 1 says this common success is $V(S \mid X, Y)$.

11.4.4. Interpretation

Below the ceiling, the model only teaches you the population. An adversary who does not know $\mathcal{D}$ can use the model to learn it, and so raise its success on non-members towards $V(S \mid X, Y)$, but it cannot go further. For a person outside the training data, the model is no more dangerous than a perfect description of the population.

This is the point of the "smoking causes cancer" example in Dwork & Roth (2014, §1). A study shows that smoking causes cancer. An insurer who reads it can now infer more about any smoker's health, whether or not that smoker took part in the study. The study disclosed a fact about the world, not about its participants, and a privacy definition that forbade this would forbid learning anything from data. The privacy question is the gap between members and non-members, which the ceiling isolates.

That does not make population inference harmless. Being guessed to be a smoker hurts whether or not the guess used your record. But no mechanism that limits what one record contributes can prevent it, since the harm would be there with your record removed. It is a question for policy and fairness, not for the attacks of this part.

Note also that the ceiling is a property of the population, not of the model, and it can be high. If x and y nearly determine s, every model and every statistic about the population "reveals" s. That is why attacks should be reported relative to it.

11.4.5. Example: the smoking table

Let $s = 1$ mean "smoker", x the age band (young or old) and $y = 1$ "has the disease". The population has $\Pr[s = 1] = 0.3$. Among non-smokers a fraction $\Pr[\text{old} \mid s] = 0.4$ is old, and among smokers 0.6. The disease probabilities $\Pr[y = 1 \mid x, s]$ are 0.1 (young non-smoker), 0.3 (old non-smoker), 0.4 (young smoker) and 0.7 (old smoker). The probability of a full record is the chance of the smoking status, times the chance of the age band given it, times the chance of the disease outcome given both; multiplying gives the joint table, Table 11.2. For example, $p(\text{smoker}, \text{old}, \text{disease}) = 0.3 \times 0.6 \times 0.7 = 0.126$, and $p(\text{non-smoker}, \text{young}, \text{no disease}) = 0.7 \times 0.6 \times 0.9 = 0.378$.

Table 11.2.: The smoking table: the joint distribution of smoking status s, age band x and disease y, with the column maxima in bold and the posterior probability of smoking in each column.

$p(s, x, y)$	young, no disease	young, disease	old, no disease	old, disease
non-smoker ($s = 0$)	**0.378**	0.042	**0.196**	0.084
smoker ($s = 1$)	0.072	**0.048**	0.054	**0.126**

$p(s, x, y)$	young, no disease	young, disease	old, no disease	old, disease
Pr[smoker $\mid x, y$]	0.1600	0.5333	0.2160	0.6000

The last row is each column's smoker entry divided by the column total; for young people with the disease, $0.048/(0.042 + 0.048) = 0.5333$. Now watch the best guess improve as the guesser sees more.

With no observation, the best guess is "non-smoker", right with probability $V(S) = 0.7$, as in Fact 1.

With age alone, the guesser adds the two columns of each age band. Young smokers have probability $0.3 \times 0.4 = 0.12$ and young non-smokers $0.7 \times 0.6 = 0.42$, so a young person is a smoker with probability $0.12/0.54 = 0.2222$. Old smokers have $0.3 \times 0.6 = 0.18$ and old non-smokers $0.7 \times 0.4 = 0.28$, so an old person is a smoker with probability $0.18/0.46 = 0.3913$. Both are below $\frac{1}{2}$, so the guess stays "non-smoker" in both age bands and $V(S \mid X) = 0.7$. Age changes the odds but never the decision, so it adds nothing to the success.

With age and disease, the posterior crosses $\frac{1}{2}$ in the two disease columns (Figure 11.1), so the MAP guess becomes "smoker" there. By Fact 1 the success is the sum of the largest entry in each column, the bold ones: $V(S \mid X, Y) = 0.378 + 0.048 + 0.196 + 0.126 = 0.748$.

The **min-entropy leakage** of Information theory turns this gain into bits: it is the base-2 logarithm of how many times more likely the best guess is to succeed with the observation than without. Here the disease label, given age, raises the success from 0.7 to 0.748, a leakage of $\log_2(0.748/0.7) = 0.0957$ bits.

Every one of these numbers comes from the population. A model trained on 10,000 patients from it, if it predicts well, lets an insurer reach 0.748 on *anyone* drawn from the population, and the ceiling Equation 11.8 says nobody outside the training set can be attacked more successfully than that.

11.4.6. Check yourself

- In the smoking table, which cell would the imputation guess get wrong most often, measured by probability mass? *(Old, with disease: the guess there is "smoker", which is wrong on the 0.084 of non-smokers in that cell, the largest non-bold entry.)*
- Does the ceiling Equation 11.8 hold for an adversary that sees the whole training set D, not only the model? *(Yes. The argument only needs the observation to be independent of the fresh target, and D is.)*

11.5. Model inversion: the MAP attack

11.5.1. Context

The imputation guess needs $p(y \mid x, s)$, the link between the label and the sensitive attribute, and the adversary usually does not know it. But a model that predicts y from x and s is an estimate of exactly that link. Fredrikson et al. (2014) used this in a study of warfarin dosing: a linear

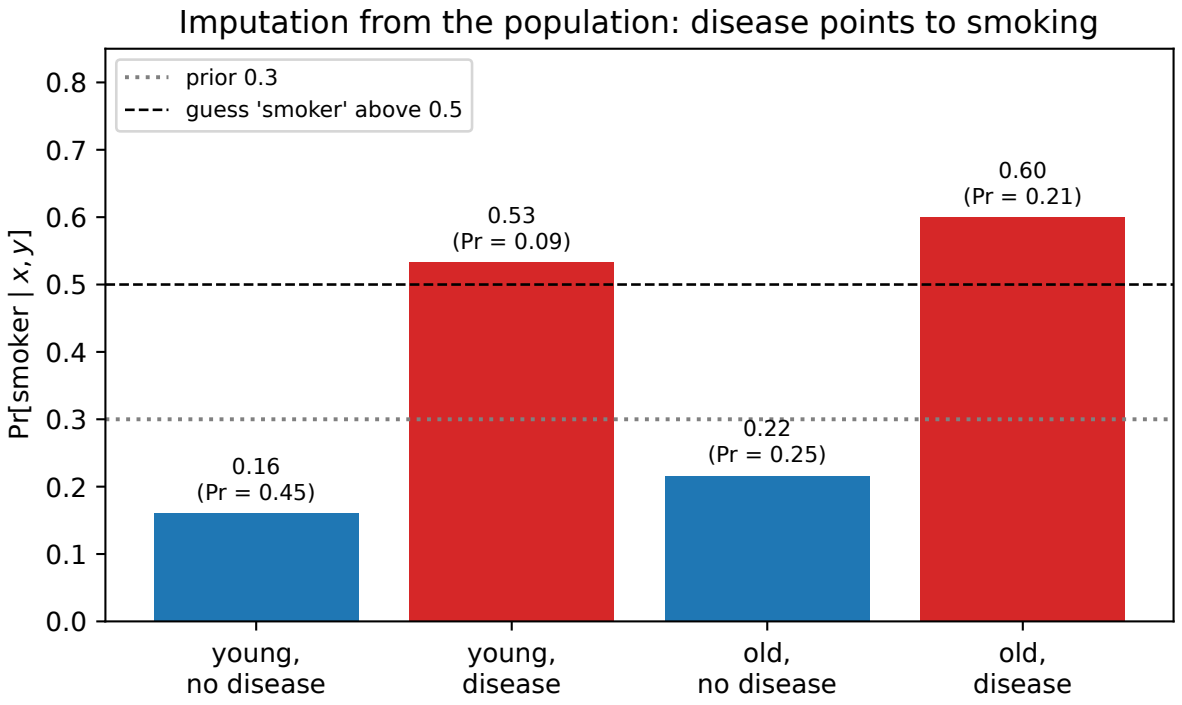

Figure 11.1.: The posterior probability of smoking in each cell of the smoking table, with each cell's probability in brackets. Red bars cross $\frac{1}{2}$, where imputation guesses "smoker"; together they add 0.048 to the 0.7 of the blind guess.

model predicted the stable dose of the drug from demographics and two genetic markers, and an adversary who knew a patient's demographics and dose could infer their genotype. They called the attack **model inversion**: run the model "backwards" from its output to an input. Fredrikson, Jha & Ristenpart (2015) extended it to models that release **confidences**, the predicted probability of each label, and showed that confidences make the attack much stronger.

11.5.2. Statement

The idea is Bayes' rule. The value of s that best explains what you see is the one with the largest product of "how plausible is s for someone with these features" and "how likely is the observed label if the attribute were s". The adversary supplies the first factor from what it knows about the population, and gets the second by querying the model with each candidate value of s. The **MAP inversion attack** guesses

$$\hat{s}_{\text{inv}}(x, y) = \arg\max_{s} \; p(s \mid x)\, f_y(x, s). \tag{11.9}$$

Here $p(s \mid x)$ is what the adversary knows about how s relates to the public features, and $f_y(x, s)$ is the model's confidence in the observed label y when it is fed the candidate s. Fredrikson et al. used the marginal $p(s)$ in place of $p(s \mid x)$, which treats s as independent of x.

If the model's confidences were exactly the population's probabilities, the second factor would be the true likelihood, and the attack would be the imputation guess. A model with that property is called **calibrated**. So, **for a calibrated model, inversion is imputation**: if $f_y(x, s) = p(y \mid x, s)$ for all s, x, y, then $\hat{s}_{\text{inv}}$ is the Bayes imputation guess, and its success is $V(S \mid X, Y)$ on members and non-members alike.

11.5.3. Derivation

1. **Bayes' rule.** The joint probability of s and y given x can be built in two stages, first s from x and then y from both: $p(s, y \mid x) = p(s \mid x)\, p(y \mid x, s)$. Dividing by $p(y \mid x)$ turns it into the posterior of s:
$$p(s \mid x, y) = \frac{p(s \mid x)\, p(y \mid x, s)}{p(y \mid x)}. \tag{11.10}$$
2. **The denominator does not depend on s.** It is the same number for every candidate, so it cannot change which candidate is largest: $\arg\max_s p(s \mid x, y) = \arg\max_s p(s \mid x)\, p(y \mid x, s)$.
3. **Plug in the model.** Replace the unknown $p(y \mid x, s)$ by the model's estimate $f_y(x, s)$. This is Equation 11.9.
4. **Calibrated case.** If $f_y = p(y \mid x, s)$ exactly, step 3 changes nothing and the guess is the MAP guess of Fact 1, with success $V(S \mid X, Y)$. The guess then uses nothing about θ beyond the population's probabilities, so it is a model-free attack, and the argument of Section 11.4 gives equal success on members and non-members.

11.5.4. Interpretation

The attack is Bayes' rule with the model as the likelihood, so everything it does well or badly comes from how the model's $f_y(x, s)$ differs from the population's $p(y \mid x, s)$. Two differences matter, one on members and one on non-members.

On members, the model is too sure of the truth. Training lowers the loss $-\ln f_y(x, s)$ on each training record at its *true* s, which pushes $f_y(x, s)$ up towards 1. The other candidate value s' was never paired with this record during training, so $f_y(x, s')$ stays closer to an honest prediction. (In the toy model below this holds exactly: each value of s has its own weight vector, so the record never touched the weights used at s'.) The ratio $f_y(x, s)/f_y(x, s')$ that decides the attack is therefore tilted towards the truth for members. This is the generalization gap of Membership inference, the difference between a model's loss on its training records and on fresh ones, seen through the sensitive attribute. In the toy experiment the mean log-loss is 0.2965 on members and 0.6690 on non-members.

On non-members, an overfit model does worse than imputation. Its confidences carry the noise of a small training set rather than the population's exact probabilities, so the attack's guesses fall below the ceiling.

More data closes both gaps. As n grows, a correctly specified model approaches $p(y \mid x, s)$ and both success rates approach $V(S \mid X, Y)$ (Figure 11.3). The population inference gets better and the individual leak gets smaller.

The same idea can invert the whole input rather than one field. Fredrikson, Jha & Ristenpart (2015) also attacked a face recognition model in which each class is one person. They searched for the input image that maximizes the confidence of a chosen class, by gradient descent on the image, and obtained a recognizable, blurred image of that person. It is the same idea with s replaced by the whole input, and the prior $p(s \mid x)$ replaced by an image regularizer that keeps the search among plausible images. What it recovers is a typical input of the class, which is population inference about the class; it is a privacy problem because the class is a single person.

11.5.5. Example: walking through the inversion

On the smoking table, with a calibrated model. Take an old patient with the disease. From the age-alone step of the smoking-table example, the adversary knows $\Pr[\text{smoker} \mid \text{old}] = 0.3913$, so $\Pr[\text{non-smoker} \mid \text{old}] = 1 - 0.3913 = 0.6087$. It queries the model at both values of s, and a calibrated model returns the disease probabilities of the population: $f_1(\text{old}, \text{smoker}) = 0.7$ and $f_1(\text{old}, \text{non-smoker}) = 0.3$. The scores of Equation 11.9 are $0.3913 \times 0.7 = 0.2739$ for "smoker" and $0.6087 \times 0.3 = 0.1826$ for "non-smoker", so it guesses "smoker". Dividing the smoker score by the sum of the two, which is the normalization that step 1 of the derivation leaves out, gives $0.2739/(0.2739 + 0.1826) = 0.6000$, the posterior of Table 11.2. The attack is imputation.

On the toy model. The population draws s with $\Pr[s = 1] = 0.3$ and ten standard normal features, the first shifted by 0.5 when $s = 1$. The label follows a logistic model whose weights depend on s. Guessing from x alone is right 0.7045 of the time, and Bayes imputation, which knows the true logistic weights, is right 0.7517 of the time (both on a million fresh records). Over 200 models trained on $n = 100$ records, imputation is right on 0.7508 of members and 0.7555 of non-members. The difference, -0.0046, is about one standard error from zero, as the

model-free argument predicts. MAP inversion, which uses the trained model's confidences, is right on 0.7832 of members, $0.7832 - 0.7517 = 0.0315$ *above* the imputation ceiling, and on 0.7262 of non-members, 0.0254 below it (computed before rounding).

The member success above the ceiling is something no population-level knowledge could produce, since the ceiling is the best that perfect population knowledge achieves. Figure 11.2 shows where it comes from. It plots the attack's evidence for the true value s over the other value s', the log of the ratio of their two scores, $\ln \frac{p(s|x) f_y(x,s)}{p(s'|x) f_y(x,s')}$. The attack is right when this is positive. For members the distribution has a thinner left tail: training has removed most of the cases where the model strongly prefers the wrong value. Figure 11.3 repeats the game for training sets from 25 to 1600 records. At $n = 25$ the attack is right on 0.8420 of members and 0.6810 of non-members, an advantage of $0.8420 - 0.6810 = 0.1610$. At $n = 400$ the advantage is 0.0111, and at $n = 1600$ it is 0.0052.

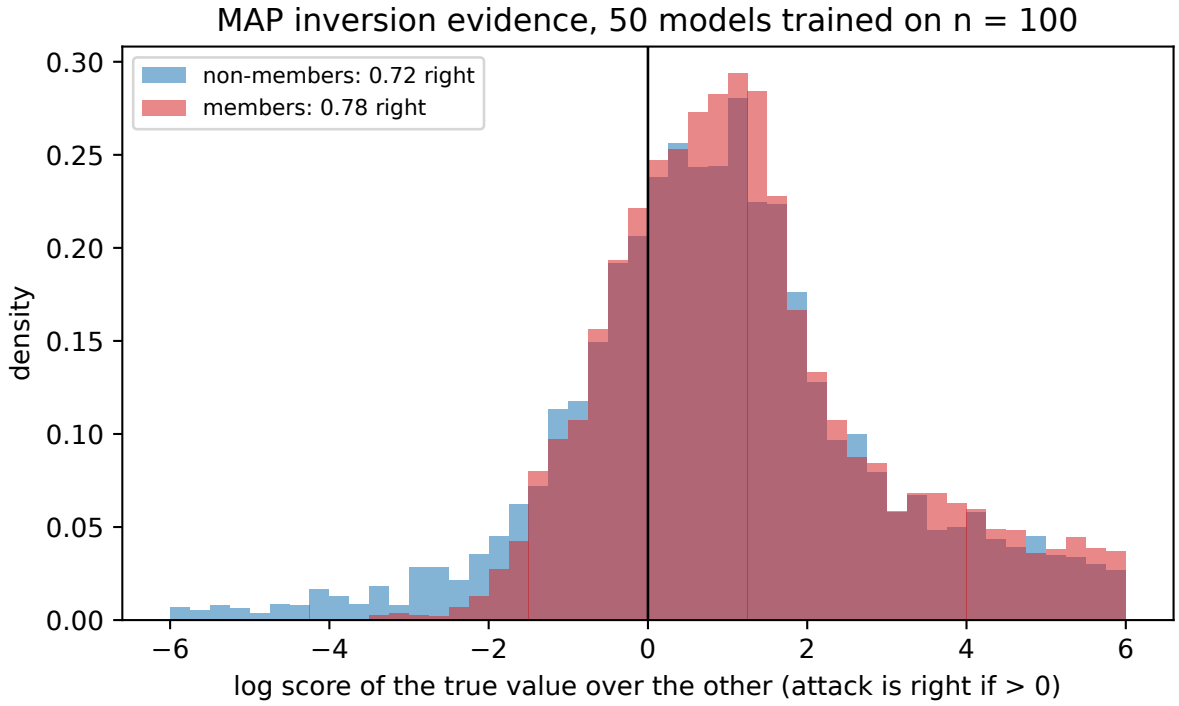

Figure 11.2.: The evidence of MAP inversion for the true attribute, the log of the score of the true value over the other, for members and non-members of 50 models trained on 100 records each. The attack is right when the evidence is positive; members have far fewer large negative values.

11.5.6. Check yourself

- If the model ignored s entirely, $f_y(x, s) = f_y(x, s')$, what would MAP inversion guess? *(The MAP guess from x alone, $\arg\max_s p(s \mid x)$: the confidence is the same factor for every candidate in Equation 11.9, so it cannot change which candidate wins.)*
- Why does using the marginal $p(s)$ instead of $p(s \mid x)$ in Equation 11.9 lose success even with a calibrated model? *(It drops the evidence that x carries about s, so the score is no longer*

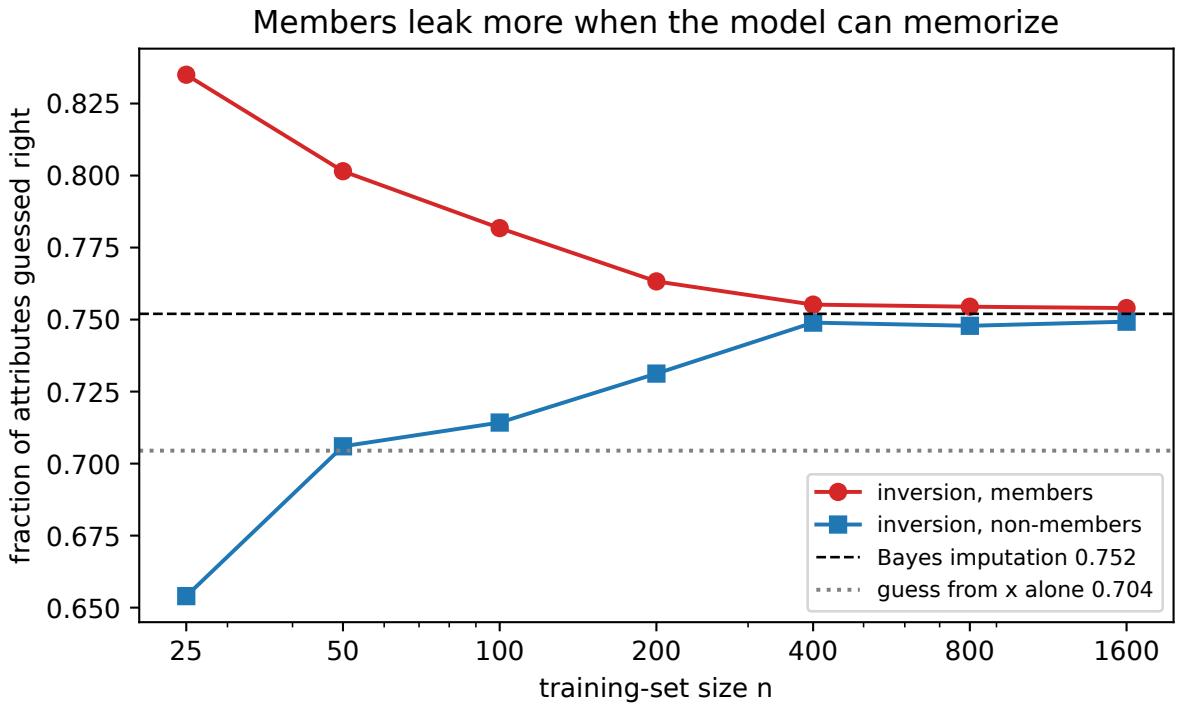

Figure 11.3.: Success of MAP inversion on members and non-members against the training-set size n, 40 models per point. Members start above the Bayes imputation ceiling and non-members below it; both converge to the ceiling as the model approaches the population.

proportional to $p(s \mid x, y)$. Exercise 2 in the exercise book computes the loss on the smoking table.)

11.6. Confidence masking

11.6.1. Context

If confidences make inversion stronger, why release them? Fredrikson, Jha & Ristenpart (2015) suggested rounding the confidences an interface returns, and many deployed interfaces return only the top label. Such **confidence masking** is cheap and leaves the predicted label unchanged. Does it close the leak?

11.6.2. Statement

Masking only coarsens what the adversary sees, so by Fact 3 it can never help the best attacker. To write this down, let $F = \big(f(x, s)\big)_s$ be the list of answers the adversary gets by querying the model at every candidate value of s, where each answer $f(x, s)$ is the model's vector of confidences over the labels. Let g be any masking function applied to these answers: rounding, keeping only the top label, adding noise. Then the best attack on the masked answers does no better than the best attack on the full ones, on members and on non-members alike:

$$V(S \mid X, Y, g(F)) \le V(S \mid X, Y, F). \tag{11.11}$$

The inequality is about the *best* attacker in each world separately. It says nothing about the *difference* between members and non-members, and masking need not shrink it.

11.6.3. Derivation

1. **A masked attack is an unmasked one.** Anyone holding the full answers can apply the mask themselves. So a rule h that guesses from $(x, y, g(F))$ is also the rule $(x, y, F) \mapsto h(x, y, g(F))$ on the unmasked answers.
2. **The best unmasked rule is at least as good.** This is Fact 3, with the observation $O = (X, Y, F)$ and the processing function $(x, y, F) \mapsto (x, y, g(F))$. It gives Equation 11.11, separately for $b = 0$ and for $b = 1$, since the argument never used which world the target came from.
3. **Why the difference can survive.** Write V_{in} and V_{out} for the best success on members and on non-members. Masking lowers both, by amounts that depend on g and on how the confidences of members and non-members differ. Nothing forces the two drops to be equal, so $V_{\text{in}} - V_{\text{out}}$ can rise or fall.

11.6.4. Interpretation

Labels alone still leak, for the same reason confidences do. With only the top label, the adversary still sees, for each candidate s, whether the predicted label $\text{label}(x, s)$ equals the known label y. On a member, the model usually predicts the training label at the true s, because it fit that record. At the other value it gives an honest prediction, which matches y less often. So "the label matches only at one candidate" points to that candidate, and on members it usually points to the truth. Non-members rarely get this help: the two predicted labels usually agree, and the attack falls back on the guess from x alone. Label-only membership inference (Choquette-Choo et al. 2021) exploits the same asymmetry.

This is why masking hurts the population inference more than the individual leak. The toy experiment below shows it: non-member success drops almost to the x-only guess, while member success stays above the imputation ceiling.

Do not read too much into small changes either way. The inequality is about the optimal attacker, and MAP inversion with an overfit model is not optimal, so a particular masking can even raise its success slightly. That does not contradict Equation 11.11.

Above all, masking is obfuscation, not a guarantee. It removes one attack's input without bounding what any attack can learn about a member. Part 3 introduces differential privacy, which bounds the member/non-member difference itself, for every attacker and every output format.

11.6.5. Example: rounding and labels on the toy model

The same 200 models of Section 11.5, attacked through three interfaces, give Table 11.3 and Figure 11.4.

Table 11.3.: MAP inversion success through three interfaces, averaged over 200 models trained on 100 records each. Guessing from x alone gives 0.7045 and Bayes imputation 0.7517.

Interface	Members	Non-members	Advantage
Full confidences	0.7832	0.7262	0.0569
Confidences rounded to one decimal	0.7836	0.7253	0.0583
Top label only	0.7741	0.7092	0.0650

Rounding to one decimal changes almost nothing. The attack only compares the scores of the two candidates, and most confidences are far enough from the rounding boundaries that the comparison keeps its sign. With labels only, non-member success drops from 0.7262 to 0.7092, close to the 0.7045 of guessing from x alone. Member success drops less, to 0.7741, still $0.7741 - 0.7517 = 0.0224$ above the imputation ceiling. So the advantage *grows*, from 0.0569 to 0.0650. The interface now leaks less about the population and as much as before about the people in the training set.

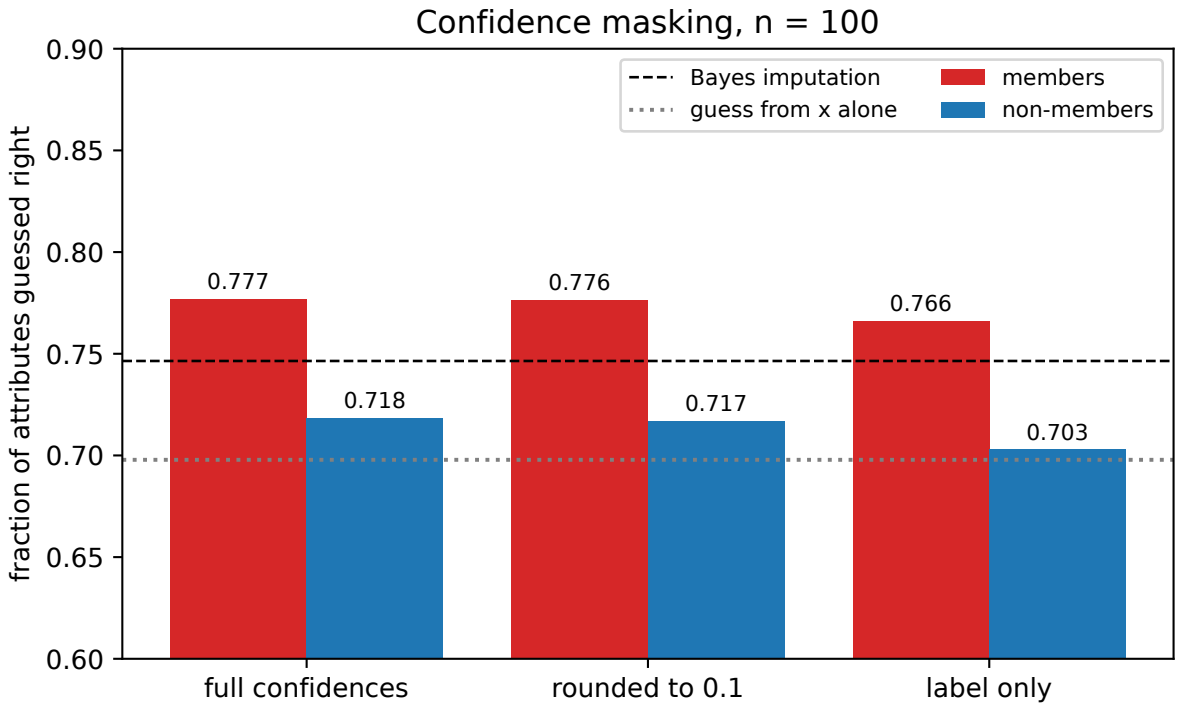

Figure 11.4.: MAP inversion success on members and non-members through three interfaces, for models trained on 100 records. The dashed line is Bayes imputation, the dotted line the guess from the public features alone.

11.6.6. Check yourself

- Can adding Gaussian noise to the returned confidences increase the best attacker's success? *(No. Noise is a randomized function of F, so a rule on the noisy answers is a randomized rule on F: it draws the noise itself and then guesses. Fact 1 shows a randomized rule does no better than the best deterministic one.)*
- Why does the label-only attack on a non-member usually fall back on the guess from x alone? *(For a fresh record, the predicted labels at the two candidate values usually agree. Both then match y or both miss, the masked confidences tie, and the tie is broken by $p(s \mid x)$.)*

11.7. Code: the game on a toy model

The script code/attribute_inference.py computes every number in this chapter and draws every figure. It works out the smoking table exactly. For the toy model it samples the population, trains a ridge-regularized logistic regression with one weight vector per value of s by Newton's method, and plays the game: each run trains a model on n records and attacks those n members and n fresh non-members with MAP inversion, Bayes imputation and the guess from x alone. The real attacks of Fredrikson et al. used a warfarin dosing model and face recognition networks; the toy keeps the structure (a sensitive input, a known label, a model queried at each candidate value) and runs in a few seconds. From the repository root:

```
uv run python code/part02-attacks/attribute_inference.py
```

Output (seed 0), summarized in Table 11.4:

Table 11.4.: The script's output with the default seed. Pairs are success on members / non-members.

Experiment	Result
Smoking table	$V(S) = 0.7000$; $V(S \mid X) = 0.7000$; $V(S \mid X, Y) = 0.7480$; leakage 0.0957 bits; posteriors 0.1600, 0.5333, 0.2160, 0.6000
Toy population, 10^6 fresh records	Guess from x alone 0.7045; Bayes imputation 0.7517
Game, $n = 100$, 200 models: mean log-loss	Members 0.2965; non-members 0.6690; gap 0.3725
Guess from x alone	Members 0.7017; non-members 0.7089
Bayes imputation	Members 0.7508; non-members 0.7555; advantage −0.0046
MAP inversion	Members 0.7832; non-members 0.7262; advantage 0.0569 (standard error 0.0045)
MAP inversion against the ceiling	Members +0.0315; non-members −0.0254
As a membership test	TPR 0.7832; FPR 0.7262; balanced accuracy 0.5285

Experiment	Result
Masking	Rounded: 0.7836 / 0.7253, advantage 0.0583. Label only: 0.7741 / 0.7092, advantage 0.0650
Training-set size, 40 models each	$n = 25$: 0.8420 / 0.6810. $n = 400$: 0.7611 / 0.7500. $n = 1600$: 0.7550 / 0.7497

tests/test_attribute_inference.py checks that the output still matches.

What to take from it. First, the ceiling holds: non-member success never exceeds Bayes imputation, at any training-set size, as the independence argument of Section 11.4 requires. Second, members beat it. At $n = 100$ the attack is 0.0315 above the best population-level guess on members, and since no knowledge of the population can do better than that guess, only individual leakage can explain the excess. Third, the model-free attacks show no advantage, as they should. Imputation and the x-only guess differ between members and non-members by less than 0.01, which is sampling noise: each rate is an average over $200 \times 100 = 20{,}000$ records, and a success rate near 0.75 averaged over that many records has a standard error of about $\sqrt{0.75 \times 0.25/20{,}000} = 0.0031$. Fourth, overfitting drives the leak. The advantage falls from 0.1610 at $n = 25$ to 0.0052 at $n = 1600$, as the gap between member and non-member loss closes. Finally, masking is not a fix: label-only outputs lower success on both members and non-members, and the advantage stays.

11.9. Cheat sheet

A record is (s, x, y); $f_y(x, s)$ is the model's confidence in label y; $V(S \mid O) = \sum_o \max_s p(s, o)$ is the success of the best guess of s from O. Table 11.5 collects the results.

Table 11.5.: Every result in this chapter.

Result	Statement	Where it comes from
Attribute advantage	$\Pr[\hat{s} = s \mid \text{member}] - \Pr[\hat{s} = s \mid \text{non-member}]$	Yeom et al.'s game
Reduction to membership	Fire when $\hat{s} = s$: TPR − FPR = attribute advantage $\leq \mathrm{TV}(P_{\text{in}}, P_{\text{out}})$	Best advantage is total variation
Non-member ceiling	$\Pr[\hat{s} = s \mid \text{non-member}] \leq V(S \mid X, Y)$	Model independent of a fresh record; MAP is optimal
Model-free attacks	Equal success on members and non-members; imputation attains $V(S \mid X, Y)$	A member is marginally a population draw
MAP inversion	$\hat{s} = \arg\max_s p(s \mid x)\, f_y(x, s)$	Bayes' rule with the model as likelihood
Calibrated model	Inversion = imputation, zero advantage	$f_y = p(y \mid x, s)$
Masking	$V(S \mid X, Y, g(F)) \leq V(S \mid X, Y, F)$, but the member/non-member gap can grow	Processing cannot help the best guesser

Rules of thumb

- Report success on members and non-members, and the imputation baseline. A single success rate says nothing about privacy.
- Success up to the imputation baseline is population inference; any model or statistic of the population gives it.
- Success on members beyond what non-members get is the individual leak. It comes from overfitting and shrinks as the training set grows.
- An attribute attack is a membership test that outputs one bit. It is weak at low false positive rates.
- Rounding confidences or returning labels only changes the attacks, not the fact that the model has memorized its training records.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

12. Property inference

12.1. Why this matters

A hospital trains a readmission model on its 1,000 patients and shares it with a research partner. Suppose you have checked that no attack on the model can tell, much better than a coin flip, whether any one patient was in the training set. The partner can still learn whether 45% or 55% of the hospital's patients are over 65, and be right almost every time. A company that shares a fraud model may reveal the share of its customers in a market it has not announced. A model trained on a lab's machines may reveal whether those machines had been patched. None of these secrets is about a record. Each is a **property** of the training set as a whole: a statistic $t(D)$ of the dataset D, such as the fraction of records that belong to some subgroup.

Property inference is the attack that recovers such a statistic from a trained model. Ateniese et al. (2015) introduced it. In their examples, the attacker learned whether a speech recognizer had been trained on speakers with a particular accent, and whether a network-traffic classifier had seen a particular kind of traffic. Ganju et al. (2018) carried the attack to fully connected neural networks, and showed that the attacker must first deal with a nuisance: the same network can be written with its hidden units in any order.

This chapter works through four questions, each building on the one before. It starts by writing the attack as a game, because only then can you ask what the most any attacker can win is. With that ceiling in hand, it explains why a property leaks when no single record does, and why the leak grows with the size of the dataset. Real models have no formula for their distribution, so it then shows how a practical attacker builds its test by training models of its own, and predicts how well that test does. Finally it turns to neural networks, whose raw weights hide the property from a simple attacker, and finds the representation that brings it back.

12.1.1. The one idea: a model is a noisy statistic, and a property moves it further than any record does

A trained model θ is a function of its training set, plus training noise. Think of it as an average over the n records. Changing one record out of n moves an average by about $1/n$. The randomness of which records were sampled moves it by about $1/\sqrt{n}$, the usual size of the error of an average. Since $1/n$ is much smaller than $1/\sqrt{n}$ when n is large, a single record is lost in the noise. That is why membership inference gets *harder* with more data.

A property is different. Raising the subgroup's share from t_0 to t_1 changes about $n|t_1 - t_0|$ records at once. Each moves the average by about $1/n$, so together they move θ by an amount proportional to $|t_1 - t_0|$ that does not shrink with n. Against noise of size $1/\sqrt{n}$, the signal-to-noise ratio is about $|t_1 - t_0|/(1/\sqrt{n}) = \sqrt{n}\,|t_1 - t_0|$, so property inference gets *easier* with more data.

Everything else in this chapter is that argument made precise. The attack is a hypothesis test that decides whether the model was trained under t_0 or under t_1, and the attacker approximates the best such test by training models of its own. Table 12.1 lists the results.

Table 12.1.: The results of this chapter and where each is used.

Result	Where it is used
The property game; advantage at most the total variation (TV) distance between the models, and between the datasets	Stating what a property attack achieves and what no attack can exceed
Membership advantage $\approx 1/\sqrt{n}$, property advantage $\to 1$ for the same released count	Why protecting records does not protect properties
Trained parameters $\approx \mathcal{N}(\theta(t), \Sigma_1/n)$; best accuracy $\Phi(\kappa\sqrt{n}\,\lvert t_1 - t_0\rvert/2)$	Predicting an attack's accuracy from the model and the data; the $\sqrt{n}\,\lvert t_1 - t_0\rvert$ scaling law
Shadow models and a linear meta-classifier	The practical attack, when the law of θ is unknown
Hidden-unit symmetries; invariant representations	Attacking neural networks through their weights or through their outputs

What this chapter assumes. Every tool the derivations need is restated where it is used, so you can read this chapter on its own. For more detail: the game view, the advantage (how much more often an attack says 1 when the answer is 1 than when it is 0) and the fact that processing the view cannot help the attacker are in Threat models and privacy games. Shadow models first appear in Membership inference. The TV distance, the data processing inequality and sufficient statistics are in Divergences. The Neyman–Pearson lemma and the Gaussian trade-off curve are in Hypothesis testing. The binomial distribution and its normal approximation are in Probability distributions.

Conventions. Records come from a population that mixes a majority group A and a subgroup B. Write $\mathcal{D}_A$ and $\mathcal{D}_B$ for the distributions of a record from each group. A population in which a fraction t of people belong to B is the mixture $\mathcal{D}_t = (1-t)\mathcal{D}_A + t\,\mathcal{D}_B$: to draw a record, first pick B with probability t and A otherwise, then draw from that group. A dataset D is n independent records from $\mathcal{D}_t$, written $D \sim \mathcal{D}_t^n$. A training algorithm $\mathcal{T}$ maps it to parameters $\theta = \mathcal{T}(D)$, possibly using random choices of its own (initialization, mini-batch order). $P_{n,t}$ is the distribution of θ, over both the random data and the training randomness. The secret is which of two shares, t_0 or t_1, was used. A challenger picks it with a hidden bit b, which is 0 or 1 with probability $\frac{1}{2}$ each (a **fair bit**); $b = 0$, share t_0, is the null hypothesis, and $b = 1$, share t_1, the alternative. The attacker outputs a guess b'. Its **true positive rate** (TPR), $\mathrm{TPR} = \Pr[b' = 1 \mid b = 1]$ is how often it says 1 when the bit is 1, and its **false positive rate** (FPR), $\mathrm{FPR} = \Pr[b' = 1 \mid b = 0]$ is how often it says 1 when the bit is 0. Its **advantage** is $\mathrm{TPR} - \mathrm{FPR}$: how much more often it says 1 in the world where 1 is right. Its **accuracy** is $\Pr[b' = b]$, the probability that the guess matches the hidden bit, whichever value the bit has. It is not the probability that b is 1. With a fair bit, half the games have $b = 1$, where the attacker wins with probability TPR, and half have $b = 0$, where it wins with probability $1 - \mathrm{FPR}$, so $\Pr[b' = b] = \frac{1}{2}\mathrm{TPR} + \frac{1}{2}(1 - \mathrm{FPR}) = \frac{1}{2}(1 + \text{advantage})$. An attacker who ignores the model says 1 equally often in both worlds, so its advantage is 0 and its

accuracy is $\frac{1}{2}$: that is the coin-flip baseline. $\Phi(z) = \Pr[Z \le z]$ is the standard normal distribution function, for $Z \sim \mathcal{N}(0,1)$.

12.2. Toolkit: three facts every derivation uses

12.2.1. Fact 1 — The best advantage is the total variation distance

The attacker sees a view, such as the trained parameters, whose distribution is P when $b = 0$ and Q when $b = 1$. Some views are more likely in one world than in the other, and that difference is all the attacker has to go on. The best it can do is say 1 exactly on the views that are more likely under Q. How well that works is measured by the **total variation distance**, half the total absolute difference between the two probability tables p and q:

$$\mathrm{TV}(P,Q) = \tfrac{1}{2}\sum_x |p(x) - q(x)|. \tag{12.1}$$

(For continuous views, the sum is an integral over densities.) The fact is that every attack has advantage at most $\mathrm{TV}(P,Q)$, and the **likelihood-ratio test** "guess 1 when $q > p$" attains it. With a fair bit, the best accuracy is therefore $\frac{1}{2} + \frac{1}{2}\mathrm{TV}(P,Q)$.

The argument takes two lines. An attack may randomize, so describe it by $\phi(x)$, the probability that it says 1 on view x. Its TPR is $\sum_x \phi(x)q(x)$ and its FPR is $\sum_x \phi(x)p(x)$, so its advantage is $\sum_x \phi(x)(q(x) - p(x))$. Each term is largest when $\phi(x) = 1$ where $q(x) > p(x)$ and $\phi(x) = 0$ elsewhere, and the maximum is the total excess of q over p. Both tables sum to 1, so the excess of q over p equals the excess of p over q, and each is half the total absolute difference: the TV distance. This is the best-advantage result of Hypothesis testing, restated for games in Threat models and privacy games.

A Gaussian case gives a number you will see again. Let $P = \mathcal{N}(0,1)$ and $Q = \mathcal{N}(1,1)$. The two densities cross halfway between the means, at $\frac{1}{2}$, and $q > p$ to the right of it, so the best test says 1 when the view exceeds $\frac{1}{2}$. Its TPR is $\Pr[\mathcal{N}(1,1) > \frac{1}{2}] = \Phi(\frac{1}{2})$, because $\frac{1}{2}$ is half a standard deviation below the mean 1. Its FPR is $\Pr[\mathcal{N}(0,1) > \frac{1}{2}] = 1 - \Phi(\frac{1}{2})$. So $\mathrm{TV} = \Phi(\frac{1}{2}) - (1 - \Phi(\frac{1}{2})) = 2\Phi(\frac{1}{2}) - 1 = 0.3829$, and the best accuracy is $\frac{1}{2} + \frac{1}{2}(0.3829) = 0.6915$, which is $\Phi(\frac{1}{2})$ itself. This fact sets the ceiling on the property game and turns every advantage in this chapter into an accuracy.

12.2.2. Fact 2 — Training cannot add information about the property

The attacker sees the model, not the data, and the model is computed from the data. Whatever the attacker could learn from θ, someone holding D could learn too: they could train θ themselves, using the same algorithm and fresh random choices, and run the attacker's test on it. So the best test on θ can be no better than the best test on D. In terms of Fact 1, if $\theta = \mathcal{T}(D)$, where $\mathcal{T}$ may use randomness that does not depend on b, then

$$\mathrm{TV}(P_{n,t_0}, P_{n,t_1}) \le \mathrm{TV}(\mathcal{D}^n_{t_0}, \mathcal{D}^n_{t_1}). \tag{12.2}$$

This is the **data processing inequality** of Divergences: passing a view through any channel whose behaviour does not depend on the secret cannot increase its TV distance. It is the same as the "processing cannot help the adversary" fact of Threat models and privacy games.

Equality holds when θ is a **sufficient statistic** for t, which means that the likelihood ratio between the two worlds can be computed from θ alone, so θ keeps everything in D that bears on t. The two extreme cases show the range. A model that ignores its data entirely has $P_{n,t_0} = P_{n,t_1}$, and TV 0. Releasing the dataset itself attains the ceiling. Fact 2 gives the ceiling in the game section, and it is why a released count turns out to be the worst case.

12.2.3. Fact 3 — Two Gaussians with a shared covariance: the best test is linear

The trained parameters of many models are approximately Gaussian, as Section 12.5 shows. So the most useful special case of Fact 1 is two Gaussians in $\mathbb{R}^d$ with the same covariance Σ and different means, $P = \mathcal{N}(m_0, \Sigma)$ and $Q = \mathcal{N}(m_1, \Sigma)$. How hard are they to tell apart? In one dimension, the answer depends on how far apart the means are, measured in standard deviations. In d dimensions the noise can be larger in some directions than in others, so a shift along a noisy direction counts for less than the same shift along a quiet one. The **Mahalanobis distance** measures the shift in exactly this way, in standard deviations along its own direction:

$$\gamma = \sqrt{(m_1 - m_0)^\top \Sigma^{-1} (m_1 - m_0)}. \tag{12.3}$$

For $d = 1$ and $\Sigma = \sigma^2$, it is $|m_1 - m_0|/\sigma$.

The fact has two parts. First, the log of the likelihood ratio is a linear function of θ: it measures how far θ lies past the midpoint of the two means, along a direction ω,

$$\ln \frac{q(\theta)}{p(\theta)} = \omega^\top \Big(\theta - \frac{m_0 + m_1}{2}\Big), \qquad \omega = \Sigma^{-1}(m_1 - m_0). \tag{12.4}$$

So the best test of Fact 1, "say 1 when $q > p$", is a linear test: say 1 when θ lies on m_1's side of a hyperplane through the midpoint. Second, its accuracy with a fair bit depends only on the Mahalanobis distance,

$$\Phi(\gamma/2). \tag{12.5}$$

Derivation. The idea is to write out the two Gaussian log-densities, watch the quadratic parts cancel because the covariances are equal, and then find the distribution of what is left.

1. **Expand the two quadratics.** A Gaussian log-density is $-\frac{1}{2}(\theta - m)^\top \Sigma^{-1}(\theta - m)$ plus a constant that depends only on Σ, and that constant is the same for P and Q. So $\ln q - \ln p = -\frac{1}{2}(\theta - m_1)^\top \Sigma^{-1}(\theta - m_1) + \frac{1}{2}(\theta - m_0)^\top \Sigma^{-1}(\theta - m_0)$. Multiplying out, the terms $\theta^\top \Sigma^{-1} \theta$ appear with opposite signs and cancel, which leaves $(m_1 - m_0)^\top \Sigma^{-1}\theta - \frac{1}{2}(m_1^\top \Sigma^{-1} m_1 - m_0^\top \Sigma^{-1} m_0)$.
2. **Factor the constant.** $m_1^\top \Sigma^{-1} m_1 - m_0^\top \Sigma^{-1} m_0 = (m_1 - m_0)^\top \Sigma^{-1}(m_1 + m_0)$, because when you multiply out the right-hand side, the cross terms $m_1^\top \Sigma^{-1} m_0$ and $m_0^\top \Sigma^{-1} m_1$ are equal (Σ^{-1} is symmetric) and cancel. Pulling out $\omega^\top = (m_1 - m_0)^\top \Sigma^{-1}$ gives the linear form.
3. **Find its distribution.** $L = \omega^\top(\theta - \frac{m_0 + m_1}{2})$ is a linear function of a Gaussian, so it is Gaussian. Under Q, θ has mean m_1, so L has mean $\omega^\top(m_1 - \frac{m_0 + m_1}{2}) = \omega^\top \frac{m_1 - m_0}{2} = \frac{\gamma^2}{2}$, by the definition of γ. Under P the same computation with m_0 gives $-\frac{\gamma^2}{2}$. Under both, its variance is $\omega^\top \Sigma \omega = (m_1 - m_0)^\top \Sigma^{-1} \Sigma \Sigma^{-1}(m_1 - m_0) = \gamma^2$, so its standard deviation is γ.
4. **Compute the accuracy of the best test.** By Fact 1, the best test guesses 1 when $q > p$, that is, when $L > 0$. Under Q, L has mean $\frac{\gamma^2}{2}$ and standard deviation γ, so 0 lies $\frac{\gamma^2/2}{\gamma} = \frac{\gamma}{2}$ standard deviations below the mean, and the test is right with probability

$\Pr[\mathcal{N}(\gamma^2/2, \gamma^2) > 0] = \Phi(\gamma/2)$. Under P, L has mean $-\frac{\gamma^2}{2}$, and the test is right when $L < 0$, which lies $\frac{\gamma}{2}$ standard deviations above that mean: the same probability, $\Phi(\gamma/2)$. Averaging the two worlds gives Equation 12.5.

In one dimension with $\Sigma = 1$, $\gamma = |m_1 - m_0|$, and Equation 12.5 is the Gaussian pair of Fact 1: $\gamma = 1$ gives $\Phi(0.5) = 0.6915$. In many dimensions, only the length of the mean shift measured with Σ^{-1} matters, so a shift along a direction where θ is noisy counts for little. This fact gives the accuracy of every attack on a model whose parameters are approximately Gaussian, and it says which meta-classifier to train: a linear one.

12.3. The property-inference game

12.3.1. Context

"Can the attacker learn the property?" needs the same care as any attack: who draws the data, what the attacker sees and knows, and how its guess is scored. Threat models and privacy games writes attacks as games between a **challenger**, who runs the training pipeline with a hidden secret, and an **adversary**, who tries to guess the secret. It follows Salem et al. (2023). The property game is the version in which the secret is one bit about the population that produced the training set: was the subgroup's share t_0 or t_1? Suri & Evans (2022) call it **distribution inference** and study it in this form.

12.3.2. Statement

The **property-inference game** with parameters (n, t_0, t_1) runs in four steps. The secret is drawn at random by a fair bit so that neither answer is right more often by default, and an attacker who learns nothing scores exactly $\frac{1}{2}$.

1. The challenger draws a fair bit b.
2. It draws a dataset $D \sim \mathcal{D}_{t_b}^n$ and trains $\theta = \mathcal{T}(D)$.
3. The adversary receives a view of θ: the parameters (white-box), or answers to queries (black-box). It knows $\mathcal{D}_A$, $\mathcal{D}_B$, n, t_0, t_1 and the training algorithm $\mathcal{T}$.
4. It outputs b' and wins if $b' = b$.

What limits the adversary? Its view is a model whose distribution is P_{n,t_0} or P_{n,t_1}, so by Fact 1 its advantage is at most the TV distance between them. The model is computed from the data, so by Fact 2 that distance is at most the TV distance between the two dataset distributions. For every adversary,

$$\mathrm{TPR} - \mathrm{FPR} \le \mathrm{TV}(P_{n,t_0}, P_{n,t_1}) \le \mathrm{TV}(\mathcal{D}_{t_0}^n, \mathcal{D}_{t_1}^n). \tag{12.6}$$

The right-hand side becomes concrete when the group of each record can be read off the record ($\mathcal{D}_A$ and $\mathcal{D}_B$ have disjoint supports: no record could come from both groups). Then the only thing in D that says anything about t is how many records come from the subgroup. Call that count S. It is a sufficient statistic, and S is binomial: each of the n records is from the subgroup with probability t, independently. So the right-hand side is exactly

$$\mathrm{TV}(\mathrm{Bin}(n, t_0), \mathrm{Bin}(n, t_1)). \tag{12.7}$$

12.3.3. Derivation

1. **The game is a test.** The view has distribution P_{n,t_0} when $b = 0$ and P_{n,t_1} when $b = 1$. By Fact 1, no attacker's advantage exceeds the TV distance between them. This is the left inequality of Equation 12.6.
2. **Training is a channel.** The view is a randomized function of D, with randomness that does not depend on b. Fact 2 says such processing cannot increase the TV distance, which gives the right inequality.
3. **Write the likelihood ratio of a dataset.** To find what in D matters, compare how likely D is under the two shares. With disjoint supports, a record x from B has density $t\,\mathcal{D}_B(x)$ under $\mathcal{D}_t$ (pick group B, then draw x), and a record from A has $(1-t)\mathcal{D}_A(x)$. The records are independent, so the density of D is the product over its n records. Divide the t_1 version by the t_0 version. The factors $\mathcal{D}_A(x)$ and $\mathcal{D}_B(x)$ are the same in both and cancel. Each of the S subgroup records leaves a factor t_1/t_0, and each of the $n - S$ others a factor $(1-t_1)/(1-t_0)$:
$$\frac{d\mathcal{D}_{t_1}^n}{d\mathcal{D}_{t_0}^n}(D) = \Big(\frac{t_1}{t_0}\Big)^S \Big(\frac{1-t_1}{1-t_0}\Big)^{n-S}. \tag{12.8}$$
4. **Conclude that the count is sufficient.** The likelihood ratio depends on D only through S, so S is sufficient: the best test of Fact 1 can be computed from S alone, and the data processing inequality of Fact 2 holds with equality. The TV distance between the datasets therefore equals the TV distance between the laws of S, which are $\mathrm{Bin}(n, t_0)$ and $\mathrm{Bin}(n, t_1)$. That is Equation 12.7.

12.3.4. Interpretation

The first lesson is that **releasing the count is the worst case**. When the group is visible in each record, no model trained on D can leak more about t than the count of subgroup records, because the count already carries everything D says about t. A model that does not see the group, like the logistic regression of Section 12.5, leaks less, and how much less is a number you can measure.

The game also says **what the attacker needs**. It gives the adversary $\mathcal{D}_A$, $\mathcal{D}_B$ and $\mathcal{T}$. In practice this means auxiliary data from both groups and the ability to train models the way the victim does. Ateniese et al. and Ganju et al. assume exactly this. It is the same assumption that makes shadow models work in Membership inference: the attacker trains its own copies of the victim's pipeline on data it controls.

The secret belongs to a group, not a person, and that changes how the attack is scored. The game has no target record. Its baseline is a coin flip, and the score is accuracy, not the true positive rate at a low false positive rate. In membership inference, the attacker faces many targets, and a few records exposed with high confidence matter even if most are not, so the end of the curve with few false positives is what counts. Here each dataset carries one secret, so the plain probability of guessing it is the natural score.

You may ask whether this **is an attack at all**. Learning that smokers get more lung cancer is the purpose of a medical study, not a breach. Property inference is a harm when the property describes the *data owner* rather than the world: the share of a company's customers in a region,

the demographics of one hospital's patients, the configuration of one lab's machines. When D is a small sample from a public population, its property is public knowledge anyway.

Finally, the game has **variants**. The secret can be a real number (estimate t rather than choose between t_0 and t_1), or the presence of any record with a given feature. Some games fix the subgroup count at exactly $\lfloor tn \rfloor$ instead of drawing it at random. With a fixed count and the group visible, the ceiling is 1, because the count itself differs between the two worlds and reveals the bit. The attacker's difficulty then comes only from the training noise and from the group being hidden.

12.3.5. Example: one hospital's patients

A hospital has $n = 1{,}000$ patients. Whether 45% or 55% of them are over 65 is the secret. If age group is part of each record, Equation 12.7 gives the ceiling $\mathrm{TV}(\mathrm{Bin}(1000, 0.45), \mathrm{Bin}(1000, 0.55)) = 0.9985$ for every model trained on the data. You can see why it is so close to 1. The count has mean 450 in one world and 550 in the other, and its standard deviation is $\sqrt{1000 \times 0.45 \times 0.55} \approx 15.7$, so the two means are more than six standard deviations apart and the two distributions barely overlap. A model from which the count can be read off reaches the ceiling: by Fact 1 its attacker is right with probability $\frac{1}{2} + \frac{1}{2}(0.9985)$, more than 99.9% of the time.

At $n = 100$ the means are 45 and 55, the standard deviation is about 5, and the distributions overlap much more. The ceiling is 0.6827, and 200,000 simulated games with the likelihood-ratio test on the count give an advantage of 0.6811, within sampling error of the formula.

12.3.6. Check yourself

- Why can no attacker on any model trained on D beat Equation 12.7 when the group is visible in every record? *(The model is a randomized function of D, so by the data processing inequality its TV is at most that of D, and the count S is sufficient, so the TV of D equals that of S.)*
- A defender trains on a dataset from which the group column has been deleted. Does Equation 12.6 still hold, and does Equation 12.7? *(Equation 12.6 holds for any training algorithm. Equation 12.7 still bounds it, because the defender's dataset is a function of the original one; it may no longer be attained.)*

12.4. Why a property leaks when no record does

12.4.1. Context

Take the simplest model of all: the training algorithm releases the count S of subgroup records. Two attackers look at the same release. One asks about a record: "is my target, a member of the subgroup, in D?" The other asks about the property: "was D drawn with t_0 or t_1?" For a count, both best advantages can be computed exactly, and they move in opposite directions as n grows. This makes the one idea of the chapter exact.

12.4.2. Statement

Membership. In the membership game, D holds $n-1$ records from $\mathcal{D}_t$ plus one more: either the target (a subgroup member) or a fresh record from $\mathcal{D}_t$. Let $X \sim \mathrm{Bin}(n-1,t)$ be the subgroup count among the $n-1$ other records. The target adds exactly 1 to the count, and a fresh record adds 1 only a fraction t of the time. So the target is detectable only through how much one extra unit changes the distribution of a count that already varies by about $\sqrt{n}$. That change is governed by the height of the most likely count, and the best advantage is

$$\mathrm{Adv}_{\mathrm{mem}}(n) = (1-t)\max_k \Pr[X=k] \approx \frac{1-t}{\sqrt{2\pi(n-1)t(1-t)}}. \tag{12.9}$$

Property. Under the two hypotheses the fraction S/n centres on t_0 or on t_1, with standard deviation about $\sqrt{t(1-t)/n}$. The best advantage is the TV distance between the two binomials, and by the normal approximation it depends on how many standard deviations apart the two centres are. With the midpoint share $\bar{t} = \frac{t_0+t_1}{2}$,

$$\mathrm{Adv}_{\mathrm{prop}}(n) = \mathrm{TV}(\mathrm{Bin}(n,t_0), \mathrm{Bin}(n,t_1)) \approx 2\Phi\Big(\frac{\sqrt{n}\,|t_1-t_0|}{2\sqrt{\bar{t}(1-\bar{t})}}\Big) - 1. \tag{12.10}$$

The first falls like $1/\sqrt{n}$. The second rises to 1 once $\sqrt{n}\,|t_1-t_0|$ is a few times $\sqrt{\bar{t}(1-\bar{t})}$.

12.4.3. Derivation

Membership. The plan is to write the two views as distributions of the count, notice that one of them is a mixture containing the other, and reduce the TV distance to the effect of shifting a binomial by one.

1. **Write the two views.** With the target in D, $S = X+1$. With a fresh record, $S = X + B'$, where $B' \sim \mathrm{Bern}(t)$ is 1 when the fresh record is from the subgroup.
2. **See the second view as a mixture.** $X + B'$ equals $X+1$ with probability t and X with probability $1-t$, so its law is $t\,\mathrm{Law}(X+1) + (1-t)\,\mathrm{Law}(X)$, where $\mathrm{Law}(\cdot)$ means "the distribution of". A fraction t of the time the non-member world looks exactly like the member world.
3. **Mixing scales the TV distance.** For any P and Q, $\mathrm{TV}(P, tP+(1-t)Q) = \frac{1}{2}\sum_x |p(x) - tp(x) - (1-t)q(x)| = \frac{1}{2}\sum_x |(1-t)(p(x)-q(x))| = (1-t)\mathrm{TV}(P,Q)$. By Fact 1, the best advantage is therefore $(1-t)\,\mathrm{TV}(\mathrm{Law}(X+1), \mathrm{Law}(X))$.
4. **Shift a single-peaked distribution by one.** Write $p_k = \Pr[X=k]$. Then $\Pr[X+1=k] = p_{k-1}$, so $\mathrm{TV}(\mathrm{Law}(X+1), \mathrm{Law}(X)) = \frac{1}{2}\sum_k |p_k - p_{k-1}|$, half the total size of the steps between neighbouring probabilities. A binomial probability mass function is **unimodal**: it rises to its most likely value, the mode k^*, and then falls. So the upward steps add up to the climb from 0 to the top, p_{k^*}, and the downward steps add up to the descent back to 0, also p_{k^*}. Half of the total is $p_{k^*} = \max_k p_k$. Table 12.2 walks through $X \sim \mathrm{Bin}(4, \frac{1}{2})$.
5. **Estimate the height of the mode.** By the normal approximation of Probability distributions, a binomial with many trials is close to a normal with the same mean and variance, here $\mathcal{N}((n-1)t, (n-1)t(1-t))$. A normal density with variance s^2 has height $1/\sqrt{2\pi s^2}$ at its peak, here $1/\sqrt{2\pi(n-1)t(1-t)}$. The probability of the most likely integer is close to

that peak height, because the integers are spaced one apart and the density is nearly flat over a unit interval at the top. (Section E.2 in the appendices proves both facts, and makes the second exact: for a binomial with N trials and success probability p, once $Np(1-p) \geq 4$ the most likely value's probability is within a factor $e^{\pm 3.5/(Np(1-p))}$ of the peak height.) That gives Equation 12.9.

Table 12.2.: Shifting $X \sim \text{Bin}(4, \frac{1}{2})$ by one. The positive differences add up to 6/16, the height of the mode, and so do the negative ones. Half the total absolute difference is $\frac{1}{2} \times \frac{12}{16} = \frac{6}{16} = 0.375 = \max_k \Pr[X = k]$.

k	0	1	2	3	4	5
$16 \Pr[X = k]$	1	4	6	4	1	0
$16 \Pr[X + 1 = k]$	0	1	4	6	4	1
$16\times$ difference	1	3	2	-2	-3	-1

Property. Here the plan is to use the exact answer from the game section, then approximate both binomials by normals with a common spread so that the Gaussian pair of Fact 1 applies.

1. **Start from the exact answer.** By Section 12.3, the released count S is a sufficient statistic, so the best advantage is the TV distance between the two binomials.
2. **Approximate by two normals.** By the normal approximation, S/n is close to $\mathcal{N}(t, t(1-t)/n)$. The two variances $t_0(1-t_0)/n$ and $t_1(1-t_1)/n$ are close when the gap is small, so replace both by the one at the midpoint, $\bar{t}(1-\bar{t})/n$. Now divide S/n by its standard deviation $\sqrt{\bar{t}(1-\bar{t})/n}$. The problem becomes a pair of unit-variance Gaussians whose means are $\mu = \sqrt{n}\,|t_1 - t_0|/\sqrt{\bar{t}(1-\bar{t})}$ apart.
3. **Use the Gaussian pair.** As in the example of Fact 1, two unit-variance Gaussians with means μ apart have densities that cross at the midpoint, $\mu/2$ from each mean, so the best test has TPR $= \Phi(\mu/2)$ and FPR $= 1 - \Phi(\mu/2)$, and the TV distance is $2\Phi(\mu/2) - 1$. Substituting μ gives Equation 12.10.

The general pattern. Neither argument is special to counts. Most estimators behave like averages: $\theta \approx \theta(\mathcal{D}) + \frac{1}{n}\sum_i \psi(x_i)$, where $\theta(\mathcal{D})$ is the value the estimator would take on the whole population and $\psi(x)$ is the **influence** of one record x, how far it pulls the estimate (Section 12.5 derives this for logistic regression). One record z shifts θ by $\psi(z)/n$, while the sampling noise has size $\sigma/\sqrt{n}$, where σ is the standard deviation of $\psi(x)$. The shift measured in noise units is $(|\psi(z)|/n)/(\sigma/\sqrt{n}) = |\psi(z)|/(\sigma\sqrt{n}) \to 0$. The property instead shifts the centre from $\theta(\mathcal{D}_{t_0})$ to $\theta(\mathcal{D}_{t_1})$, a fixed distance, so in noise units the shift grows like $\sqrt{n}$.

12.4.4. Interpretation

The headline is that **more data protects records and exposes properties**. Figure 12.1 (right) shows both advantages against n on log axes. The membership advantage falls along a line of slope $-\frac{1}{2}$, which is what $1/\sqrt{n}$ looks like on log axes. The property advantage climbs to 1, sooner for a larger gap $|t_1 - t_0|$.

The reason is that **a property is a group of records**. Moving from t_0 to t_1 changes about $n|t_1 - t_0|$ records: for the hospital, $1{,}000 \times 0.1 = 100$ of its 1,000 patients. A protection measured

one record at a time says little about a change to 100 records at once. Part 3 makes this precise with its group-privacy property, whose guarantee weakens with the size of the group.

It follows that **hiding the property means hiding the population**. To push the property advantage down, the released statistic must be noisy on the scale of $n|t_1 - t_0|$, not on the scale of one record. That much noise also destroys what the statistic was for (Exercise 6 in the exercise book).

The approximations are good here. At $n = 100$ the normal approximation to the property advantage is exact to four decimals, and the one to the membership advantage is off by less than 1% (Table 12.3).

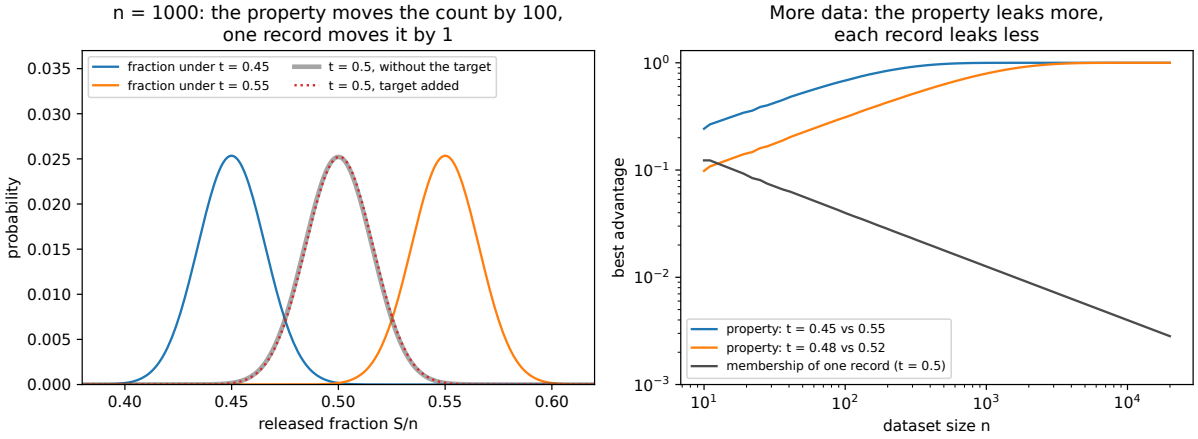

Figure 12.1.: Left: the released fraction S/n at $n = 1{,}000$ under $t = 0.45$ and $t = 0.55$, and under $t = 0.5$ with and without one target from the subgroup; the last two curves are indistinguishable. Right: the best property advantage for two gaps, and the best membership advantage of one record, against n.

12.4.5. Example: the same release, two attackers

Table 12.3 gives both advantages for $t_0 = 0.45$, $t_1 = 0.55$, and for membership at $t = 0.5$. You can check the first row by hand. For the property, $\bar{t} = 0.5$, so $\sqrt{\bar{t}(1-\bar{t})} = 0.5$ and the argument of Φ in Equation 12.10 is $\sqrt{100} \times 0.1/(2 \times 0.5) = 1$; then $2\Phi(1) - 1 = 2(0.8413) - 1 = 0.6827$. For membership, Equation 12.9 gives $0.5/\sqrt{2\pi \times 99 \times 0.25} = 0.5/12.47 = 0.0401$.

Table 12.3.: Best advantages from a released count of subgroup records. Property: $t_0 = 0.45$ against $t_1 = 0.55$. Membership: one subgroup record, population share $t = 0.5$.

n	Property, exact	Property, Equation 12.10	Membership, exact	Membership, Equation 12.9
100	0.6827	0.6827	0.0398	0.0401
1,000	0.9985	0.9984	0.0126	0.0126
10,000	1.0000	1.0000	0.0040	0.0040

At $n = 10{,}000$, an attacker who wants to know whether one patient is in the data has advantage 0.0040: with a fair bit it is right with probability $\frac{1}{2} + \frac{1}{2}(0.0040) = 0.502$. An attacker who wants the share of patients over 65 is never wrong to four decimals. The data, the release and the attacker's knowledge are the same; only the question differs.

12.4.6. Check yourself

- In step 4 of the membership derivation, why does the argument need the probability mass function to be unimodal? *(For one that rises and falls several times, the climbs and descents add up to more than twice the maximum. For X uniform on $\{0, 2\}$, $\mathrm{TV}(X, X+1) = 1$ while the maximum is $\frac{1}{2}$.)*
- Doubling the gap $|t_1 - t_0|$ has the same effect on Equation 12.10 as multiplying n by what? *(By 4: the formula depends on n and the gap only through $\sqrt{n}\,|t_1 - t_0|$.)*

12.5. Shadow models and meta-classifiers

12.5.1. Context

For a real model nobody can write down $P_{n,t}$, the distribution of the trained parameters, so the likelihood-ratio test of Fact 1 is out of reach. Ateniese et al. (2015) gave the recipe every later attack uses: if you cannot compute the two distributions, sample from them. Draw many datasets from $\mathcal{D}_{t_0}$ and from $\mathcal{D}_{t_1}$, using auxiliary data. Train a **shadow model** on each, exactly as the victim trains. Label each shadow model's parameters with the bit that produced them, and train a classifier on these labelled parameter vectors: the **meta-classifier**. Then apply it to the victim's model. This is the shadow-model idea of Membership inference, with whole models as the data points.

Which meta-classifier should you train, and how accurate can it be? For models fitted by minimizing an average loss, the parameters turn out to be approximately Gaussian with a covariance that shrinks like $1/n$. Fact 3 then answers both questions: train a linear classifier, and expect accuracy $\Phi(\gamma/2)$.

12.5.2. Statement

The setting is a model fitted by minimizing an average loss. Let θ minimize the average loss $\frac{1}{n}\sum_i \ell(\theta; x_i)$ over the training records, and let $\theta(t)$ minimize the expected loss under $\mathcal{D}_t$: the model you would get from infinitely many records. How noisy θ is around $\theta(t)$ depends on two matrices. H is the average curvature of the loss at $\theta(t)$: a sharply curved loss pins the minimizer down. G is the covariance of the per-record gradients at $\theta(t)$: how much each record pulls in its own direction. Together they give $\Sigma_1(t)$, the covariance of the fit for a single record's worth of data (the subscript 1):

$$H = \mathbb{E}_{\mathcal{D}_t} \nabla^2 \ell(\theta(t); x), \qquad G = \mathbb{E}_{\mathcal{D}_t}\big[\nabla \ell(\theta(t); x) \nabla \ell(\theta(t); x)^\top\big], \qquad \Sigma_1(t) = H^{-1} G H^{-1}. \quad (12.11)$$

Σ_1 is called the **sandwich covariance**, because G sits between two copies of H^{-1}. Then, for large n:

1. **The parameters are approximately Gaussian,** centred on the population fit with covariance shrinking like $1/n$: $\theta \approx \mathcal{N}(\theta(t), \Sigma_1(t)/n)$.
2. **The best attack is linear,** and its accuracy is that of Fact 3 with the shift $\theta(t_1) - \theta(t_0)$ measured against the noise $\bar{\Sigma}_1/n$:

$$\Phi(\gamma/2), \qquad \gamma = \sqrt{n\,(\theta(t_1) - \theta(t_0))^\top \bar{\Sigma}_1^{-1} (\theta(t_1) - \theta(t_0))}, \tag{12.12}$$

   where $\bar{\Sigma}_1$ is the average of $\Sigma_1(t_0)$ and $\Sigma_1(t_1)$.
3. **For a small gap, only $\sqrt{n}\,|t_1 - t_0|$ matters.** The shift is then about the slope $\theta'(\bar{t}) = \frac{d\theta}{dt}$ times the gap, so γ is the gap times $\sqrt{n}$ times a constant κ, which is the length of the slope measured against the noise:

$$\gamma \approx \kappa\sqrt{n}\,|t_1 - t_0|, \qquad \kappa = \sqrt{\theta'(\bar{t})^\top \Sigma_1(\bar{t})^{-1} \theta'(\bar{t})}. \tag{12.13}$$

   For the released fraction $\theta = S/n$, $\kappa = 1/\sqrt{\bar{t}(1-\bar{t})}$, which is $1/\sqrt{0.25} = 2$ at $\bar{t} = \frac{1}{2}$, and Equation 12.12 becomes Equation 12.10.

12.5.3. Derivation

The parameters are approximately Gaussian. This is the standard asymptotic normality of **M-estimators**, estimators defined as the minimizer of an average loss (van der Vaart 1998, ch. 5; Section G.5 in the appendices proves it step by step for logistic regression). The idea: near its minimum, the fitted parameter is a linear function of an average of per-record gradients, and an average is approximately Gaussian. Four steps make this precise.

1. **The fit solves an average equation.** At a minimizer the gradient is zero, so $\frac{1}{n}\sum_i \nabla\ell(\theta; x_i) = 0$.
2. **Linearize around $\theta(t)$.** For large n, θ is close to $\theta(t)$, so a first-order Taylor expansion of the gradient around $\theta(t)$ is accurate: $0 \approx \frac{1}{n}\sum_i \nabla\ell(\theta(t); x_i) + H(\theta - \theta(t))$. Here the sample average of the Hessians has been replaced by its expectation H, which the law of large numbers allows for large n. Solving for θ,

$$\theta - \theta(t) \approx -H^{-1}\,\frac{1}{n}\sum_i \nabla\ell(\theta(t); x_i). \tag{12.14}$$

   This is the average form of Section 12.4, with influence $\psi(x) = -H^{-1}\nabla\ell(\theta(t); x)$: each record pulls the fit by its gradient, scaled by the inverse curvature.
3. **The average gradient has mean zero.** $\theta(t)$ minimizes the expected loss, so the expected gradient there is zero, $\mathbb{E}_{\mathcal{D}_t}\nabla\ell(\theta(t); x) = 0$. Each gradient therefore has mean zero and covariance G, and an average of n independent copies has covariance G/n.
4. **Apply the central limit theorem.** An average of many independent terms is approximately Gaussian, so the average gradient is approximately $\mathcal{N}(0, G/n)$. Multiplying a Gaussian vector by the matrix $-H^{-1}$ multiplies its covariance by H^{-1} on both sides (H is symmetric), which gives $\mathcal{N}(0, H^{-1}GH^{-1}/n)$.

The best attack and its accuracy. Under the two hypotheses, θ is approximately $\mathcal{N}(\theta(t_0), \Sigma_1(t_0)/n)$ and $\mathcal{N}(\theta(t_1), \Sigma_1(t_1)/n)$. Fact 3 needs a shared covariance; when the two covariances are close, replace both by $\bar{\Sigma}_1/n$. Fact 3 then applies with $m_b = \theta(t_b)$ and

$\Sigma = \bar{\Sigma}_1/n$. Since $\Sigma^{-1} = n\,\bar{\Sigma}_1^{-1}$, the factor n comes out of the Mahalanobis distance, which gives Equation 12.12. Fact 3 also says the best test is linear in θ: a **linear discriminant**, which is the meta-classifier to train.

The scaling law. For a small gap, the population fit changes almost linearly in t, so $\theta(t_1) - \theta(t_0) \approx \theta'(\bar{t})(t_1 - t_0)$, and the covariance hardly changes, so $\bar{\Sigma}_1 \approx \Sigma_1(\bar{t})$. Substituting into Equation 12.12 gives $\gamma^2 \approx n(t_1 - t_0)^2\,\theta'(\bar{t})^\top \Sigma_1(\bar{t})^{-1}\theta'(\bar{t})$, whose square root is Equation 12.13.

The released fraction. The count fits the same mould, which checks the general formula against Section 12.4. Take $\ell(\theta; x) = \frac{1}{2}(\theta - a)^2$, where $a \in \{0, 1\}$ marks the subgroup. The minimizer of the average of $\frac{1}{2}(\theta - a_i)^2$ is the mean of the a_i, which is $\theta = S/n$. Its population version is $\theta(t) = \mathbb{E}[a] = t$, so $\theta' = 1$. The second derivative of the loss is $H = 1$, and the gradient $\theta(t) - a = t - a$ has variance $G = t(1 - t)$, the variance of a Bern(t) variable. So $\Sigma_1 = t(1 - t)$ and $\kappa = 1/\sqrt{t(1 - t)}$. With this κ, the accuracy $\Phi(\gamma/2)$ turns into the advantage $2\Phi(\gamma/2) - 1$ of Equation 12.10, because advantage is twice accuracy minus 1.

12.5.4. Interpretation

Two numbers set the leak. $\theta'(t)$ says how much the property moves what the model learns, and Σ_1 says how noisy that is. If the property does not affect what the model fits, then $\theta' = 0$ and, to first order, nothing leaks, however large n is. If it does, the leak is a side effect of fitting the data well, and no amount of care in the training code removes it.

κ compares any model with the count. With the group visible, the count has $\kappa = 1/\sqrt{\bar{t}(1 - \bar{t})}$. Suppose a model has a smaller κ. How many records n' would the count need to leak as much as the model does on n? Setting the two values of γ equal, $\kappa\sqrt{n} = \sqrt{n'}/\sqrt{\bar{t}(1 - \bar{t})}$, so $n' = n(\kappa\sqrt{\bar{t}(1 - \bar{t})})^2$, a fraction of the real n. Suri & Evans (2022) measure leakage in exactly these units, as the number of records an attacker would need to see directly to match the model (Exercise 3 in the exercise book).

Where the Gaussian picture fails. The derivation used a Taylor expansion and the central limit theorem, both of which need large n. When n is small or the model is far from its large-n regime, the parameters are skewed and the linear meta-classifier is no longer optimal. A second gap comes from the attacker's own sampling. When the meta-classifier is trained on few shadow models, it estimates its direction ω with error, and falls short of $\Phi(\gamma/2)$. That shortfall is largest when the true effect is small, because then the noise in the shadow models swamps the shift it is trying to find.

The real pipeline. Ganju et al. (2018) attack networks trained on census income data and other datasets, with many shadow models per hypothesis and a neural network as the meta-classifier. The toy below keeps every step but runs in seconds.

12.5.5. Example: logistic regression with a hidden subgroup

Each record has two features $x \sim \mathcal{N}(0, I_2)$ and a label. The majority labels with $\Pr[y = 1 \mid x] = \sigma(2x_1 + x_2)$, the subgroup with $\sigma(2x_1 - x_2)$, where $\sigma(z) = 1/(1 + e^{-z})$ is the logistic function. Think of a symptom x_2 that raises risk in most patients and lowers it in a minority. **The group is never a feature**: the model sees (x_1, x_2, y) only. A logistic regression with weights (θ_1, θ_2) and an intercept is trained on n records, by Newton's method with a tiny ridge penalty 10^{-3}.

The script computes $\theta(t)$ and $\Sigma_1(t)$ exactly, by Gauss–Hermite quadrature over x (a numerical rule for integrals against a Gaussian), as Table 12.4 shows.

Table 12.4.: The population fit $\theta(t)$ of the logistic regression, against the subgroup share t. The intercept is 0 for every t.

t	0	0.25	0.5	0.75	1
$\theta_1(t)$	2.000	1.767	1.704	1.767	2.000
$\theta_2(t)$	1.000	0.442	0.000	−0.442	−1.000

To use Equation 12.13 you need the slope θ' and the noise Σ_1 at the midpoint $t = \frac{1}{2}$. Start with the slope, which says **the property moves** θ_2. At $t = \frac{1}{2}$ the two rules cancel in θ_2: half the population pushes it up and half down. As t grows, the subgroup's rule wins and θ_2 goes negative, with slope $\theta'(\frac{1}{2}) = (0, -1.704, 0)$ for $(\theta_1, \theta_2, \text{intercept})$. The table agrees: between $t = 0.25$ and $t = 0.75$, θ_2 falls by $0.442 - (-0.442) = 0.884$ over a step of 0.5 in t, a slope of -1.768, close to the slope at $\frac{1}{2}$. Mixing the rules also makes the labels noisier, which shrinks θ_1 from 2 to 1.704. But the table shows it shrinks symmetrically in t (1.767 at both 0.25 and 0.75), so θ_1 is flat at $\frac{1}{2}$ and carries no information there. The intercept is 0 for every t, so it carries none either.

Next, **the noise.** $\Sigma_1(\frac{1}{2})$ has diagonal $(12.59, 6.94, 6.04)$ for $(\theta_1, \theta_2, \text{intercept})$, and zero off-diagonal entries. The zeros come from two symmetries of the population at $t = \frac{1}{2}$. Flipping the sign of x_2 swaps the two groups' rules, and with half of each the mixture is unchanged. The flip turns a fitted $(\theta_1, \theta_2, \text{intercept})$ into $(\theta_1, -\theta_2, \text{intercept})$, so the two are equally likely, and θ_2 is therefore uncorrelated with the other two parameters. Flipping the sign of x and swapping the labels $y \to 1 - y$ also leaves the population unchanged and flips only the sign of the intercept, which makes the intercept uncorrelated with the weights. To test the Gaussian picture, the script trains two thousand models on $n = 1{,}000$ records at $t = \frac{1}{2}$. n times their variances are $(11.92, 6.80, 6.08)$, and their mean θ_1 is 1.693. The Gaussian picture is right to within about 5%. Almost all of the difference in θ_1 comes from the ridge penalty 10^{-3} the models are trained with: including it in the population objective lowers the predicted value from 12.59 to 11.83 (Section G.5 in the appendices).

Now **the constant.** Only θ_2 has a nonzero slope, and Σ_1 is diagonal, so Equation 12.13 reduces to the slope of θ_2 over its standard deviation: $\kappa = 1.704/\sqrt{6.94} = 0.647$, against 2 for the count. By the comparison in the interpretation, the model leaks the property as well as $(0.647/2)^2 = 0.105$ of its records would: about one record in ten.

Figure 12.2 shows the trained models for $t_0 = 0.4$ and $t_1 = 0.6$. At $n = 100$ the two clouds overlap. At $n = 1{,}000$ they have separated along θ_2, and a line splits them.

Now the attack itself. For each n and gap, with t_0, t_1 centred on $\frac{1}{2}$, the script trains 150 shadow models per hypothesis, fits the linear discriminant on their three parameters, and measures its accuracy on 150 fresh target models per hypothesis (Table 12.5). Each accuracy is an average over 300 right-or-wrong outcomes, each with variance at most $\frac{1}{2} \cdot \frac{1}{2} = 0.25$, so its standard error is at most $\sqrt{0.25/300} = 0.029$.

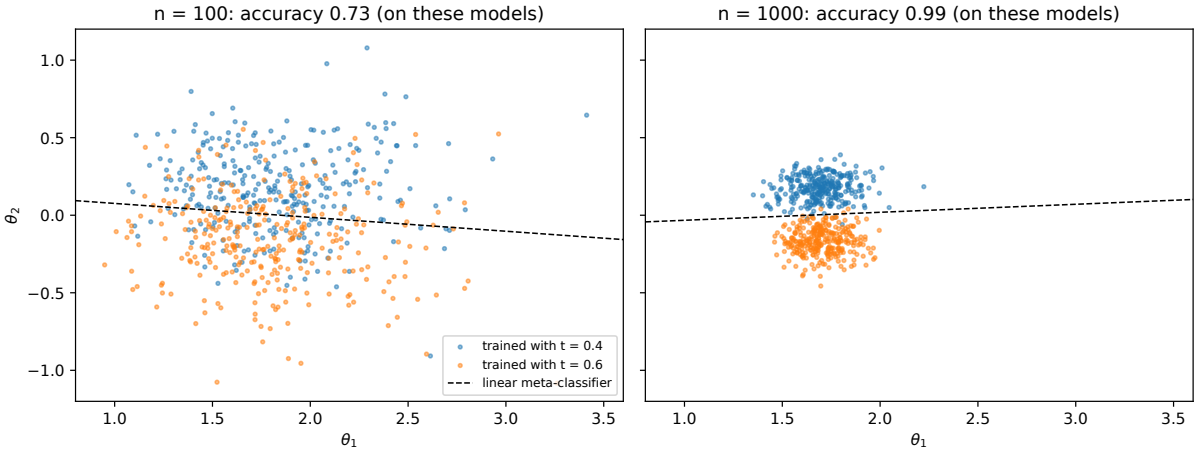

Figure 12.2.: The parameters (θ_1, θ_2) of 300 logistic regressions trained with subgroup share $t = 0.4$ and 300 with $t = 0.6$, at $n = 100$ (left) and $n = 1{,}000$ (right), with the linear meta-classifier fitted to them. The clouds shrink like $1/\sqrt{n}$; the gap between their centres stays fixed.

Table 12.5.: Accuracy of the meta-classifier against logistic regressions, by dataset size n and gap $|t_1 - t_0|$, with the prediction $\Phi(\gamma/2)$ of Equation 12.12 in parentheses.

n	gap 0.05	gap 0.1	gap 0.2	gap 0.4
50	0.523 (0.546)	0.520 (0.590)	0.653 (0.676)	0.830 (0.818)
100	0.523 (0.564)	0.670 (0.627)	0.733 (0.741)	0.863 (0.901)
200	0.503 (0.590)	0.670 (0.676)	0.803 (0.819)	0.957 (0.965)
500	0.633 (0.641)	0.787 (0.765)	0.910 (0.926)	0.997 (0.998)
1,000	0.713 (0.695)	0.867 (0.847)	0.980 (0.979)	1.000 (1.000)

The prediction holds. Most cells agree with $\Phi(\gamma/2)$ to within two standard errors. The exceptions are at small effects ($n \leq 200$, gap ≤ 0.1), where the meta-classifier, fitted to 300 noisy shadow models, finds the direction of ω badly. There the attack is weaker than the best test, as the interpretation predicted.

The scaling law holds. Equation 12.13 says the accuracy depends on n and the gap only through $\sqrt{n}\,|t_1 - t_0|$. Plotted against that product, the four curves fall on one, the curve $\Phi(\kappa\sqrt{n}\,|t_1 - t_0|/2)$ with $\kappa = 0.647$ (Figure 12.3). So a gap of 0.05 at $n = 1{,}000$ is about as easy as a gap of 0.1 at $n = 200$ or so: $\sqrt{1000} \times 0.05 = 1.58$, against $\sqrt{200} \times 0.1 = 1.41$.

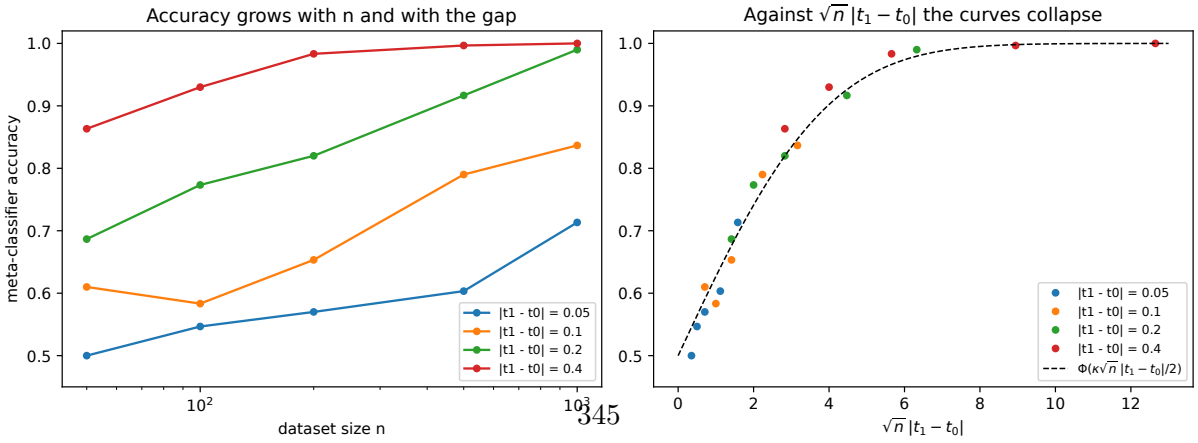

Figure 12.3.: Left: accuracy of the meta-classifier against n for four gaps $|t_1 - t_0|$ (150 shadow and 150 target models per hypothesis, seed 1). Right: the same accuracies against $\sqrt{n}\,|t_1 - t_0|$, with the Gaussian prediction $\Phi(\kappa\sqrt{n}\,|t_1 - t_0|/2)$, $\kappa = 0.647$.

12.6. Permutation invariance

12.6.1. Context

A logistic regression has one parameter vector per function: different weights give different predictions. A neural network has many. Swap two hidden units, together with their incoming and outgoing weights, and the network computes exactly the same function. Ganju et al. (2018) observed that a meta-classifier fed the flattened weights must then learn the same pattern in every slot and every order, and does poorly. Their remedy is a representation that does not depend on the order of the units. This section works it out for a network with one hidden layer of tanh units, which has a second symmetry as well: because tanh is odd, flipping the signs of a unit's weights in and out also leaves the function unchanged.

12.6.2. Statement

Let $f_\theta(x) = \sigma(v^\top \tanh(Wx + \beta) + c)$ be a network with h hidden units. Row j of W and entry β_j compute unit j's input, v_j is its outgoing weight, and c is the output bias. Collect unit j's parameters as $u_j = (W_{j\cdot}, \beta_j, v_j)$. The two symmetries are a reordering of the units and a sign flip of some of them. A **permutation matrix** Π reorders the entries of a vector, and a diagonal matrix F with entries ± 1 flips the sign of some of them. Applying $g = F\Pi$ to the rows of W and the entries of β and v reorders the units and flips some. It does not change the function:

$$f_{(gW,\ g\beta,\ gv,\ c)} = f_{(W,\ \beta,\ v,\ c)}. \tag{12.15}$$

There are $h!$ orders and 2^h sign patterns, so each generic network has $h!\,2^h$ parameter vectors: $4! \times 2^4 = 24 \times 16 = 384$ for $h = 4$. Suppose the initialization is invariant under every g (for example, independent entries drawn from a distribution symmetric about 0) and training is gradient descent. Then the symmetry carries over from the function to the distribution of the trained weights, with three consequences:

1. the law of the trained parameters is invariant under every g, under both hypotheses;
2. every coordinate of every u_j has mean zero under both hypotheses, so a linear meta-classifier on the raw parameters can use none of them;
3. the second-moment features $\sum_j u_j u_j^\top$ are invariant under every g, and keep information that the raw means lose.

12.6.3. Derivation

The plan is to show that g passes through tanh, so it leaves the network's output unchanged; then that it passes through every step of gradient descent; and then to read off what this means for averages.

1. **tanh commutes with g.** tanh acts entry by entry, so permuting its input permutes its output in the same way. tanh is odd, $\tanh(-z) = -\tanh(z)$, so flipping the sign of an entry flips the sign of its output. Hence $\tanh(gz) = g\tanh(z)$.

2. **The output is unchanged.** Using step 1, $(gv)^\top \tanh(gWx+g\beta) = v^\top g^\top g \tanh(Wx+\beta) = v^\top \tanh(Wx+\beta)$, because $g^\top g = \Pi^\top F^2 \Pi = I$: $F^2 = I$ since each entry is ± 1, and $\Pi^\top \Pi = I$ since undoing a reordering gives back the original. This is Equation 12.15. Distinct Π and F give distinct parameter vectors when the units are distinct and no v_j is 0, which gives the count $h!\,2^h$.
3. **Gradient descent commutes with g.** Let $\mathcal{L}$ be the training loss and let g also denote its action on the whole parameter vector, which is linear and orthogonal (it only reorders entries and flips signs). Step 2 says $\mathcal{L}(g\theta) = \mathcal{L}(\theta)$ for every θ. Differentiating both sides with the chain rule gives $g^\top \nabla \mathcal{L}(g\theta) = \nabla \mathcal{L}(\theta)$, so $\nabla \mathcal{L}(g\theta) = g \nabla \mathcal{L}(\theta)$. One step of gradient descent from $g\theta$ therefore lands at $g\theta - \eta g \nabla \mathcal{L}(\theta) = g(\theta - \eta \nabla \mathcal{L}(\theta))$, where η is the learning rate: g applied to the step from θ. Repeating, if T steps of gradient descent from θ_0 reach θ_T, then from $g\theta_0$ they reach $g\theta_T$.
4. **The law is invariant.** By assumption, the initial parameters θ_0 have the same law as $g\theta_0$. Training maps θ_0 to θ_T and, by step 3, $g\theta_0$ to $g\theta_T$, so θ_T and $g\theta_T$ have the same law, for every dataset. Averaging over datasets drawn under either hypothesis keeps this.
5. **Raw means vanish.** Take the g that flips unit j only. Invariance says u_j and $-u_j$ have the same law, so $\mathbb{E}[u_j] = \mathbb{E}[-u_j] = -\mathbb{E}[u_j]$, which forces $\mathbb{E}[u_j] = 0$, under both hypotheses. The linear discriminant of Fact 3 puts weight $\Sigma^{-1}(m_1 - m_0)$ on the features, where m_0 and m_1 are the mean parameter vectors under the two hypotheses; their difference is zero in every unit coordinate, so the weight is zero apart from the output bias c, which no g touches.
6. **Second moments are invariant.** A permutation only reorders the terms of $\sum_j u_j u_j^\top$, which does not change the sum. A sign flip turns u_j into $-u_j$, and $(-u_j)(-u_j)^\top = u_j u_j^\top$.

12.6.4. Interpretation

Raw weights hide the property from a linear attacker. Because of the symmetries, each unit slot holds a random one of the network's units, with a random sign. The property shows in *which* units the network has, not in which slot holds which unit, so averaging over networks slot by slot washes it out.

There are **three ways to undo the symmetry**. A **canonical form** picks one parameter vector per function: flip each unit so that $v_j > 0$, then sort the units by v_j. Sorting the neurons of each layer is the first of the two remedies Ganju et al. propose; their networks use ReLU units, which have no sign symmetry, so for them sorting alone gives the canonical form, and it beats raw weights in their experiments. It is fragile, because two units with nearly equal v_j swap places from one network to the next. A **set representation** feeds each unit through the same map ϕ, adds the results, and applies a second map: $\rho(\sum_j \phi(u_j))$. The sum does not depend on the order of the units. Ganju et al. use this DeepSets form (Zaheer et al. 2017), with ϕ and ρ learned networks. The features $\sum_j u_j u_j^\top$ are the case $\phi(u) = uu^\top$, which is also unchanged by sign flips. **Query features** use the network's outputs on fixed probe inputs. A function does not depend on how it is parameterized, so these are invariant automatically, and they need only black-box access.

Deeper networks have the same problem at each layer. Each hidden layer has its own permutations, and they compose, so a set representation is applied layer by layer.

Finally, **black-box can beat white-box.** Fact 2 of Threat models and privacy games says that processing the view cannot help the attacker: whoever holds the weights can compute any query

output, so white-box access is never weaker *for the best attack*. That says nothing about a fixed simple attack. For a linear meta-classifier, a better representation of the same model can matter more than more access, and the example shows probe outputs beating raw weights. Zhang, Tople & Ohrimenko (2021) attack properties through queries alone.

12.6.5. Example: a tanh network with four hidden units

The data are as in Section 12.5, with $t_0 = 0.2$ and $t_1 = 0.8$. Each network has $h = 4$ tanh units and is trained on $n = 200$ records by 300 steps of full-batch gradient descent from a random start. On each side, 150 shadow networks fit the linear discriminant and 150 target networks measure its accuracy. The script also checks Equation 12.15 directly: a network with permuted and sign-flipped units gives the same logits on 1,000 inputs, to 10^{-12}.

Each unit has four parameters (two input weights, a bias and an output weight), so the raw parameters number $4 \times 4 + 1 = 17$, counting the output bias c. The canonical form reorders the same 17. The second-moment matrix $\sum_j u_j u_j^\top$ is a symmetric 4×4 matrix with $4 \times 5/2 = 10$ distinct entries, plus c, which gives 11. To see which features carry signal, Table 12.6 also reports each representation's largest **standardized mean gap**: for each feature, the difference of its means under t_0 and t_1, divided by its pooled standard deviation.

Table 12.6.: The linear meta-classifier against tanh networks, by representation. The standardized gap of a feature is the difference of its means under t_0 and t_1, over its pooled standard deviation, on the shadow networks.

Representation	Features	Largest standardized mean gap	Accuracy
Raw parameters	17	0.34	0.497
Canonical order (flip so $v_j > 0$, sort by v_j)	17	0.66	0.807
Unit second moments $\sum_j u_j u_j^\top$	11	2.24	0.877
Outputs on 16 probe inputs	16	2.81	1.000

Raw parameters are at chance, as step 5 predicts. Their largest standardized gap, 0.34, is the size expected from noise alone. A standardized feature has variance 1, so its mean over 150 networks has variance $1/150$, and the difference of two such means has variance $2/150$, a standard deviation of $\sqrt{2/150} = 0.115$. The largest of 17 such gaps is typically two to three times that.

Canonical order recovers most of the signal, with one feature carrying most of it (Figure 12.4, left). **Second moments do better with fewer features,** because they need no tie-breaking between units with nearly equal v_j. **Probe outputs are best.** The property changes the function the network computes, and probe outputs measure that function directly, without passing through any parameterization.

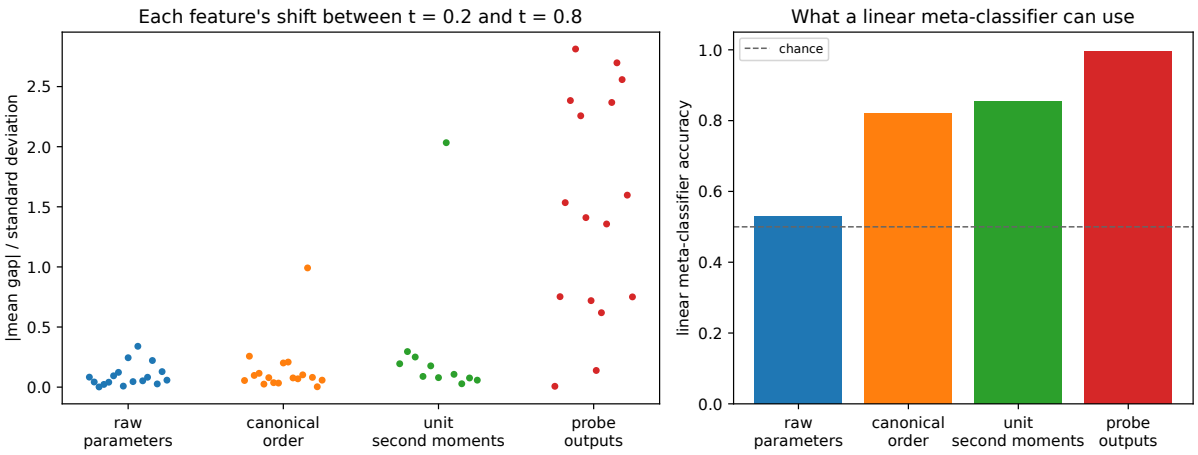

Figure 12.4.: Left: for each representation of 100 tanh networks per hypothesis ($t = 0.2$ against $t = 0.8$), the standardized mean gap of every feature. Right: accuracy of the linear meta-classifier on 100 further networks per hypothesis (seed 1). Raw parameters carry no mean signal; invariant representations do.

12.6.6. Check yourself

- Would the raw means vanish for a network with ReLU units instead of tanh? *(Not by this argument. ReLU is not odd, so the sign flip is not a symmetry; only the permutations remain. They force every unit slot to have the same mean, but that common mean can differ between t_0 and t_1.)*
- Why does a linear meta-classifier on the sum $\sum_j u_j$ fail for tanh networks, even though the sum is permutation invariant? *(The sign flips still apply: $\mathbb{E}[u_j] = 0$ for every j, so the sum has mean zero under both hypotheses. An invariant feature needs to be even in each u_j, like $u_j u_j^\top$.)*

12.7. Code: check every result by computation and simulation

The script code/property_inference.py computes every number in this chapter and draws every figure. The binomial advantages are exact sums. The population fit and the sandwich covariance of the logistic regression are computed by Gauss–Hermite quadrature on a 40×40 grid. Shadow and target models are trained in batches with NumPy: logistic regressions by Newton's method, tanh networks by full-batch gradient descent. From the repository root:

```
uv run python code/part02-attacks/property_inference.py
```

Output (seed 0), summarized in Table 12.7:

Table 12.7.: The script's output with the default seed.

Experiment	Result
Released count, $t_0 = 0.45$, $t_1 = 0.55$	Property advantage 0.6827, 0.9985, 1.0000 at $n = 100$, 1,000, 10,000 (Table 12.3)
Released count, membership at $t = 0.5$	0.0398, 0.0126, 0.0040 at the same n
Simulated property game, $n = 100$	Advantage 0.6811 over 200,000 games (exact 0.6827)
Logistic regression, population view at $t = \frac{1}{2}$	$\theta = (1.704, 0, 0)$; $\theta' = (0, -1.704, 0)$; Σ_1 diagonal $(12.59, 6.94, 6.04)$; $\kappa = 0.647$
2,000 logistic regressions, $n = 1{,}000$, $t = \frac{1}{2}$	Mean $\theta_1 = 1.693$; $n\times$ variances $(11.92, 6.80, 6.08)$
Meta-classifier sweep	Table 12.5
tanh networks, $h = 4$, $n = 200$, $t = 0.2$ against 0.8	Accuracy 0.497 (raw), 0.807 (canonical), 0.877 (second moments), 1.000 (probes); symmetry check passed

tests/test_property_inference.py checks that the output still matches.

What to take from it. Four things stand out. First, more data helps the property attacker: the same release that hides each record better as n grows reveals the property better. Second, the Gaussian picture predicts real attacks: two numbers computed from the population, θ' and Σ_1, predict the meta-classifier's accuracy across a 20-fold range of n and an 8-fold range of gaps. Third, hiding the group column does not hide the property: the logistic regression never sees the group, and still leaks the property as well as a tenth of its records would. Fourth, representation matters before access does: the same networks are opaque to a linear attacker in raw form and transparent once the hidden-unit symmetries are removed.

12.9. Cheat sheet

$\mathcal{D}_t$ mixes the majority and a subgroup of share t; $D \sim \mathcal{D}_t^n$; $\theta = \mathcal{T}(D) \sim P_{n,t}$; $\bar{t} = \frac{t_0+t_1}{2}$. Table 12.8 collects the results.

Table 12.8.: Every result of the chapter.

Result	Formula	Note
Ceiling on any attack	$\mathrm{Adv} \le \mathrm{TV}(P_{n,t_0}, P_{n,t_1}) \le \mathrm{TV}(\mathcal{D}_{t_0}^n, \mathcal{D}_{t_1}^n)$	Equals $\mathrm{TV}(\mathrm{Bin}(n,t_0), \mathrm{Bin}(n,t_1))$ when the group is visible
Property, released count	$2\Phi(\sqrt{n}\,\lvert t_1 - t_0\rvert/(2\sqrt{\bar{t}(1-\bar{t})})) - 1$	$\to 1$ as n grows
Membership, released count	$(1-t)\max_k \Pr[\mathrm{Bin}(n-1,t) = k] \approx (1-t)/\sqrt{2\pi(n-1)t(1-t)}$	$\to 0$ like $1/\sqrt{n}$
Two Gaussians, shared Σ	Best accuracy $\Phi(\gamma/2)$; linear test $\omega = \Sigma^{-1}(m_1 - m_0)$	γ the Mahalanobis distance
Trained parameters	$\theta \approx \mathcal{N}(\theta(t), H^{-1}GH^{-1}/n)$	M-estimators, large n
Meta-classifier accuracy	$\Phi(\kappa\sqrt{n}\,\lvert t_1 - t_0\rvert/2)$, $\kappa = \lvert\theta'\rvert_{\Sigma_1^{-1}}$	Count: $\kappa = 1/\sqrt{\bar{t}(1-\bar{t})}$
Hidden-unit symmetry	$f_{(gW,g\beta,gv,c)} = f_{(W,\beta,v,c)}$, $g = F\Pi$	$h!\,2^h$ copies; raw means vanish for tanh

Rules of thumb

- Property inference gets easier with more data, membership inference harder. What matters for a property is $\sqrt{n}\,\lvert t_1 - t_0\rvert$.

- A property changes about $n|t_1 - t_0|$ records at once. Defences sized for one record do not cover it.
- Removing the sensitive column does not remove the property. Whatever correlates with it moves the model.
- Train the meta-classifier on a representation that respects the model's symmetries: canonical order, sums over units, or outputs on probe inputs.
- Report accuracy for property attacks: there is one secret per dataset, not a population of targets.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

13. Memorization and training-data extraction

13.1. Why this matters

A language model trained on scraped text sees phone numbers, addresses, keys and private messages. Ask it to continue "Anna Smith's phone number is" and it may finish the sentence with the real number. Nobody queried a database and nothing was leaked by a breach: the number is stored in the weights, and it comes out through the model's normal interface. That is what **training-data extraction** means. Membership inference (Membership inference) asks "was this record in the training set?" and needs the record in hand. Extraction asks for more: the attacker gets the record itself, often without knowing it existed.

This chapter answers three questions, in order. The first is what it means for a model to memorize a string. There are several definitions, from "greedy decoding reproduces it when you prompt with the text that preceded it in training" to "some prompt makes the model emit it", and they differ in what the attacker must already know. Once you know what to measure, the second question is which strings get memorized. Two things decide it: duplication and model capacity. A string repeated often, or seen by a model large enough to give it a context of its own, comes back verbatim. The third question is how you measure memorization and how an attacker finds it. Planted random secrets called canaries, and a score called exposure, measure how much a model has memorized a secret you put there yourself. Generate-rank-verify pipelines find real training data among a model's samples.

13.1.1. The one idea: the rank of the secret under the model

A language model is a distribution over strings: it gives every possible string a probability. Memorization is the model putting a training string *far above* the other strings that could have stood in its place. To make that precise, fix the context in which the secret appears, say "my pin is", and list all possible fillers r (all five-digit pins) in order of the model's probability $p(r \mid \text{context})$, most likely first. The **rank** of the true secret is its position in that list. It is also the number of guesses an attacker needs if they try fillers from most to least likely, so a low rank means the model has done most of the attacker's work.

Every measure in this chapter reads that rank, in a different way. Greedy extraction, which writes out the model's single most likely next symbol at each step, reproduces the secret when the secret's next symbol is the top choice, rank 1, at every step. Exposure compares the secret's rank with the size of the space, on a logarithmic scale: it is $\log_2$ of the number of candidates minus $\log_2$ of the rank, which counts how many halvings of the search the model has saved the attacker, in bits. Sampling-based extraction, which draws random outputs from the model, hits the secret quickly when the secret has high probability, and high probability is what puts it near the top of the list.

Table 13.1 lists the results of the chapter and where each is used.

Table 13.1.: The results of this chapter and where each is used.

Result	Where it is used
Definitions: verbatim, approximate, discoverable, extractable, k-eidetic	Reading and comparing extraction papers; choosing what to measure
Samples needed to extract a string, $m \approx \ln(1/\beta)/p$	Turning a probability into an attack budget
Copies needed for greedy extraction, k^*	Why duplication and model size drive memorization; why deduplication helps
Exposure, its null distribution	Auditing a trained model with planted canaries
$\Pr[\text{exposure} \geq e] \leq 2^{-e}$	
Exposure as bits of guessing saved	Linking memorization to min-entropy and guessing
Ranking generations by a likelihood ratio to a reference model	Extraction attacks without the prefix; the same calibration as in membership inference

The chapter builds on four earlier ones, and restates what it uses from them where it uses it. Algorithmic stability and generalization defined memorization as self-influence and showed that atypical examples are memorized most. Information theory introduced min-entropy and guessing, which give exposure its meaning. Threat models and privacy games set up attacks as games, and membership inference introduced the likelihood-ratio tests and reference models that extraction attacks reuse. The defence that bounds every quantity here, differential privacy, starts in Part 3.

The running example. Every experiment uses one toy that runs in seconds. The training set is a contact list: each line is a user name made of three random syllables, a space, and a five-digit pin, such as `toneka 14524`. There are 5,000 background lines, each seen once, and 600 secret lines, 100 each duplicated 1, 2, 4, 8, 16 and 32 times: 11,300 lines and 146,900 symbols in all, counting the end of each line. The model is a character n-gram language model with add-α smoothing, which predicts each character from the few characters before it by counting (Fact 2 below says exactly how). The order n (the model sees the last $n-1$ characters) plays the role of model size: an order-3 model stores 2,734 distinct n-grams and an order-8 model 54,614. It is the smallest model that has every property this chapter needs: a probability for every string, greedy decoding, sampling, and a capacity you can turn up. When a context is written out, `_` stands for a space: `gule_` is the five characters before the first digit of `migule 16430`.

13.2. Toolkit: three facts every derivation uses

13.2.1. Fact 1 — A language model is the chain rule

A language model never scores a whole string at once. It answers one smaller question many times: given everything written so far, how likely is each possible next symbol? Write $p(x_t \mid x_{<t})$

for the probability it gives to the next symbol x_t after the symbols $x_{<t} = x_1 \dots x_{t-1}$ that come before it. To get the probability of a whole string $x = x_1 \dots x_L$ of length L after a prompt c, you multiply these one-step probabilities. That is the chain rule of probability: the chance that the first symbol is x_1, *and then* the second is x_2 given the first, and so on, is the product of the conditional chances. Taking logarithms turns the product into a sum:

$$p(x \mid c) = \prod_{t=1}^{L} p(x_t \mid c, x_{<t}), \qquad \ln p(x \mid c) = \sum_{t=1}^{L} \ln p(x_t \mid c, x_{<t}). \tag{13.1}$$

For the pin `16430` after the prompt `migule`, the model multiplies five numbers: the probability of `1` after `migule_`, of `6` after `migule_1`, of `4` after `migule_16`, of `3` after `migule_164`, and of `0` after `migule_1643`.

The negative of the log in base 2, $-\log_2 p(x \mid c)$, is called the **log-perplexity** of x in bits. It measures how surprised the model is by x: a string the model finds likely has low log-perplexity, and each extra bit means the model found it half as likely. Every score in this chapter (exposure, the probability that a sample reproduces a string, the ranking of generations) is built from this sum of per-symbol log-probabilities.

13.2.2. Fact 2 — An n-gram model is a table of counts

An order-n model looks only at the last $n-1$ symbols, which it calls the context c. Training is nothing more than counting: for every context c and every possible next symbol w, the model stores the count $N(c, w)$ of times w followed c in the training text. The natural prediction would be the fraction of times w followed c, but that gives probability 0 to anything never seen, and one zero in the chain rule makes a whole string impossible. **Add-α smoothing** fixes this by pretending every symbol was seen α extra times in every context. With an alphabet of V symbols, the α is added to each of the V counts, so the total grows by αV:

$$p(w \mid c) = \frac{N(c, w) + \alpha}{N(c) + \alpha V}, \qquad N(c) = \sum_{w} N(c, w). \tag{13.2}$$

Three consequences of this formula do most of the work in the chapter.

The first is that **training is counting**. A line of text passes through a sequence of (context, next symbol) pairs, and training on it adds 1 to each of those counts. Training on k copies of a line adds k to each, and changes no other count.

The second is that **smoothing does not change the most likely symbol**. In a fixed context c, every count gets the same $+\alpha$, and the denominator $N(c) + \alpha V$ is the same for every w. So the symbol with the largest count still has the largest probability: $\arg\max_w p(w \mid c) = \arg\max_w N(c, w)$, where $\arg\max_w$ means "the w that makes this largest". Greedy decoding, which emits the most likely symbol, therefore just follows the largest counts.

The third is what happens at a **context that occurs only in the copies of one line**. Say the line has been inserted k times and its context c appears nowhere else. Then the line's own next symbol has count k, every other symbol has count 0, and the total is $N(c) = k$. Putting those counts into Equation 13.2 gives

$$p(\text{true} \mid c) = \frac{k + \alpha}{k + \alpha V}, \qquad p(\text{other} \mid c) = \frac{\alpha}{k + \alpha V}. \tag{13.3}$$

The two share a denominator, so the true symbol is $(k+\alpha)/\alpha$ times as likely as any other, whatever V is. A context never seen at all has every count 0, and gives every symbol $\alpha/(\alpha V) = 1/V$.

The toy uses $\alpha = 0.1$ and $V = 39$ symbols: 26 letters, 10 digits, the space, a start symbol and an end-of-line symbol, $26 + 10 + 1 + 1 + 1 = 39$. Table 13.2 evaluates Equation 13.3. For one copy, $\alpha V = 3.9$, so $p(\text{true} \mid c) = 1.1/4.9 = 0.2245$ and $p(\text{other} \mid c) = 0.1/4.9 = 0.0204$, a ratio of $1.1/0.1 = 11$. The last column turns the ratio into bits, $\log_2 11 = 3.46$: one copy makes the true digit as much more likely than any rival as 3.46 halvings would.

Table 13.2.: Add-α probabilities at a context that occurs only in the k copies of one line ($\alpha = 0.1$, $V = 39$).

Copies k	$p(\text{true} \mid c)$	$p(\text{other} \mid c)$	Ratio	Bits per digit, $\log_2$ ratio
1	0.2245	0.0204	11.0	3.46
4	0.5190	0.0127	41.0	5.36
16	0.8090	0.0050	161.0	7.33

So a single copy already makes the true digit 11 times more likely than any other. That is the mechanism of memorization in this toy: a context that belongs to one training line alone, followed by that line's next symbol.

13.2.3. Fact 3 — Guessing in order of probability takes "rank" guesses

Let a secret r come from a finite set $\mathcal{R}$ of possible values, with $|\mathcal{R}|$ elements. An attacker who has a score for every candidate, here the model's probability, should guess candidates from the highest score down, because each guess then has the best remaining chance of being right. The number of guesses this takes is the rank of the true secret: the number of candidates at least as likely as it,

$$\text{rank}(r) = \big|\{r' \in \mathcal{R} : p(r') \geq p(r)\}\big|, \tag{13.4}$$

counting r itself and every candidate tied with it (ties are counted against the attacker, who may have to try them all first).

Without a model, the attacker has no reason to prefer one order over another. A uniform secret is then equally likely to sit at each position $1, \ldots, |\mathcal{R}|$ of whatever order is used, so the number of guesses is on average the middle position, $(|\mathcal{R}| + 1)/2$. Information theory measures the same difficulty with one guess. The best single guess is the most likely value, and it succeeds with probability $\max_r p(r)$, which Information theory calls the **vulnerability**. Its negative logarithm, the **min-entropy** $H_\infty = -\log_2 \max_r p(r)$, expresses that difficulty in bits: a secret with H_∞ bits is as hard to guess in one try as a uniform choice among 2^{H_∞} values. A uniform 5-digit pin has 10^5 equally likely values, so $H_\infty = \log_2 10^5 = 5 \log_2 10 = 16.61$ bits.

The rank is what the rest of the chapter measures. Exposure is defined from the rank of a secret among all secrets of its format, and greedy decoding asks for rank 1 among the possible next symbols at every step.

13.3. Verbatim, approximate, discoverable, extractable

13.3.1. Context

"The model memorized its training data" can mean several things. A model that completes a famous quotation has memorized it, but so has every reader, and nothing private leaked. A model that emits a phone number seen once in training has leaked it. Some definitions assume the attacker knows the beginning of the training string. Others ask whether any prompt at all brings it out. Before measuring anything you need to say which notion you measure, because the numbers differ by orders of magnitude.

13.3.2. Statement

Let f be a language model trained on a dataset D of documents, and let $\text{greedy}_f(c)$ be the string produced by greedy decoding from the prompt c: at each step, append the most likely next symbol. The definitions below are parallel options that differ in what the attacker gets to use and in how close the output must be.

1. **Extractable** (Carlini et al. 2021): a string s is extractable from f if there is some prompt c, any prompt at all, such that $\text{greedy}_f(c)$ begins with s.
2. **k-eidetic** (Carlini et al. 2021): s is k-eidetically memorized if it is extractable and it appears in at most k documents of D. Small k is the dangerous case: a secret seen once and given back.
3. **Discoverable** (Carlini et al. 2023, named by Nasr et al. 2023): if the training data contain $[p \,\|\, x]$, a prefix p followed by a suffix x, then x is discoverably memorized if prompting with that same prefix makes greedy decoding produce the suffix: $\text{greedy}_f(p)$ begins with x.
4. **Approximate** (Ippolito et al. 2023): x is approximately memorized if $\text{greedy}_f(p)$ is within distance τ of x in some string distance d. In this chapter's toy d is the number of wrong digits and $\tau = 1$, so a pin with at most one wrong digit counts. Definitions 1 to 3 are **verbatim**: the output must match exactly.

Two relations follow directly from the definitions. Discoverable is a special case of extractable, with the training prefix as the prompt, and an exact match is a special case of a close one:

$$\text{discoverable} \;\Rightarrow\; \text{extractable}, \qquad \text{verbatim} \;\Rightarrow\; \text{approximate}. \tag{13.5}$$

Real systems sample rather than decode greedily, so it is useful to know how many samples bring a string out. Each sample is a fresh, independent try that produces the string x with its probability $p = p(x \mid c)$ after the prompt c, like a biased coin that lands heads with probability p. The chance that at least one of m samples is x is one minus the chance that all of them miss, $1 - (1-p)^m$, and this is at least $1 - e^{-mp}$. Asking that to be at least $1 - \beta$, for a small failure probability β, gives a sample budget:

$$m \geq \frac{\ln(1/\beta)}{p} \quad \text{samples suffice to extract } x \text{ with probability at least } 1 - \beta. \tag{13.6}$$

13.3.3. Derivation

Discoverable implies extractable. If $\text{greedy}_f(p)$ begins with x, then $c = p$ is a prompt that makes the model emit x, which is the definition of extractable. The converse fails: an extractable string may come out after a prompt that is not its training prefix, or after a prompt the attacker cannot know, while its own prefix leads elsewhere.

Verbatim implies approximate. A verbatim match has distance 0, and $0 \le \tau$.

Samples needed. The idea is to compute the probability that every sample misses, and bound it by an exponential that is easy to solve for m.

1. **One sample hits with probability p.** A temperature-1 sample from c draws each next symbol with exactly the model's probabilities $p(x_t \mid c, x_{<t})$. By the chain rule (Equation 13.1), the chance that it writes out exactly x is the product of those probabilities, which is $p = p(x \mid c)$.
2. **All m samples miss with probability $(1-p)^m$.** Each sample misses with probability $1-p$, and the samples are independent, so the misses multiply.
3. **Replace $1-p$ by e^{-p}.** The curve e^{-p} is convex, and the straight line $1-p$ is its tangent at $p = 0$ (both equal 1 there, with slope -1). A convex curve lies above its tangent lines, so $1 - p \le e^{-p}$, and raising both sides to the power m gives $(1-p)^m \le e^{-mp}$.
4. **Solve for m.** The miss probability is then at most β as soon as $e^{-mp} \le \beta$. Taking logarithms, $-mp \le \ln \beta$, that is $m \ge \ln(1/\beta)/p$.

13.3.4. Interpretation

The definitions answer different threat models. Discoverable memorization assumes an attacker who holds the training prefix. That is a strong assumption, but it makes the quantity easy to measure: prompt with every training prefix and compare the output with the true suffix. Extractable memorization fits the real attacker, who has only the model, but it is hard to measure, because you would have to search over all prompts. So the discoverable rates are what papers report on open models, and attacks then show how much of that an outsider can actually reach.

Verbatim matching is a weak notion of leakage, because it misses near copies. A model that emits a phone number with one digit changed, or a paragraph with its punctuation changed, has leaked it to any reader. Ippolito et al. (2023) show that a filter blocking verbatim training text is easy to bypass with prompts that change the style, while the approximate copies still come out. A verbatim rate is therefore a lower bound on the leak, not a measure of it.

Greedy decoding is a convenience for measurement; real deployments sample. Equation 13.6 converts a probability into an attack budget. For a string with probability 10^{-3} after its prefix and 99% confidence ($\beta = 0.01$), the budget is $\ln(100)/10^{-3} = 4.605/0.001$, so the string comes out within about 4,600 samples.

13.3.5. Example: one secret, six model sizes

Take the secret line `migule 16430`, inserted 4 times, and prompt each model with its prefix `migule`. Greedy decoding gives `07` followed by an end of line at order 3, `81554` at order 4, `14032` at order 5, and the true `16430` at orders 6, 7 and 8. The order-5 output gets the first and fourth digits right and the other three wrong, so it is not approximately memorized either. The reason the switch happens at order 6 is Fact 2. An order-6 model reads five characters of context, and from the first digit on its contexts (`gule_`, then `ule_1`, and so on) occur in this line and nowhere else. In such a context the line's own next digit has count 4 and every rival digit has count 0, so greedy decoding, which follows the largest count, emits the line's digit every time. Shorter contexts, such as the four characters `ule_` an order-5 model reads, are shared with other lines, whose digits can outvote the four copies.

Sampling gives a graded version of the same picture. At order 5, the probability that one sample from the true prefix reproduces a secret's pin, averaged over the 100 secrets of each group, is 1.4×10^{-3} at 4 copies and 0.142 at 32 copies. With $\beta = 0.01$ that means 3,252 and 31 samples for a 99% chance of extracting the pin. These are the exact budgets, the smallest m with $(1-p)^m \leq \beta$; Equation 13.6 gives slightly larger ones, since it replaces $1-p$ by the larger e^{-p}. For $p = 0.142$, for instance, $\ln(0.01)/\ln(1-0.142) = 4.605/0.153 = 30.1$, which rounds up to 31. Repetition turns a needle in a haystack into the model's favourite answer.

13.3.6. Check yourself

- Can a string be extractable but not discoverable? *(Yes. Another prompt, say a different name that shares the last syllables, may lead greedy decoding into it while its true prefix leads elsewhere.)*
- A model emits a training string with probability 10^{-6} after its prefix. Is it memorized? *(Not in the greedy sense, and by Equation 13.6 an attacker needs about* $\ln(100)/10^{-6} \approx 4.6 \times 10^6$ *samples for 99% success. Whether that counts as a leak depends on the attacker's budget, which is why exposure, which uses the rank rather than the probability, is useful.)*

13.4. Duplication and model size: the copies a string needs

13.4.1. Context

Carlini et al. (2023) measured discoverable memorization on a family of open models and found that it grows log-linearly with three things: the number of times a string is duplicated in the training set, the size of the model, and the length of the prompt. Kandpal, Wallace & Raffel (2022) found that a sequence repeated 10 times is generated about 1,000 times more often than one seen once. The n-gram toy lets you derive why, for every string, from counts.

13.4.2. Statement

The idea is a vote. Greedy decoding follows the largest count at each step (Fact 2). Each copy of a line adds one vote for the line's own next symbol in every context the line passes through. So the line comes out when, at every step, its own votes plus whatever the rest of the corpus already gave its symbol beat the strongest rival symbol. The number of copies needed is set by the step where the rival is furthest ahead.

To write this down, let s be a training line with prompt p and secret suffix $x = x_1 \dots x_L$, inserted k times. Let c_t be the context at step t (the last $n-1$ symbols of the prompt followed by the first $t-1$ symbols of the suffix, $p\,x_{<t}$), and let $N_{-}(c, w)$ be the counts in the rest of the training set, *without* the copies of s. At step t, the **gap** is how far the strongest rival $w \neq x_t$ is ahead of the true symbol in those counts, $\max_{w \neq x_t} N_{-}(c_t, w) - N_{-}(c_t, x_t)$. Assume each context c_t occurs only once within s, so a copy of s adds to the true pair (c_t, x_t) and to no rival pair (c_t, w); this holds for almost every line. Then greedy decoding from p emits x if and only if $k \geq k^*(s)$, where the copies needed are the largest gap plus one:

$$k^*(s) = \max_{t \leq L} \Big[\max_{w \neq x_t} N_{-}(c_t, w) - N_{-}(c_t, x_t) \Big] + 1. \tag{13.7}$$

There is one refinement for ties. Greedy decoding breaks a tie toward the symbol with the lowest code, so at a step where the true symbol has the lower code, a tie is already a win, and the bracket is reduced by one there.

Over a population of lines, the fraction memorized at k copies is then the fraction of lines whose k^* is at most k:

$$\Pr[\text{discoverably memorized at } k \text{ copies}] = \Pr[k^*(s) \leq k]. \tag{13.8}$$

In particular, a line whose contexts are unique to it ($N_{-} = 0$ everywhere, so every gap is 0) has $k^* = 1$: it is memorized from a single copy.

13.4.3. Derivation

1. **Greedy picks the largest count.** By Fact 2, adding α to every count does not change which count is largest, so at context c_t greedy decoding emits $\arg\max_w N(c_t, w)$, the symbol with the largest count.
2. **What the copies add.** Training is counting (Fact 2), so k copies of s add k to $N(c_t, x_t)$. By the assumption that c_t occurs once in s, they add nothing to $N(c_t, w)$ for $w \neq x_t$. With the copies, the true symbol's count is $N_{-}(c_t, x_t) + k$ and each rival's is still $N_{-}(c_t, w)$.
3. **Winning one step.** The true symbol wins strictly when its count beats the largest rival count, $N_{-}(c_t, x_t) + k > \max_{w \neq x_t} N_{-}(c_t, w)$. Moving $N_{-}(c_t, x_t)$ to the right, this is $k > \text{gap}_t$, with gap_t the bracket in Equation 13.7. Since k and the gap are whole numbers, that is $k \geq \text{gap}_t + 1$.
4. **Every step must win.** Greedy decoding stays on the line's path $c_1, c_2, \dots$ only while it keeps emitting the true symbols. One wrong symbol puts it in a different context, from which in general it does not return to x. So x comes out exactly when every step wins, that is when $k \geq \text{gap}_t + 1$ for every t, which is $k \geq \max_t(\text{gap}_t + 1)$, Equation 13.7.
5. **Unique contexts.** If $N_{-}(c_t, \cdot) = 0$ for every t, every gap is $0 - 0 = 0$, so $k^* = 1$.

6. **The population rate.** Each line is memorized at k copies exactly when $k^*(s) \leq k$. The fraction of lines memorized is therefore the fraction for which this holds, which is $\Pr[k^*(s) \leq k]$ for a line drawn at random from the population.

Figure 13.1 draws steps 3 and 4 for one line.

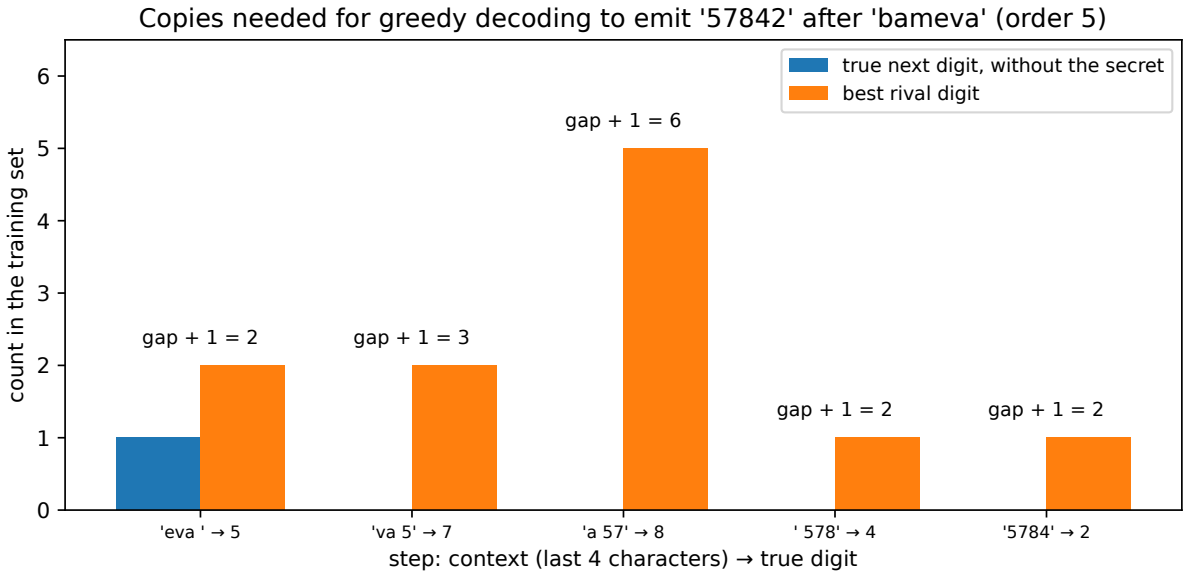

Figure 13.1.: For one secret line inserted once, an order-5 model: at each step of its pin, the count of the true next digit (blue) and of its strongest rival (orange) in the rest of the training set. The label is the gap plus one, the copies that step needs. The line needs as many copies as its hardest step.

13.4.4. Interpretation

Duplication works as a vote. Each copy is one more vote for the line's continuation in every context it passes through, and a line comes out when it outvotes the rest of the corpus at its most contested step.

Model size works by splitting the vote. A longer context is a finer partition of the training positions: fewer positions share any one context of length 7 than of length 2. So the rival counts in a longer context are smaller, while the line's own k votes stay with it in every context it passes through. In the limit every line has contexts of its own and $k^* = 1$. This is the toy version of "larger models memorize more": a larger model can afford to give rare strings their own parameters.

For the same reason, rare data are exposed first. A line whose name shares few syllables with other names reaches a context of its own sooner. This is the pattern Algorithmic stability and generalization found for **self-influence**, how much a model's prediction on a training example changes when that one example is removed: atypical examples can only be fitted by memorizing them, so they have the largest self-influence.

Deduplication is the cheapest defence, because it lowers k for every repeated string. Lee et al. (2022) found that models trained on deduplicated data emit memorized text about ten times less often, without losing quality, and Kandpal et al. (2022) found that deduplication sharply lowers the success of extraction attacks. It does nothing for singletons in a high-capacity model, where $k = 1$ already and $k^* = 1$.

13.4.5. Example: discoverable memorization against copies and order

The script prompts each of the 600 secrets with its true prefix (the name and the space), decodes five symbols greedily, and compares them with the pin. Table 13.3 gives the verbatim rate and the approximate rate (at most one digit wrong) for each order and number of copies. It also computes k^* for every secret from Equation 13.7, and the prediction $\Pr[k^* \le k]$ matches the verbatim rate exactly in all 36 cells, as the derivation says it must: the formula is not an approximation but a restatement of what greedy decoding does with counts.

Table 13.3.: Fraction of 100 secret lines per cell whose pin greedy decoding reproduces from the true prefix, verbatim / with at most one digit wrong. Rows are model orders, columns copies in the training set.

Order n	$k = 1$	$k = 2$	$k = 4$	$k = 8$	$k = 16$	$k = 32$
3	0.00 / 0.00	0.00 / 0.03	0.00 / 0.00	0.00 / 0.00	0.00 / 0.02	0.00 / 0.05
4	0.00 / 0.00	0.00 / 0.00	0.00 / 0.01	0.00 / 0.00	0.00 / 0.00	0.13 / 0.17
5	0.00 / 0.00	0.00 / 0.00	0.05 / 0.06	0.11 / 0.15	0.42 / 0.42	0.70 / 0.70
6	0.08 / 0.13	0.65 / 0.69	0.76 / 0.78	0.80 / 0.85	0.90 / 0.91	0.96 / 0.97
7	0.70 / 0.78	0.95 / 0.96	0.98 / 0.98	0.98 / 0.99	0.99 / 0.99	0.97 / 0.98
8	0.98 / 0.98	1.00 / 1.00	1.00 / 1.00	0.99 / 0.99	1.00 / 1.00	1.00 / 1.00

Read it along both axes. Along a row, more copies means more memorization: at order 5 the rate climbs from 0 at one copy to 0.70 at 32. Down a column, a larger model memorizes more: a line seen once is safe at orders up to 5, memorized 8% of the time at order 6, 70% at order 7 and 98% at order 8. The order-8 model has memorized its training set almost completely, singletons included. In the language of the definitions, those singletons are 1-eidetic: seen in one document and given back. Figure 13.2 plots the same table for a second training set.

The approximate rates are barely above the verbatim ones. In this toy, a pin either sits in contexts of its own and comes out whole, or it loses a contest early, after which greedy decoding is in the wrong context and wanders off. Natural text has many near-ties (synonyms, punctuation), and that is where approximate memorization adds the most (Ippolito et al. 2023).

The real experiment of Carlini et al. (2023) has the same shape at scale. Take GPT-Neo models from 125 million to 2.7 billion parameters and GPT-J (6 billion), all trained on the Pile, a large public collection of web and book text. Sample training sequences, grouped by how many times they are duplicated in the Pile. Prompt each model with the first 50 tokens and decode 50 tokens greedily. Count exact matches. They found that the largest model reproduces at least 1% of its training data this way, and that the rate rises log-linearly with model size, duplication and prompt length. The toy replaces tokens by characters, parameters by the context length and the Pile by a contact list, and keeps the measurement.

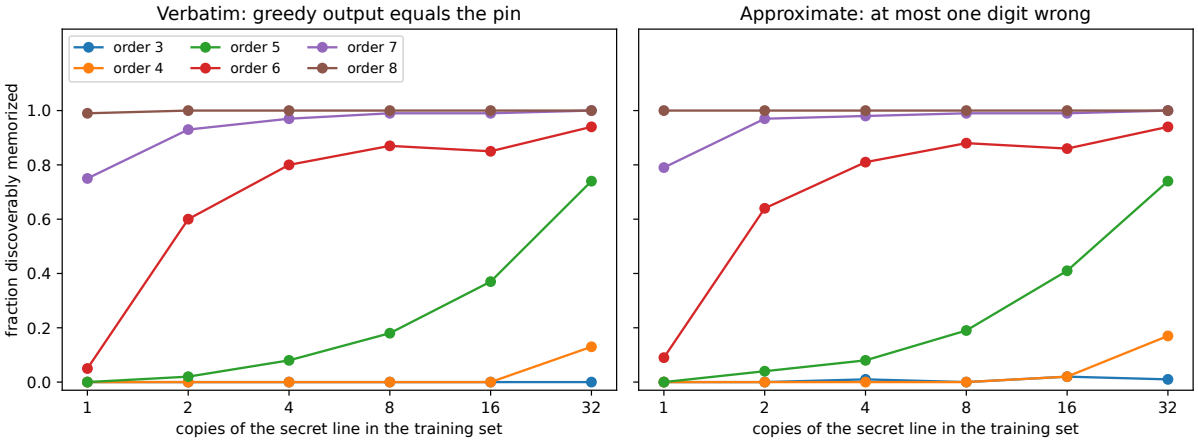

Figure 13.2.: Discoverable memorization against copies of the secret in the training set, for n-gram models of order 3 to 8, on an independent draw of the corpus. Left: greedy decoding reproduces the pin exactly. Right: at most one digit is wrong. Both rise with duplication and with order, and the approximate rate is only slightly higher.

13.4.6. Check yourself

- In Figure 13.1, why does the line need as many copies as its worst step, and not the sum over steps? *(The copies count at every step at once: each copy adds one to every pair on the line's path. So k copies close every gap up to k, and the largest gap decides.)*
- Does deduplication help an order-8 model on this corpus? *(Barely. Its singletons are already memorized 98% of the time, because their contexts are unique. Deduplication works by lowering k, and here $k^* = 1$.)*

13.5. Canaries and the exposure metric

13.5.1. Context

Discoverable memorization is all or nothing: the secret comes out or it does not. An auditor wants a graded answer: how much closer to the secret does the model put an attacker? Carlini et al. (2019, "The Secret Sharer") proposed planting **canaries**, random secrets of a fixed format such as "my pin is" followed by five random digits, in the training data, then measuring where the trained model ranks the planted secret among all secrets of the same format. Because the canary is random and planted, you know the right answer and the size of the space, so you can quantify memorization exactly.

13.5.2. Statement

A canary has a format $s[\cdot]$ with a hole, and a randomness space $\mathcal{R}$ of values that can fill the hole. Here $s[r]$ is "my pin is r", with r one of the $|\mathcal{R}| = 10^5$ pins. A value $\hat{r}$ is drawn uniformly at random from $\mathcal{R}$, and $s[\hat{r}]$ is inserted k times into the training data. After training, order all of $\mathcal{R}$

by the model's probability $p(r \mid \text{"my pin is"})$; the **rank** of $\hat{r}$ is its position in that order (Fact 3), the number of guesses an attacker who follows the model needs.

The exposure turns the rank into a number of bits saved. Without the model, the attacker faces all $|\mathcal{R}|$ candidates, which is $\log_2 |\mathcal{R}|$ bits of search. With the model, it faces $\text{rank}(\hat{r})$ candidates, $\log_2 \text{rank}(\hat{r})$ bits. The **exposure** is the difference:

$$\text{exposure}(\hat{r}) = \log_2 |\mathcal{R}| - \log_2 \text{rank}(\hat{r}). \tag{13.9}$$

Two properties follow from this definition directly. Because the rank lies between 1 and $|\mathcal{R}|$, the exposure lies between 0 and $\log_2 |\mathcal{R}|$, with the maximum when the canary is the model's top candidate. And exposure counts guesses saved: an attacker who guesses in the model's order needs $\text{rank}(\hat{r}) = 2^{\log_2 |\mathcal{R}| - \text{exposure}}$ guesses instead of $|\mathcal{R}|$, so each bit of exposure halves the work.

The third property is what makes exposure an audit tool: you know how it behaves when nothing was memorized. If the model does not depend on $\hat{r}$, for instance because the canary was never inserted, then $\hat{r}$ is just a random point in a fixed ordering, and a high exposure is unlikely. Precisely, for every $e \geq 0$,

$$\Pr\left[\text{exposure}(\hat{r}) \geq e\right] \leq 2^{-e}, \tag{13.10}$$

and, when no two candidates tie, its average is a fixed small number of bits:

$$\mathbb{E}\big[\text{exposure}(\hat{r})\big] = \log_2 |\mathcal{R}| - \frac{\log_2(|\mathcal{R}|!)}{|\mathcal{R}|} \;\longrightarrow\; \log_2 e = 1.4427 \text{ bits}. \tag{13.11}$$

So exposure is $-\log_2$ of a p-value. A **p-value** is the probability, under the assumption that nothing happened, of seeing a result at least as extreme as the one observed. Here it is the probability that a canary that was never inserted would look at least this memorized, and Equation 13.10 says it is at most $2^{-\text{exposure}}$.

13.5.3. Derivation

Range and guesses. The rank is between 1 and $|\mathcal{R}|$, so $\log_2 \text{rank}$ is between 0 and $\log_2 |\mathcal{R}|$. Subtracting from $\log_2 |\mathcal{R}|$ gives an exposure between $\log_2 |\mathcal{R}|$ and 0. Solving Equation 13.9 for the rank gives $\text{rank} = 2^{\log_2 |\mathcal{R}| - \text{exposure}}$.

Null distribution. The idea is that, without the canary, the model's scores are fixed before $\hat{r}$ is drawn, so $\hat{r}$ lands at a uniformly random position in their order.

1. **The order is fixed.** If the model was trained without the canary, its scores $p(r \mid \cdot)$ are fixed numbers that do not depend on $\hat{r}$. With no ties they order $\mathcal{R}$ into positions $1, \ldots, |\mathcal{R}|$.
2. **The canary's position is uniform.** $\hat{r}$ is uniform on $\mathcal{R}$ and independent of the scores, so its position is equally likely to be any of $1, \ldots, |\mathcal{R}|$.
3. **Count the positions with high exposure.** By Equation 13.9, exposure $\geq e$ means $\log_2 \text{rank} \leq \log_2 |\mathcal{R}| - e$, that is $\text{rank} \leq |\mathcal{R}| 2^{-e}$. There are $\lfloor |\mathcal{R}| 2^{-e} \rfloor$ such positions (the whole numbers up to that bound), each with probability $1/|\mathcal{R}|$, so the probability is $\lfloor |\mathcal{R}| 2^{-e} \rfloor / |\mathcal{R}| \leq 2^{-e}$.
4. **Ties only help the bound.** The rank counts every candidate at least as likely as $\hat{r}$, so a tie can only raise the rank of $\hat{r}$. A higher rank means a lower exposure, so the probability of a high exposure can only fall, and the bound still holds.

5. **The mean.** With the rank uniform on $1, \dots, |\mathcal{R}|$, the average of $\log_2$ rank is $\frac{1}{|\mathcal{R}|}\sum_{i=1}^{|\mathcal{R}|}\log_2 i$. A sum of logarithms is the logarithm of the product, and $1 \cdot 2 \cdots |\mathcal{R}| = |\mathcal{R}|!$, so this is $\log_2(|\mathcal{R}|!)/|\mathcal{R}|$; subtracting it from $\log_2|\mathcal{R}|$ gives Equation 13.11. For the limit, Stirling's approximation of the factorial (derived in Section E.2) says $\ln N! = N\ln N - N + O(\ln N)$, where $O(\ln N)$ is a correction that grows no faster than a multiple of $\ln N$. Dividing by $N\ln 2$ to get base-2 logarithms per candidate, $\log_2(N!)/N = \log_2 N - 1/\ln 2 + O(\ln N/N) = \log_2 N - \log_2 e + O(\ln N/N)$, since $1/\ln 2 = \log_2 e$. The correction vanishes as N grows, so the mean exposure tends to $\log_2 e$.

A space of four candidates makes all of this concrete. With $|\mathcal{R}| = 4$ the rank is 1, 2, 3 or 4 with probability $\frac{1}{4}$ each, and the exposure is $2 - \log_2(\text{rank})$:

Table 13.4.: The four equally likely exposures of a canary from a space of four candidates that was never inserted.

Rank	1	2	3	4
Exposure $2 - \log_2(\text{rank})$	2	1	0.415	0

The third entry is $2 - \log_2 3 = 2 - 1.585 = 0.415$. The mean is $\frac{1}{4}(2 + 1 + 0.415 + 0) = 0.854$, which matches $2 - \log_2(24)/4 = 2 - 4.585/4$, since $4! = 24$. The probability of exposure at least 1 is $\frac{1}{2} = 2^{-1}$ (ranks 1 and 2), and of exposure at least 2 is $\frac{1}{4} = 2^{-2}$ (rank 1 only): the bound is tight at integer exposures.

13.5.4. Interpretation

Exposure is a membership test with a known null. "Was this canary inserted?" is a membership question (Membership inference), and the exposure is the score of a test that says "inserted" when the exposure is at least a threshold e. By Equation 13.10 that test has false positive rate (the chance of saying "inserted" about a canary that was not) at most 2^{-e}. In membership inference, calibrating a test means training **shadow models**, extra models trained with and without a record, to learn how the score behaves for non-members. Here none are needed: the randomness of the canary does the calibration, playing the role that the population of non-members plays in membership inference.

Exposure is also guessing work saved, in the sense of Fact 3. A uniform canary has min-entropy $\log_2|\mathcal{R}|$: before seeing the model, the attacker's best single guess succeeds with probability $1/|\mathcal{R}|$. After the model, the attacker who guesses in the model's order needs $2^{\log_2|\mathcal{R}| - \text{exposure}}$ tries. Carlini et al. (2019) note that exposure close to $\log_2|\mathcal{R}|$ means the secret can actually be extracted, for example by a shortest-path search: treat each digit position as a step, weight each choice of digit by its negative log-probability, and find the cheapest path through the model's predictions, which is the most likely pin.

For large spaces exposure has to be estimated, because enumerating $\mathcal{R}$ is impossible for, say, a 9-digit number. Two estimators replace enumeration. The first is sampling: score m random candidates and use the fraction of them at least as likely as the canary as the estimate of rank $/|\mathcal{R}|$. It cannot resolve exposures above $\log_2 m$, because a canary above all m sampled candidates only tells you its rank fraction is below about $1/m$. The second is extrapolation: fit a distribution

to the sampled scores and read off its tail beyond the canary's score; Carlini et al. (2019) fit a skew-normal, a normal distribution with an extra parameter that lets one tail be heavier than the other. The fit is only as good as its tail, and the tail is exactly the part you cannot sample.

Ties hide memorization. A model that has never seen the canary's contexts gives every candidate the same score. Every candidate is then tied with all the others, so every rank is $|\mathcal{R}|$ and every exposure 0. On this corpus the order-8 model without a canary gives every pin exactly the same probability after "my pin is", and the exposure of every candidate is 0.

Finally, canaries test defences, not only models. Because you control what was planted, you can compare exposure across two training runs that differ in one thing. Train with and without deduplication, and the change in exposure measures what deduplication bought. Train with a differentially private algorithm (Part 3), and exposure near the null mean says the planted secrets were not memorized; Carlini et al. (2019) found that private training kept their canaries at the exposure of canaries never inserted. Plant canaries, unlearn them, and measure exposure again, and you have a test of an unlearning method. Auditing differentially private training uses the same tool, with canaries designed to be as exposed as possible.

13.5.5. Example: one canary, three model sizes

The script plants "my pin is 58745" and computes the exact exposure by scoring all 10^5 pins. Table 13.5 gives it for orders 2, 3 and 4.

Table 13.5.: Exposure in bits of the canary "my pin is 58745" against the number of copies k in the training set. The maximum is $\log_2 10^5 = 16.61$.

Order n	$k=0$	$k=1$	$k=2$	$k=4$	$k=8$	$k=16$	$k=32$	$k=64$
2	0.40	0.41	0.43	0.47	0.55	0.73	1.21	2.54
3	0.89	4.05	4.44	4.71	5.24	6.59	9.69	15.61
4	3.76	9.98	12.15	15.02	15.61	16.61	16.61	16.61

The jump from $k=0$ to $k=1$ follows from Fact 2: what matters is whether a digit of the canary sits in a context that only the canary's copies fill. No background line contains `s_`, an `s` followed by a space, because names end in a vowel. So the three orders behave differently.

At order 2 the model reads one character of context, and the first digit's context is a single space, shared by all 11,300 lines. No digit of the canary has a context of its own, so one copy is a single vote among thousands, and it moves the exposure by $0.41 - 0.40 = 0.01$ bits.

At order 3 the first digit's context is `s_`, which occurs only in the canary. By Fact 2 and Table 13.2, one copy makes the first digit 11 times as likely as each other first digit, a factor worth $\log_2 11 = 3.46$ bits. The exposure goes from 0.89 to 4.05, a rise of $4.05 - 0.89 = 3.16$ bits: close to 3.46 but not equal, because the rank also depends on how the other pins' scores are spread.

At order 4 the first two digits have unique contexts, `is_` and `s_5`, worth about $2 \times 3.46 = 6.92$ bits. The exposure goes from 3.76 to 9.98, a rise of $9.98 - 3.76 = 6.22$ bits.

The remaining digits share their contexts with the 5,000 background pins and move only as the copies outvote them. Figure 13.3 shows the same movement on the full distribution of scores, and Figure 13.4 averages several canaries.

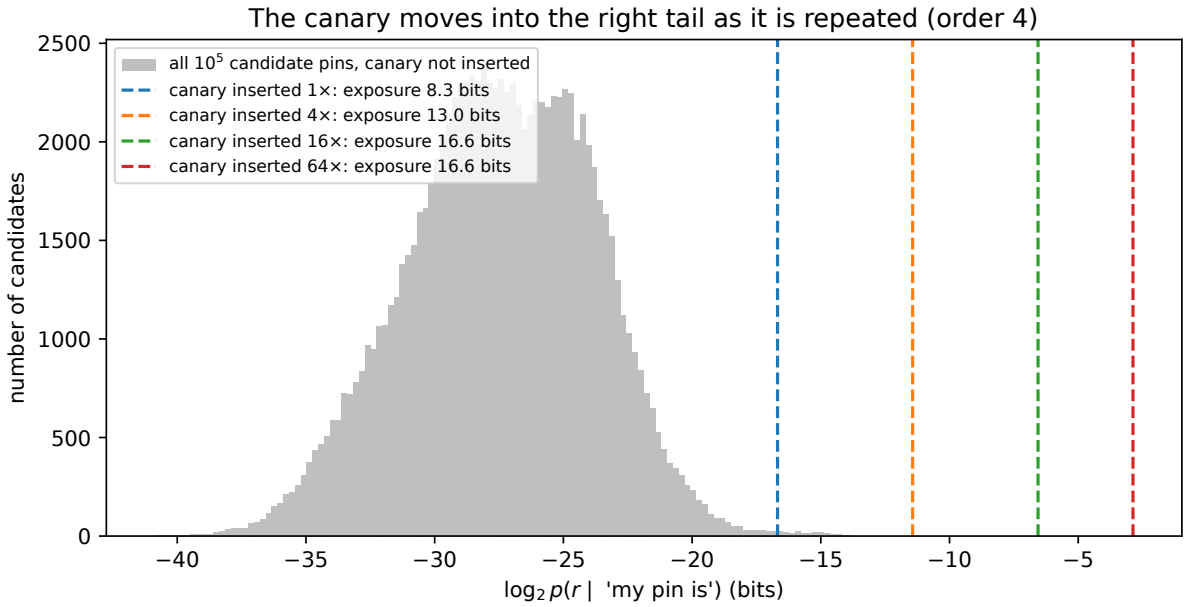

Figure 13.3.: Histogram of $\log_2 p(r \mid \text{my pin is})$ over all 10^5 pins for an order-4 model without the canary (grey), and the score of the canary after it is inserted 1, 4, 16 and 64 times (dashed). Each insertion pushes the canary further into the right tail, past more and more of the other pins.

The null in practice. For a pin that was never inserted, the derivation predicts a uniform rank. For orders 2, 3 and 4 the scores have no ties, so the exposures of all 10^5 uninserted pins are exactly the uniform-rank values: mean 1.443 bits, against 1.4426 from Equation 13.11, and a fraction $0.03125 = 1/32 = 2^{-5}$ with exposure at least 5, exactly on the bound Equation 13.10.

Estimating instead of enumerating. At order 3, the script estimates the canary's exposure from 10,000 random pins, by the two estimators of the interpretation: counting how many sampled pins score at least as high as the canary, and fitting a normal distribution to the sampled scores and reading off its tail (Table 13.6).

Table 13.6.: Exposure of the canary at order 3, computed exactly over all 10^5 pins and estimated from 10,000 random pins, by counting and by fitting a normal to their scores.

Copies k	Exact exposure	Rank	Sampling estimate	Normal fit
1	4.05	6,018	4.13	4.47
2	4.44	4,606	4.43	5.57
4	4.71	3,823	4.68	6.81
8	5.24	2,648	5.35	8.28

Counting is accurate here, because every exposure is well below $\log_2 10^4 = 13.3$ bits, the largest value 10,000 samples can resolve. The normal fit overestimates by up to 3 bits (at 8 copies,

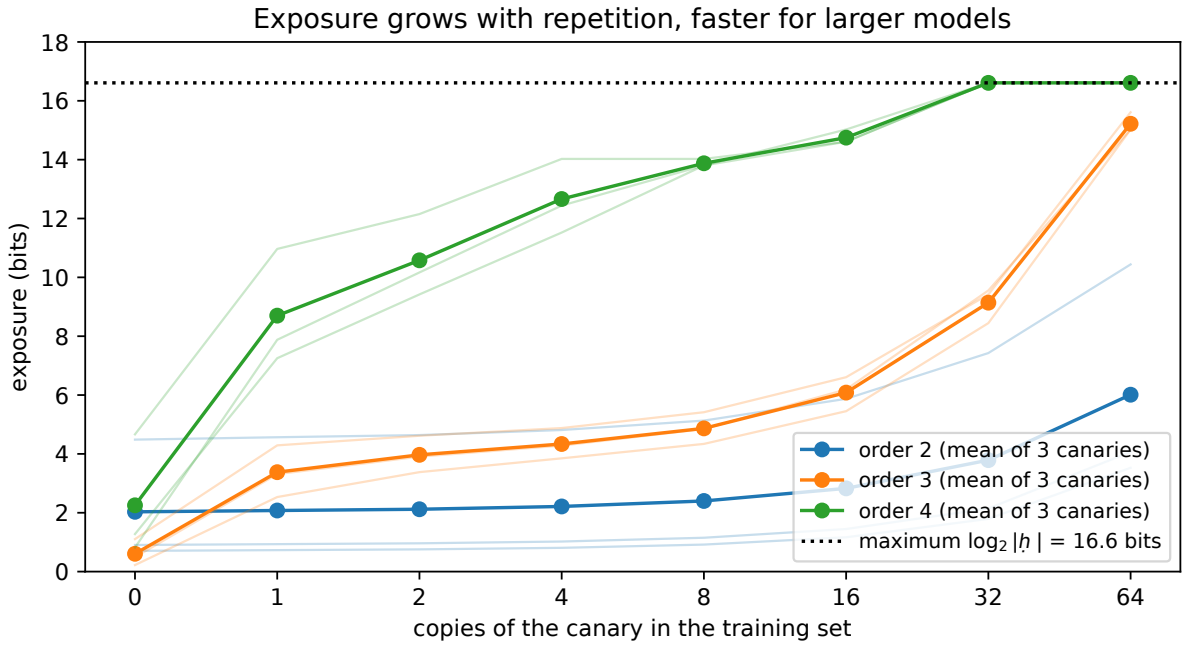

Figure 13.4.: Exposure against copies of the canary for n-gram models of order 2, 3 and 4. Thin lines are individual canaries and markers their mean; the dotted line is the maximum, $\log_2 10^5$. Larger models reach the maximum with fewer copies.

$8.28 - 5.24 = 3.04$). The score distribution has a heavier right tail than a normal, so the normal puts too few pins above the canary, which makes the canary's rank look smaller and its exposure larger. This is why the choice of tail model matters, and why Carlini et al. (2019) fit a skewed distribution.

13.5.6. Check yourself

- An auditor plants one canary, trains, and measures exposure 10 bits on a space of 10^9. What is the chance a non-inserted canary scores that high? *(At most $2^{-10} = 1/1024 \approx 0.001$, by Equation 13.10. The size of the space does not enter.)*
- Why does the order-2 model barely react to the canary even at 64 copies? *(Every context it sees is a single character, shared with thousands of training positions. The 64 votes are a small fraction of the counts in each context. The model is too small to give the canary anything of its own.)*

13.6. Extraction without the prefix: generate, rank, verify

13.6.1. Context

The attacker of Section 13.3 had the training prefix. A real attacker has only the model. Carlini et al. (2021) showed how such an attacker extracts training data from GPT-2: generate a large

number of samples, rank them by how likely they are to be memorized, and check the top of the ranking. The checking step is easy for whoever has the training data (a search) and, for an outside attacker, can be done against public sources. The hard step is the ranking, and it is a hypothesis test: for each sample, decide between two explanations of why the model produced it.

13.6.2. Statement

A model can find a string likely for two different reasons. The string may be ordinary, the kind of text any model of the language would find likely, or the model may have memorized it from its training set. Only the second is a leak. So for a generated string x, test H_0: "x is likely because text like it is common" against H_1: "x is likely because the target model memorized it". To score the two explanations you need a model of each. A **reference model** p_{ref}, trained on data from the same distribution but not on the target's training set, stands in for "common text", the distribution under H_0. The target model p_θ itself stands in for H_1. The best evidence for memorization is then how much more likely the target finds x than the reference does, which on a log scale is a difference. The most powerful test at every false positive rate ranks generations by this log-likelihood ratio,

$$\Lambda(x) = \ln p_\theta(x) - \ln p_{\text{ref}}(x), \tag{13.12}$$

not by $\ln p_\theta(x)$ alone.

13.6.3. Derivation

1. **The two hypotheses give two probabilities.** Under H_0 the string has probability $p_{\text{ref}}(x)$, and under H_1 it has probability $p_\theta(x)$.
2. **The best test thresholds their ratio.** The Neyman–Pearson lemma of Hypothesis testing says that, among all tests with a given false positive rate (the fraction of H_0 strings wrongly flagged), the one with the highest true positive rate (the fraction of H_1 strings caught) flags a string when the likelihood ratio $p_\theta(x)/p_{\text{ref}}(x)$ is above a threshold. The reason is a budget argument: each flagged string costs false positives in proportion to $p_{\text{ref}}(x)$ and gains true positives in proportion to $p_\theta(x)$, so for a fixed budget of false positives you catch the most by flagging the strings with the largest ratio first.
3. **Take logarithms.** The logarithm is increasing, so it keeps the order of the ratios, and thresholding the ratio is the same as thresholding its logarithm, Equation 13.12.
4. **Why raw likelihood falls short.** Ranking by $\ln p_\theta(x)$ alone is the same as using Equation 13.12 with p_{ref} constant, as if every string were equally common a priori. That assumption is wrong exactly for strings that are likely under any model, such as boilerplate, licences and famous quotations, and those are the strings raw likelihood puts first.

This is the same move as the per-example calibration of Membership inference: there, a record's raw loss under the target model is compared with the loss that models which did not see the record would give it.

13.6.4. Interpretation

Raw likelihood finds the common, not the private. The most likely generations of a large model are text that appears everywhere: software licences, news boilerplate, number sequences. These are in the training data, but extracting them reveals nothing. A reference model knows them too, so their ratio is close to 1 and the difference in Equation 13.12 cancels them.

The reference can be crude. Carlini et al. (2021) used three: a smaller model of the same family, the length of the text after compression with zlib (a general-purpose compressor, so the compressed length is a model-free measure of how predictable the text is), and the target's own likelihood on the lowercased text. Each gives a different idea of "generic", and each catches strings the others miss.

What the attacker cares about is precision, not recall. An attacker who checks the top 100 candidates by hand cares about how many of those are real training data, the precision of the top of the ranking, not about how many of all memorized strings it eventually finds. A high precision among a few flagged strings is a high true positive rate at a tiny false positive rate, the same operating point that matters in membership inference.

13.6.5. Example: extracting secrets from the contact-list model

The attacker samples 20,000 lines from the order-6 model, starting each at the beginning of a line. To make the ranking problem realistic, 50 **public** lines (think of a published directory) are added 100 times each to the target's training set; the attacker's own reference data, an independent contact list of 5,000 lines from the same generator, also contain them. The reference model is trained on those reference data. A generation counts as a hit if it is a private training line: in the target's training set and not public.

Of the 20,000 samples, 14,852 are distinct. Among them are 197 private training lines and all 50 public lines. By duplication group, the samples contain none of the secrets inserted 1, 2 or 4 times, 11% of those inserted 8 times, 86% of those inserted 16 times and all of those inserted 32 times. Compare the discoverable rates at order 6 (Table 13.3): 8% of the singletons and 65% of the lines seen twice come out when you hold their prefix. Without the prefix, a sample must first produce the right name before it can produce the pin, and only heavily duplicated lines make their names likely enough. What this attack extracts is much less than what is discoverable.

Ranking matters (Figure 13.5). Among the top 100 distinct generations by target likelihood, 45 are private training lines; the rest are mostly the 50 public lines, which, repeated 100 times each, are the most likely strings the model knows. Ranking by Equation 13.12, 85 of the top 100 are private training lines, because the reference model also finds the public lines likely and cancels them.

13.6.6. The production attack in prose

Nasr et al. (2023) carried this to deployed models. Their measurements separate the two notions of Section 13.3, discoverable and extractable. On open models whose training data are public (Pythia, GPT-Neo and others), they measured how much of what an attacker generates is verbatim training data, by checking every 50-token window of the output against a suffix array of the

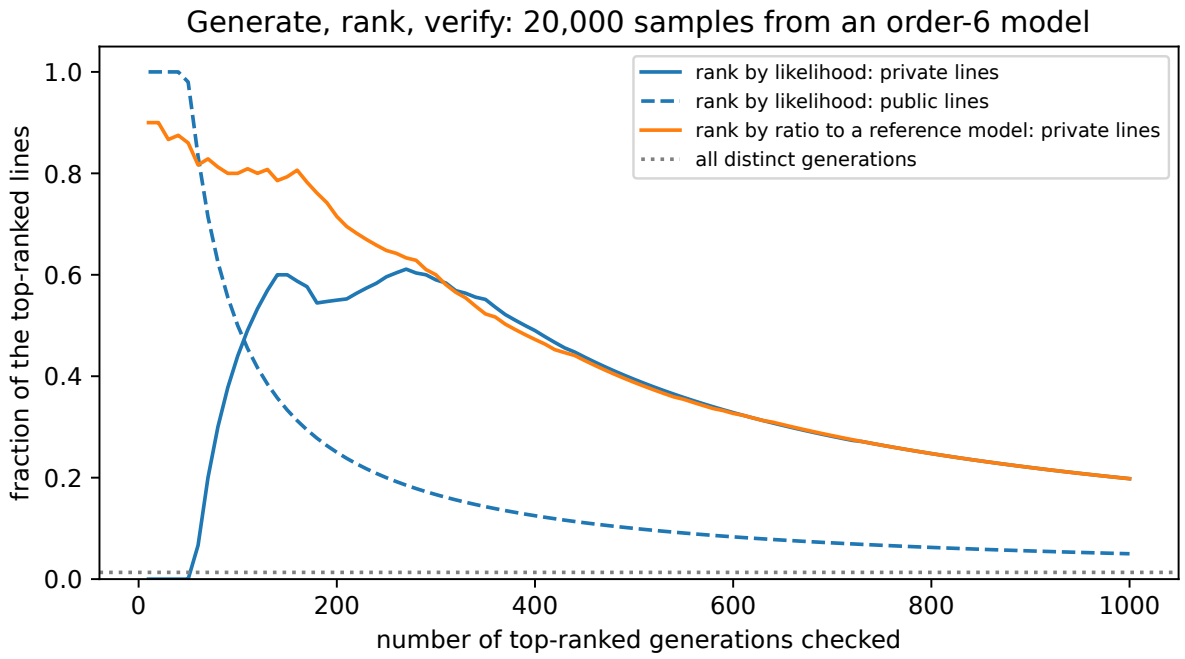

Figure 13.5.: Fraction of the top-ranked distinct generations that are private training lines (solid) or public lines (dashed), from 20,000 samples of an order-6 model trained with 50 public lines repeated 100 times. Ranking by likelihood puts the public lines first. Ranking by the likelihood ratio to a reference model trained on other data puts the private lines first.

training set, an index that finds any substring of a huge text quickly. For closed models, whose training data are unknown, they built a 9-terabyte auxiliary corpus of public web text and counted 50-token matches against it as a lower bound.

The aligned chat model they attacked, ChatGPT (gpt-3.5-turbo), rarely emitted training data when used normally: alignment training, a later stage that fine-tunes the model to follow instructions, had taught it to answer as an assistant, not to continue documents. Their **divergence attack** asked it to repeat a single word forever. After many repetitions the model diverged from the chat behaviour and began to emit text that looked like pretraining documents, and a sizeable part of that text matched the web corpus verbatim. They report that the attack made the model emit training data at a rate about 150 times higher than normal use, and that about 200 US dollars of queries extracted over 10,000 unique memorized training examples, including personal contact details. The structure is the one of this chapter: generate (with a prompt that escapes the aligned behaviour), verify (against a corpus), and estimate the total from what was found.

13.6.7. Check yourself

- Why are none of the secrets inserted 4 times generated, although at order 6 76% of them are discoverably memorized? *(An unprompted sample must first produce the secret's name. With 343,000 possible names, a sample hits a particular one only if that name is likely, which takes many copies.)*
- When would ranking by raw likelihood be as good as the ratio? *(When nothing is generically likely: if every string had the same prior probability, p_{ref} would be constant and the two rankings would agree.)*

13.7. Code: check every number by computation and simulation

The script code/memorization.py builds the contact list, trains the n-gram models by counting, and runs every experiment in this chapter: greedy and sampled extraction from true prefixes, the copies needed k^* for every secret, exact and estimated exposure of canaries over all 10^5 pins, and the generate-rank-verify attack. Every model is a small typed dataclass of sorted count arrays, so scoring all 10^5 pins is one vectorized lookup. From the repository root:

```
uv run python code/part02-attacks/memorization.py
```

Output (seed 0), summarized in Table 13.7:

Table 13.7.: The script's output with the default seed.

Experiment	Result
Corpus	5,000 background lines, 600 secrets (100 each at 1, 2, 4, 8, 16, 32 copies), 11,300 lines, 146,900 symbols
Model size, distinct n-grams	Order 3: 2,734; 4: 19,129; 5: 42,407; 6: 52,610; 7: 54,334; 8: 54,614

Experiment	Result
One secret, `migule 16430` × 4	$k^* = 151, 43, 9, 1, 1, 1$ for orders 3 to 8; greedy reproduces it from order 6
Discoverable memorization	Table 13.3; $\Pr[k^* \le k]$ matches greedy in 36 of 36 cells
Sampling from the prefix, order 5	Mean $p(\text{pin} \mid \text{prefix})$ 1.4×10^{-3} at 4 copies, 0.142 at 32; 3,252 and 31 samples for 99%
Exposure null, orders 2–4	Mean 1.443 bits (theory 1.4426); $\Pr[\text{exposure} \ge 5] = 0.03125$ (bound 2^{-5}); order 8: all tied, exposure 0
Canary exposure	Table 13.5
Exposure estimates, order 3	Table 13.6
Extraction, order 6	14,852 distinct of 20,000 samples; 197 private lines; top 100 precision 0.45 by likelihood, 0.85 by ratio

tests/test_memorization.py checks that the output still matches.

What to take from it. Four things stand out. First, the count formula is exact: k^* from Equation 13.7 predicts which secrets greedy decoding reproduces in every cell, ties included, because it is a restatement of how greedy decoding reads counts. The `migule 16430` row shows the mechanism in one line: the secret, inserted 4 times, would need 151 copies at order 3, 43 at order 4 and 9 at order 5, but only 1 from order 6 on, which is why greedy decoding reproduces it from order 6. Second, duplication and model size both matter, and they trade off against each other: a small model needs dozens of copies, a large one needs one. Third, exposure behaves like a p-value. Without the canary, exposures follow the uniform-rank law exactly; with it, each digit of the canary that has a context of its own adds about 3.5 bits at one copy, the $\log_2 11$ of Fact 2. Fourth, the attacker without the prefix gets less, and needs a reference. Only heavily duplicated secrets come out of unprompted samples, and ranking by the likelihood ratio nearly doubles the precision of the top 100, from 0.45 to 0.85.

13.9. Cheat sheet

p is a training prefix and x its suffix, k the number of copies of a string in the training set, n the order of an n-gram model, $\mathcal{R}$ a canary's randomness space. Table 13.8 collects the results.

Table 13.8.: Every result in this chapter.

Result	Statement	Key fact
Extractable	Some prompt c makes greedy decoding emit s	The real attacker's notion; hard to measure
Discoverable	Greedy from the true prefix p emits x	Easy to measure; implies extractable
k-eidetic	Extractable and in at most k documents	$k = 1$: a secret seen once comes back
Approximate	Greedy output within distance τ of x	Verbatim rates understate the leak
Samples needed	$m \geq \ln(1/\beta)/p(x \mid c)$	From $(1-p)^m \leq e^{-mp}$
Copies needed (n-gram)	$k^* = \max_t[\max_{w \neq x_t} N_{-}(c_t, w) - N_{-}(c_t, x_t)] + 1$	Largest gap on the path decides; unique contexts give $k^* = 1$
Exposure	$\log_2 \lvert\mathcal{R}\rvert - \log_2 \text{rank}$	Bits of guessing saved
Exposure null	$\Pr[\text{exposure} \geq e] \leq 2^{-e}$; mean $\to \log_2 e = 1.443$	Exposure is $-\log_2$ of a p-value
Ranking generations	$\ln p_\theta(x) - \ln p_{\text{ref}}(x)$	Neyman–Pearson; cancels generically likely text

Rules of thumb

- Memorization is a rank: the secret above the strings it could have been.

- Duplication is a vote in every context the string passes through; the most contested context decides.
- Larger models split contexts and give rare strings their own parameters, so they memorize more and from fewer copies.
- Deduplicate first: it is cheap and helps, but not for singletons in a high-capacity model.
- Report exposure, not just extraction: it is graded and has a known null.
- Rank generations against a reference, never by raw likelihood.
- An attacker without the prefix gets less than the discoverable rate suggests, but production attacks show "less" is still thousands of records.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

14. Gradient inversion

14.1. Why this matters

A phone keyboard learns from what its users type. The raw text never leaves the phones. Instead, a server sends the current model θ to each phone, the phone computes the gradient of the loss on its own few examples, and only that gradient goes back. The server averages the gradients of many phones and takes a step. This is the setting of **federated learning (FL)**, and it is often described as private because "the data stay on the device". Later parts study FL itself. This chapter asks one question about it: **what does a single client's gradient reveal about the client's data?**

The answer is: often, everything. A gradient is not a summary statistic chosen to hide the data. It is the derivative of a loss with respect to millions of parameters, and many of those derivatives are simple functions of the input. This chapter shows four ways to read the data back out of the gradient, going from the exact to the approximate. The first is **exact recovery**: for a fully connected layer with a bias, dividing one row of the weight gradient by one entry of the bias gradient gives back the layer's input, with no search at all. The second is **label recovery**: the signs of the last layer's gradient name the label, so the label can be taken off the list of unknowns. The third handles layers where no such closed form exists. You guess an input, compute the gradient it would produce, and move the guess until that gradient matches the one you saw. This is **Deep Leakage from Gradients (DLG)**. The fourth asks what happens when the client sends the average gradient of a whole batch of examples. Averaging mixes the examples together, but much less than you might hope.

14.1.1. The one idea: a gradient is a sum of outer products

Why should a gradient contain the input at all? Take a fully connected layer, which computes $a = Wx + b$: each output a_j is a weighted sum of the inputs x_k, with weights W_{jk}, plus a bias b_j. The weight W_{jk} multiplies the input x_k, so a small change in W_{jk} changes a_j by x_k times that change. The loss ℓ in turn responds to a change in a_j at some rate, $\gamma_j = \partial \ell / \partial a_j$, which depends on everything that happens after this layer. The chain rule multiplies the two rates: the loss changes with W_{jk} at the rate $\gamma_j x_k$. Collecting these numbers into a matrix with the shape of W, the gradient of the loss with respect to W is

$$\nabla_W \ell = \gamma \, x^\top, \qquad \gamma = \frac{\partial \ell}{\partial a}. \tag{14.1}$$

A matrix whose (j, k) entry is $\gamma_j x_k$ is called the **outer product** of γ and x. Here it is the outer product of what flows backward (γ) with what flowed forward (x). Row j is the input x multiplied by the single number γ_j, so the layer's input sits, unchanged up to a scale, in every row of the gradient. Every attack in this chapter exploits that. With one example the scale can

be divided out. With a batch of B examples the gradient is a sum of B such outer products, and the attacker's job is to pull the sum apart.

Table 14.1 lists the results and where each is used.

Table 14.1.: The results of this chapter and where each is used.

Result	Where it is used
$\nabla_W \ell = \gamma x^\top$, $\nabla_b \ell = \gamma$ (Toolkit)	Every attack below; per-example gradients in later parts
Exact recovery $x = (\nabla_W \ell)_{j,:}/(\nabla_b \ell)_j$	Inverting any model whose first layer is fully connected with a bias
Labels from the sign of $\nabla_{b_2} \ell = p - e_y$; counts from its size	Removing the label from the unknowns; label leakage in batches
Deep Leakage from Gradients: $\min_{\hat{x}} \|\nabla_\theta \ell(\hat{x}) - g\|^2$	Inverting layers with no closed form, such as convolutions
Rank and isolation in a batch: $1 - (1 - 2^{-B})^m$	How much batching protects, and why it is not a defence

14.1.2. The setting and the game

The server is **honest-but-curious** in the sense of Threat models and privacy games: it runs the training protocol as specified, sends the real model and does not tamper with anything, and only analyses what it receives. Its access is the **transcript**, the strongest level of that chapter: it sees each client's own update, which is more than the final model, and it knows the architecture and every parameter of θ because it chose them. A client holds a batch of B labelled examples $(x_1, y_1), \dots, (x_B, y_B)$. Its training loss is the average of the B per-example losses, and what it sends is the gradient of that average with respect to all the parameters θ. Since the derivative of an average is the average of the derivatives, this is the average of the per-example gradients:

$$g = \frac{1}{B} \sum_{i=1}^{B} \nabla_\theta \ell(\theta; x_i, y_i). \tag{14.2}$$

This is the **reconstruction game** of that chapter, played on one client. A game there has three parts: a challenger who draws a hidden secret, an adversary who sees only what the threat model allows, and a score for the adversary's guess. Here the challenger draws the batch from the population and the secret is the inputs. The adversary sees (θ, g) and outputs reconstructions $\hat{x}_1, \dots, \hat{x}_B$, and its gain is how close they come to the true inputs. We measure closeness by the **relative error** $\|\hat{x} - x\|/\|x\|$: the length of the mistake as a fraction of the length of the input, so that 0 is a perfect reconstruction and 1 is a mistake as large as the image itself. Each true example is matched to its closest reconstruction, because an average does not change when you reorder the examples, so the gradient carries no record of which example came first.

The baseline is a guess from the population alone, such as the average image of a shape, which knows nothing of the client's own position, noise or pixels. The attacks below either recover the client's exact pixels or, for large enough batches, produce blends; there is little in between.

The model. All experiments use a network with one hidden layer, written in NumPy. An input $x \in \mathbb{R}^d$ first goes through a fully connected layer (W_1, b_1) that gives one number a_j per hidden unit. An activation σ is applied to each unit, giving h. A second fully connected layer (W_2, b_2) turns h into one score z_k per class, called a **logit**. The **softmax** turns the logits into probabilities by exponentiating and normalizing, $p_k = e^{z_k} / \sum_{k'} e^{z_{k'}}$, so that every p_k is positive and they sum to 1. The loss is the **cross-entropy**, minus the log of the probability the model gives to the true label y, which is small when the model is confidently right. In one line:

$$a = W_1 x + b_1, \quad h = \sigma(a), \quad z = W_2 h + b_2, \quad p = \mathrm{softmax}(z), \quad \ell = -\ln p_y, \tag{14.3}$$

with m hidden units, K classes, $W_1 \in \mathbb{R}^{m \times d}$ and $W_2 \in \mathbb{R}^{K \times m}$. The activation σ is either the ReLU $\max(a, 0)$, which passes positive values and replaces negative ones by 0, or the sigmoid $1/(1 + e^{-a})$, which squashes every value smoothly into $(0, 1)$. The inputs are synthetic 8×8 grey-scale images ($d = 64$) of $K = 4$ shapes (a horizontal bar, a vertical bar, a diagonal and a square outline), shifted at random and with pixel noise. The network has $m = 32$ hidden units and is at its random initialization, as in the first round of training. Counting the $64 \cdot 32$ weights and 32 biases of the first layer and the $32 \cdot 4$ weights and 4 biases of the second, it has $64 \cdot 32 + 32 + 32 \cdot 4 + 4 = 2{,}212$ parameters, so the gradient has 2,212 entries, against 64 unknown pixels per example.

What this chapter assumes. Gradients, stochastic gradient descent (SGD), minibatches and the limits of non-convex optimization are in Optimization. The threat-model vocabulary and the games are in Threat models and privacy games. The facts this chapter needs from both are restated where they are used. For a different route to reconstruction, from noisy answers to many queries rather than from one gradient, see Reconstruction attacks.

Conventions. e_y is the y-th standard basis vector: 1 in position y and 0 elsewhere, the "one-hot" encoding of the label. $\odot$ is the elementwise product, which multiplies two vectors entry by entry. For a matrix A, $A_{j,:}$ is its j-th row. Gradients are column vectors and $\nabla_W \ell$ has the shape of W. We write $\gamma_1 = \partial \ell / \partial a \in \mathbb{R}^m$ and $\gamma_2 = \partial \ell / \partial z \in \mathbb{R}^K$ for the backward signals at the two layers: how fast the loss changes with each hidden unit's pre-activation and with each logit. Texts on backpropagation usually write these signals as δ; this book keeps δ for the privacy parameter of the later parts.

14.2. Toolkit: three facts every derivation uses

14.2.1. Fact 1 — The gradient of a fully connected layer is an outer product

This is the fact behind the whole chapter: in a fully connected layer, the gradient of each weight is the backward signal of its output times the input it multiplies. Let $a = Wx + b$ with $W \in \mathbb{R}^{m \times d}$, and let $\gamma = \partial \ell / \partial a$ be the backward signal. Then

$$\nabla_W \ell = \gamma \, x^\top, \qquad \nabla_b \ell = \gamma. \tag{14.4}$$

Why. Write out one output: $a_j = \sum_k W_{jk} x_k + b_j$. The weight W_{jk} appears in a_j only, with coefficient x_k, so $\partial a_j / \partial W_{jk} = x_k$. The loss depends on W_{jk} only through a_j, so the chain rule gives $\frac{\partial \ell}{\partial W_{jk}} = \frac{\partial \ell}{\partial a_j} \frac{\partial a_j}{\partial W_{jk}} = \gamma_j x_k$, which is the (j, k) entry of $\gamma x^\top$. The bias b_j enters a_j with coefficient 1, so $\frac{\partial \ell}{\partial b_j} = \gamma_j \cdot 1$.

A concrete case. With $m = 2$, $d = 3$, $\gamma = (-0.3279, 0.9838)$ and $x = (0.5, 1, 0.2)$, the two rows of $\nabla_W \ell$ are $-0.3279\, x = (-0.1640, -0.3279, -0.0656)$ and $0.9838\, x = (0.4919, 0.9838, 0.1968)$. Both are multiples of x. This is the worked example of Table 14.2.

Every attack in this chapter uses this fact. The point to keep is the split between the two factors: γ depends on everything above the layer (the rest of the network, the loss, the label), but the factor $x^\top$ does not. Whatever the rest of the network does, it can only rescale the rows, never change their direction.

14.2.2. Fact 2 — Softmax with cross-entropy has gradient $p - e_y$

At the last layer the backward signal has a very simple form: the predicted probabilities minus the one-hot label. In words, raising the logit of a wrong class k raises the loss at the rate p_k, the probability the model already gives that class, and raising the logit of the true class lowers the loss at the rate $1 - p_y$. With $p = \mathrm{softmax}(z)$ and $\ell = -\ln p_y$,

$$\gamma_2 = \frac{\partial \ell}{\partial z} = p - e_y. \tag{14.5}$$

Why. Write the loss without the fraction. Since $p_y = e^{z_y} / \sum_k e^{z_k}$, its log is $z_y - \ln \sum_k e^{z_k}$, so $\ell = -z_y + \ln \sum_k e^{z_k}$. Now differentiate in one logit z_k. The first term depends only on z_y, so it contributes -1 when $k = y$ and 0 otherwise, which is $-\mathbf{1}[k = y]$. The second term is the log of a sum, and the derivative of $\ln u$ is u'/u: here $u' = e^{z_k}$, so the term contributes $e^{z_k} / \sum_{k'} e^{z_{k'}} = p_k$. Together, $\partial \ell / \partial z_k = p_k - \mathbf{1}[k = y]$, which is entry k of $p - e_y$.

A concrete case. With logits $z = (-0.35, 0.295)$ and $y = 1$ (the first class), the first probability is $p_1 = e^{-0.35} / (e^{-0.35} + e^{0.295}) = 1/(1 + e^{0.645}) = 1/(1 + 1.906) = 0.3441$, so $p = (0.3441, 0.6559)$ and $\gamma_2 = (0.3441 - 1, 0.6559) = (-0.6559, 0.6559)$. The entries sum to 0, and only the true class is negative.

This sign pattern is what label recovery uses. The softmax never gives a probability of exactly 0 or 1, since every e^{z_k} is positive, so $0 < p_y < 1$. The entry at the true label is therefore $p_y - 1 < 0$, and every other entry is $p_k > 0$.

14.2.3. Fact 3 — Backpropagation and averaging

To use Fact 1 at the first layer you need its backward signal γ_1, and that is obtained by sending γ_2 back through the network, which is what **backpropagation** does. Each hidden unit j feeds every logit z_k through the weight $W_{2,kj}$, so it collects the logits' signals weighted by those connections, $\sum_k \gamma_{2,k} W_{2,kj}$. That sum is how fast the loss changes with the unit's output h_j. The unit's output is $h_j = \sigma(a_j)$, so to get the rate with respect to a_j you multiply by the activation's slope $\sigma'(a_j)$. In vector form:

$$\gamma_1 = (W_2^\top \gamma_2) \odot \sigma'(a). \tag{14.6}$$

The second half of the fact concerns batches: the gradient of an average loss over a batch is the average of the per-example gradients.

Why. $z_k = \sum_j W_{2,kj} h_j + b_{2,k}$, so h_j enters each z_k with coefficient $W_{2,kj}$, and the chain rule sums over the logits: $\frac{\partial \ell}{\partial h_j} = \sum_k \gamma_{2,k} W_{2,kj} = (W_2^\top \gamma_2)_j$. Then $h_j = \sigma(a_j)$ multiplies this by $\sigma'(a_j)$. The

claim about batches holds because differentiation is linear: the derivative of a sum is the sum of the derivatives, and a constant factor $\frac{1}{B}$ comes out unchanged.

A concrete case. For ReLU the slope is $\sigma'(a_j) = \mathbf{1}[a_j > 0]$: 1 if the unit is switched on, 0 if it is switched off. So a unit that is switched off on an input has $\gamma_{1,j} = 0$ and, by Fact 1, a zero row in $\nabla_{W_1}\ell$. For a batch, Fact 1 applied to each example and then averaged gives the first-layer gradient $\frac{1}{B}\sum_i \gamma_{1,i} x_i^\top$: a sum of B outer products, one per example.

Label recovery uses this fact to know which rows of the weight gradient can be negative, and every batch result below uses the averaging.

14.3. Exact recovery from a fully connected layer

14.3.1. Context

The server sees g. Is there any computation, short of a search, that gives back the client's input? For the most common first layer of all, a fully connected layer with a bias, there is: one division. The observation goes back at least to Phong et al. (2018), who pointed it out for exactly this federated setting.

14.3.2. Statement

Suppose the client sends the gradient of a single example, and the first layer is fully connected, $a = W_1 x + b_1$. By Fact 1, row j of the weight gradient is the input x scaled by the number $\gamma_{1,j}$, and entry j of the bias gradient is that same number $\gamma_{1,j}$. Dividing the first by the second removes the scale. So for every unit j with $(\nabla_{b_1}\ell)_j \neq 0$,

$$x = \frac{(\nabla_{W_1}\ell)_{j,:}}{(\nabla_{b_1}\ell)_j}. \tag{14.7}$$

Moreover, since every row is a multiple of the same vector, $\nabla_{W_1}\ell$ has **rank one** (all its rows lie on a single line), and that line, its row space, is the line through x.

14.3.3. Derivation

1. **Apply Fact 1 (Equation 14.4) to the first layer.** It gives the two pieces the server sees: $(\nabla_{W_1}\ell)_{j,:} = \gamma_{1,j}\, x^\top$ and $(\nabla_{b_1}\ell)_j = \gamma_{1,j}$.
2. **Divide one by the other.** When $\gamma_{1,j} \neq 0$, the ratio is $\gamma_{1,j} x^\top / \gamma_{1,j} = x^\top$. Nothing about the rest of the network enters: the depth, the activations above, the loss and the label all sit inside the number $\gamma_{1,j}$, and that number cancels.
3. **Read off the rank.** All rows of $\nabla_{W_1}\ell = \gamma_1 x^\top$ are multiples of the same vector $x^\top$. A matrix whose rows are all multiples of one nonzero vector has rank one, so (as long as $\gamma_1 \neq 0$) the rank is one and the row space is spanned by x.

14.3.4. Interpretation

The attack is exact and costs nothing. It needs no optimization, no prior knowledge of what the data look like, and no knowledge of the label. It also checks itself: every unit with a nonzero bias gradient gives the same answer, so if all the usable ratios agree, the attacker knows it has the input.

The same division works at any fully connected layer whose input you want. Applied deeper in the network, it gives that layer's input, an intermediate feature vector. Applied at the first layer, the input is the data itself.

Three things can stop it, and only one of them stops it fully. With ReLU, units that are switched off on x have $\gamma_{1,j} = 0$ and give nothing, but a single active unit is enough. Without a bias there is no denominator, but the rank-one structure still gives the direction of x, so x is known up to one scalar, and a one-dimensional search finds that scalar (Exercise 2 in the exercise book). A convolutional first layer is what really breaks the outer-product form. A convolution applies the same small filter at every position of the image, so its gradient is a sum of outer products over all the image patches rather than a single one, and no division separates them. That is why images fed to convolutional networks need the search of Section 14.5. A batch of more than one example also breaks the formula, as Section 14.6 shows, but only partly.

Figure 14.1 shows the attack on one image.

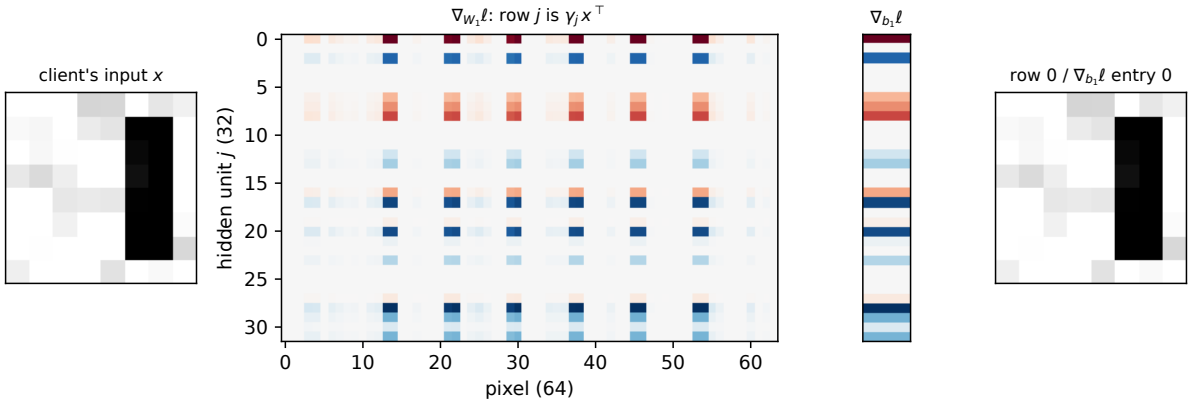

Figure 14.1.: Exact recovery from the first-layer gradient of a ReLU network with 32 hidden units. Left: the client's 8×8 input. Middle: $\nabla_{W_1}\ell$, one row per hidden unit and one column per pixel (blue positive, red negative), next to $\nabla_{b_1}\ell$. Every nonzero row is the image times the matching bias entry; switched-off units give zero rows. Right: one row divided by its bias entry, which is the input exactly.

14.3.5. Example: a network you can compute by hand

Take $d = 3$ inputs, $m = 2$ ReLU units and $K = 2$ classes, with

$$W_1 = \begin{pmatrix} 0.4 & -0.2 & 0.1 \\ 0.3 & 0.5 & -0.4 \end{pmatrix}, \quad b_1 = \begin{pmatrix} 0.1 \\ -0.1 \end{pmatrix}, \quad W_2 = \begin{pmatrix} 1 & -1 \\ 0.5 & 0.5 \end{pmatrix}, \quad b_2 = 0, \tag{14.8}$$

and the example $x = (0.5, 1, 0.2)$ with label $y = 1$ (the first class). Table 14.2 walks through the forward pass, the backward pass and the attack.

Table 14.2.: Forward pass, backward pass and exact recovery for a two-unit ReLU network. The server sees only the "Gradient" rows.

Step	Quantity	Value
Forward	$a = W_1 x + b_1$	$(0.2 - 0.2 + 0.02 + 0.1,\ 0.15 + 0.5 - 0.08 - 0.1) = (0.12, 0.47)$
	$h = \max(a, 0)$	$(0.12, 0.47)$, both units on
	$z = W_2 h$	$(0.12 - 0.47,\ 0.06 + 0.235) = (-0.35, 0.295)$
	$p = \mathrm{softmax}(z)$	$(0.3441, 0.6559)$
Backward	$\gamma_2 = p - e_y$ (Fact 2)	$(-0.6559, 0.6559)$
	$\gamma_1 = (W_2^\top \gamma_2) \odot \sigma'(a)$ (Fact 3)	$(-0.6559 + 0.5 \cdot 0.6559,\ 0.6559 + 0.5 \cdot 0.6559) = (-0.3279, 0.9838)$
Gradient	$\nabla_{W_1} \ell = \gamma_1 x^\top$ (Fact 1)	rows $(-0.1640, -0.3279, -0.0656)$ and $(0.4919, 0.9838, 0.1968)$
	$\nabla_{b_1} \ell = \gamma_1$	$(-0.3279, 0.9838)$
Attack	row 1 / (-0.3279), row 2 / 0.9838	$(0.5, 1, 0.2)$ and $(0.5, 1, 0.2)$

The server never sees a, h, z or p. From the two gradient rows alone it divides and reads off x, twice. Both units are on here ($a = (0.12, 0.47)$ is positive in both entries), so the ReLU slope is 1 for both and γ_1 is just $W_2^\top \gamma_2$.

On the images. For one 8×8 image and the 32-unit ReLU network, 13 of the 32 units are switched on and have a nonzero bias gradient. Every one of the 13 ratios equals the image to a relative error of at most 6.7×10^{-17}, which is rounding error. To check the rank, look at the **singular values** of $\nabla_{W_1} \ell$: they measure how much of the matrix lies along each of its independent directions, so a rank-one matrix has exactly one that is not zero. Here they are 1.6155 and then nothing: the second is 9.5×10^{-17} times the first. The gradient is rank one, as the statement says.

14.3.6. Check yourself

- The network has 20 layers above the first one and a custom loss. Does Equation 14.7 still hold? *(Yes. Everything above the first layer only changes γ_1, and $\gamma_{1,j}$ cancels in the ratio. All that matters is that the first layer is fully connected with a bias.)*
- For a ReLU network, which units are useless to the attacker, and could all of them be useless? *(Units switched off on x have $\gamma_{1,j} = 0$. All units are useless only if every unit is off or every active unit has $(W_2^\top \gamma_2)_j = 0$, which for a random network essentially never happens; the image above had 13 usable units out of 32.)*

14.4. Label recovery from the last layer

14.4.1. Context

The gradient depends on the label too, and the label is often the most sensitive part: the diagnosis, the word typed next, the class of a photo. Zhao, Mopuri & Bilen (2020) noticed that the label can be read off the last layer in closed form. Their attack, iDLG ("improved DLG"), then searches only for the input, which makes the search of Section 14.5 easier and more reliable.

14.4.2. Statement

There are three versions of the rule, depending on what the last layer has and how many examples the gradient covers. All three come from Fact 2: the last layer's backward signal is $p - e_y$, a vector of probabilities with 1 subtracted at the true label.

From the bias, for one example. By Fact 1 the last layer's bias gradient equals its backward signal, $\nabla_{b_2}\ell = p - e_y$. Every entry is a positive probability except the one at the true label, where subtracting 1 makes it negative. So the label is the position of the smallest entry, the only negative one:

$$y = \arg\min_k (\nabla_{b_2}\ell)_k. \tag{14.9}$$

From the weights, for one example. The weight gradient tells the same story. By Fact 1, row k of $\nabla_{W_2}\ell$ is $\gamma_{2,k}$ times the hidden activations h. If those activations are never negative ($h \geq 0$ and $h \neq 0$, as for ReLU or the sigmoid), multiplying by them keeps the sign of $\gamma_{2,k}$. So y is the only row of $\nabla_{W_2}\ell$ whose entries are non-positive, and in particular the only row with a negative sum.

Counts, for a batch. With B examples the bias gradient is the average of $p_i - e_{y_i}$ over the batch. The e_{y_i} parts add up to the label histogram: their k-th entries sum to n_k, the number of examples of class k. The p_i parts add up to the model's total predicted probability for class k, $\sum_i p_{ik}$. So the histogram is that total minus B times the bias gradient:

$$n_k = \sum_{i=1}^{B} p_{ik} - B\,(\nabla_{b_2}\ell)_k. \tag{14.10}$$

An attacker who does not know $\sum_i p_{ik}$ replaces it by $B\bar{p}_k$, where $\bar{p}$ is a guess of the model's average prediction, and rounds to the nearest integer.

14.4.3. Derivation

1. **Bias.** Fact 1 at the last layer gives $\nabla_{b_2}\ell = \gamma_2$, and Fact 2 (Equation 14.5) gives $\gamma_2 = p - e_y$. Softmax probabilities lie strictly between 0 and 1, so $(\nabla_{b_2}\ell)_y = p_y - 1 < 0$ and $(\nabla_{b_2}\ell)_k = p_k > 0$ for $k \neq y$. The smallest entry is therefore at y.
2. **Weights.** Fact 1 gives $(\nabla_{W_2}\ell)_{k,:} = \gamma_{2,k}\,h^\top$. With $h \geq 0$, row y is $(p_y - 1)h^\top$, a negative number times non-negative entries, so it is ≤ 0 entrywise. Every other row is $p_k h^\top \geq 0$. Summing a row multiplies $\gamma_{2,k}$ by $\sum_j h_j$, which is positive because $h \geq 0$ and $h \neq 0$, so the sum keeps the sign of $\gamma_{2,k}$.

3. **Counts.** By Fact 3 the batch gradient is the average of the per-example ones, so $\nabla_{b_2}\ell = \frac{1}{B}\sum_i (p_i - e_{y_i})$. Its k-th entry is $\frac{1}{B}(\sum_i p_{ik} - n_k)$, because e_{y_i} has a 1 in position k exactly when example i has class k, so $\sum_i e_{y_i}$ counts the examples of each class. Multiply by B and solve for n_k.

14.4.4. Interpretation

For one example the rule makes no errors. It is exact for every network that ends in softmax and cross-entropy with a bias, at any point of training, because the sign argument never depends on how good the model is. On 1,000 random images and random networks, both the bias rule and the weight rule name the label correctly 1.000 of the time.

For a batch, the gradient leaks the label histogram. Equation 14.10 is exact, so the only uncertainty is the total prediction $\sum_i p_{ik}$, and the attacker can estimate it well: it knows the model, so it can run the model on data of its own from the same population and average the predictions. The true counts are integers, and a number within $\frac{1}{2}$ of an integer rounds to that integer. So rounding gives the exact counts whenever the estimate of $\sum_i p_{ik}$ is off by less than $\frac{1}{2}$ for every class (Exercise 4 in the exercise book). The cruder guess $\bar{p}_k = 1/K$, which assumes the model spreads its predictions evenly over the classes, does worse, because even an untrained network is not uniform.

The label matters for inversion as well. Knowing y removes a discrete unknown from the search. Zhu et al. (2019) optimized a soft label (a probability vector standing in for the unknown label) jointly with the input, and that joint search often failed. With the label fixed by Equation 14.9, the search is over the input only.

Figure 14.2 shows both cases.

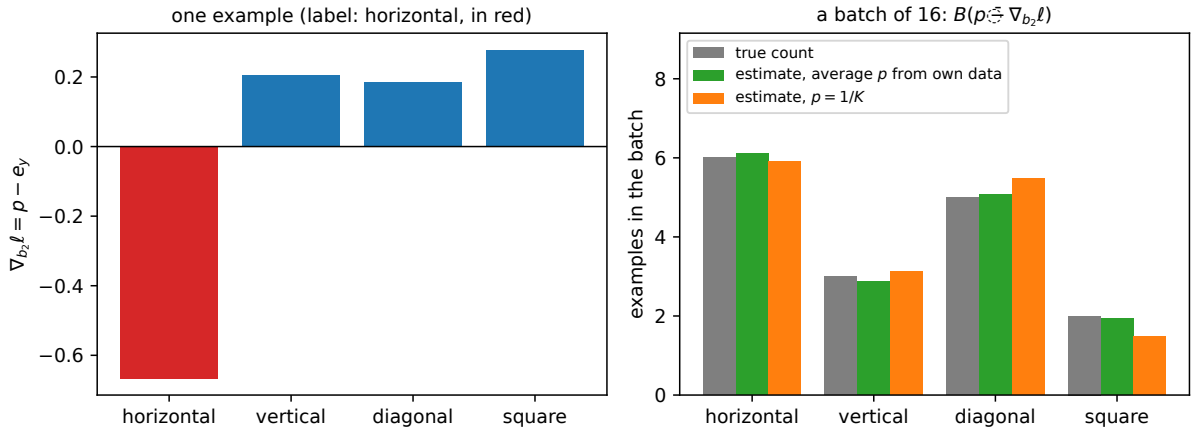

Figure 14.2.: Labels from the last-layer bias gradient. Left: for one example, $\nabla_{b_2}\ell = p - e_y$ has a single negative entry, at the true label (red). Right: for a batch of 16, the counts $B(\bar{p} - \nabla_{b_2}\ell)$ with $\bar{p}$ the model's average prediction on the attacker's own images (green) are close to the true counts (grey); with $\bar{p} = 1/K$ (orange) they are off by up to about half an example.

14.4.5. Example: a batch of 16

A batch of 16 images has true counts $(4, 2, 4, 6)$ over the four shapes. Table 14.3 reads them off the bias gradient of the 32-unit ReLU network, with three different guesses for the total prediction $\sum_i p_{ik}$ in Equation 14.10.

Table 14.3.: Label counts of one batch of 16 recovered from $\nabla_{b_2}\ell$ by Equation 14.10, under three guesses of the summed predictions.

Guess of $\sum_i p_{ik}$	Estimated counts	Rounded	All correct?
Exact, $\sum_i p_{ik}$ (not available to the attacker)	$(4.00, 2.00, 4.00, 6.00)$	$(4, 2, 4, 6)$	yes
$B\bar{p}$, $\bar{p}$ averaged over 200 of the attacker's own images	$(3.88, 2.00, 4.19, 5.92)$	$(4, 2, 4, 6)$	yes
$B/K = 4$ for every class	$(2.12, 3.01, 4.27, 6.60)$	$(2, 3, 4, 7)$	no

With the averaged guess every estimate is within $\frac{1}{2}$ of the truth (the largest miss is $4.19 - 4 = 0.19$), so rounding fixes it. With the uniform guess the first class is off by $4 - 2.12 = 1.88$, and rounding cannot help.

Over 200 random batches and networks, the rounded counts are all correct in 1.000 of batches of 4, 0.975 of batches of 16 and 0.525 of batches of 64 with the averaged guess. With the uniform guess the rates are 0.925, 0.095 and 0.000. The reason for the decline is that the error of the estimate is a sum of B deviations, one per example, each the gap between that example's prediction and the guess $\bar{p}$. These do not cancel exactly, so the error of their sum grows with B, and so does the chance that some class is off by more than $\frac{1}{2}$. Even when the counts are not all exact, they are close: Exercise 4 in the exercise book finds that at $B = 16$ the largest error over the four classes, before rounding, has median 0.233 with the averaged guess and 1.102 with the uniform one.

14.4.6. Check yourself

- Why must $p_y - 1$ be negative, even for a model that is confidently right? *(Softmax never outputs exactly 1, so $p_y < 1$. A confident model gives a tiny negative entry, but its sign is still the only negative one. In floating point a p_y that rounds to 1 would hide it, which is one reason attacks are run on early-training models.)*
- The last layer has no bias and the hidden layer uses tanh. Which rule still works? *(Neither as stated: there is no bias gradient, and tanh activations can be negative, so row y need not have a negative sum. But row y still has the opposite sign to all other rows, so for $K \geq 3$ the odd one out is the label; see Exercise 3 in the exercise book.)*

14.5. Deep Leakage from Gradients

14.5.1. Context

The closed forms need a fully connected layer with a bias. Most image models start with convolutions, and many architectures have normalization layers, attention, or no biases at all. Zhu, Liu & Han (2019) gave a generic attack that needs none of these: **guess an input, compute its gradient, and move the guess until the gradients match**. If only the true input produces the observed gradient, a matching guess is the input.

14.5.2. Statement

To turn "move the guess until the gradients match" into something you can optimize, you need one number that says how badly a guess matches. DLG uses the squared distance between the gradient the guessed batch would produce and the observed gradient g, summed over all the gradient's entries. Call it the **matching loss** R. It is zero for a perfect match and positive otherwise. Given θ, the observed gradient g and the labels $y_1, \dots, y_B$ (from Section 14.4), DLG looks for the guesses $x'_1, \dots, x'_B$ that make R smallest:

$$\hat{x}_1, \dots, \hat{x}_B = \arg\min_{x'_1,\dots,x'_B} R(x'), \qquad R(x') = \Big\| \frac{1}{B} \sum_{i=1}^{B} \nabla_\theta \ell(\theta; x'_i, y_i) - g \Big\|^2, \tag{14.11}$$

where arg min means "the inputs at which the minimum is reached". It searches by a gradient method: start from random noise and repeatedly move the guess a little downhill on R. The true batch has $R = 0$, the smallest possible value.

14.5.3. Derivation

1. **The true batch is a global minimizer of Equation 14.11.** R is a squared length, so $R \geq 0$ always. Plugging in the true x_i reproduces g exactly, so $R = 0$ there, and nothing can do better.
2. **The objective can be differentiated in x' if the network is twice differentiable.** A gradient method needs the slope of R with respect to the guess. Write $G(x') = \frac{1}{B} \sum_i \nabla_\theta \ell(\theta; x'_i, y_i)$, the function that takes a guessed batch to the gradient it would produce. Then $R = \|G(x') - g\|^2$. The squared length $\|u\|^2$ changes at the rate $2u$, and the chain rule passes this back to x' through the **Jacobian** J_G of G, the matrix of rates at which each gradient entry changes with each input pixel:

$$\nabla_{x'} R = 2\, J_G(x')^\top (G(x') - g). \tag{14.12}$$

   G is already made of first derivatives of the network, so J_G is made of second derivatives. That is why Zhu et al. replaced ReLU by the sigmoid, and the experiments here do the same. The ReLU's slope is 0 or 1, constant on each side of zero, so its second derivative is zero almost everywhere: the factor $\sigma'(a)$ in Equation 14.6 is piecewise constant in a, and the search gets no signal through it. The sigmoid's slope varies smoothly, so it does.

3. **Computing $J_G^\top v$ without forming J_G.** J_G would have one row per parameter and one column per pixel, and no one builds it. Automatic-differentiation libraries instead run backpropagation through the backward pass itself, which is called **double backpropagation**. The script writes it out by hand for the one-hidden-layer network. The forward pass computes a, h, z, p. The backward pass computes γ_2, γ_1 and the four gradient blocks. A second backward pass then sends $2(G - g)$ through every one of those steps back to x'. To check it, the script also estimates the slope by finite differences (nudge one pixel slightly and see how much R changes), and the two agree to within 1.2×10^{-10}.
4. **Optimization finds a stationary point, not necessarily the minimizer.** R is not convex in x': its surface can have dips and flat regions other than the true minimum. As the non-convex section of Optimization shows, for such a function a gradient method with a suitable step only guarantees that the slope $\|\nabla R\|$ goes to zero. That gives a **stationary point**, where the surface is flat, which may or may not be the global minimum. So success is an empirical question. The value of R at the end tells you which case you are in: $R = 0$ (up to rounding) means you found an exact match, while a value stuck well above zero means you got stuck.
5. **Uniqueness is plausible when equations outnumber unknowns.** Matching g imposes one equation per parameter: 2,212 here, against $64B$ unknown pixels. That is not a proof that the minimizer is unique, but with a single example the closed form of Section 14.3 shows that it is: the input is determined by the gradient.

14.5.4. Interpretation

DLG is a general recipe. All it needs is the ability to differentiate the gradient with respect to the input, which any automatic-differentiation library provides. So it works for convolutional networks and on real images, where no closed form exists: Zhu et al. recover CIFAR-100 pictures and text tokens from single-example gradients.

When it fails, it fails first as an optimization, not for lack of information. If the run ends with R far from zero, the attacker knows it has not found the input, and better optimizers, restarts from new random guesses, and image priors help. Geiping et al. (2020) made two changes. They replaced the squared distance by a cosine distance between gradients, which compares only the directions of the two gradients and ignores their lengths. And they added a total-variation penalty, the sum of differences between neighbouring pixels, which is small for natural images made of smooth regions. (This penalty is a measure of image roughness, not the total variation distance between distributions.) With these they recover recognizable images from trained networks and from batches.

Note what the attack does not need. The label search is gone, thanks to iDLG. And the server need not be malicious: it only computes on what it legitimately received.

Figure 14.3 shows one run.

14.5.5. Example: one image

The script starts from uniform noise and runs 600 steps of the Adam optimizer, a variant of gradient descent that scales each pixel's step by a running estimate of the size of that pixel's gradient, with learning rate 0.05 decaying linearly to 0. The label comes from Equation 14.9.

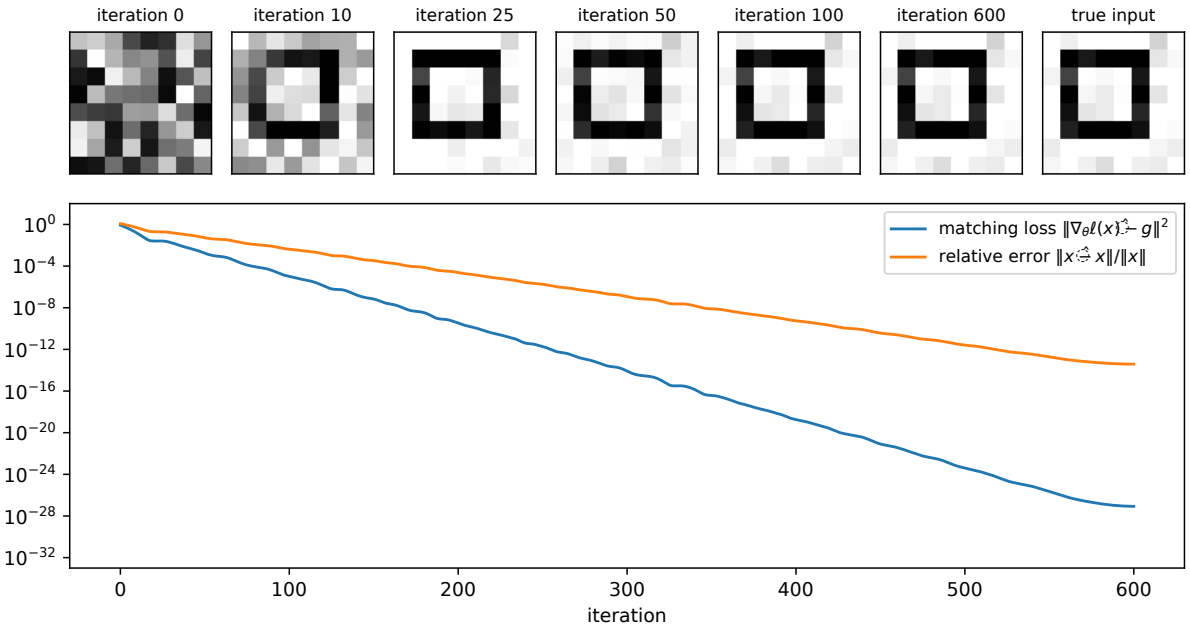

Figure 14.3.: Deep Leakage from Gradients on one 8×8 image, sigmoid network with 32 hidden units. Top: the reconstruction $\hat{x}$ at selected iterations of Adam, starting from uniform noise, and the true input. Bottom: the matching loss $R(\hat{x})$ and the relative error, on a log scale. Both fall geometrically until they reach rounding error.

Table 14.4.: Deep Leakage from Gradients on one image, sigmoid network with 32 hidden units: relative error of the reconstruction and the matching loss over the iterations.

Iteration	0	10	50	100	200	400	600
Relative error	1.6	0.67	7.5×10^{-2}	5.7×10^{-3}	3.4×10^{-5}	7.8×10^{-10}	5.8×10^{-14}
Matching loss R	1.3	0.20	2.5×10^{-3}	1.3×10^{-5}	4.6×10^{-10}	2.5×10^{-19}	1.3×10^{-27}

By iteration 50 the image is visually correct (7.5% error); by iteration 600 it is exact to about 13 digits. The matching loss falls about as the square of the error, and that is what you should expect close to the answer. Near the true input x, the gradient map G is nearly linear, so the mismatch is about the Jacobian times the error, $G(x') - g \approx J_G(x)(x' - x)$, and its squared length is quadratic in the error: $R \approx \|J_G(x)(x' - x)\|^2$. In the table, between iterations 50 and 100 the error shrinks by a factor $0.075/0.0057 \approx 13$ and R by $0.0025/0.000013 \approx 190$, close to $13^2 \approx 170$.

14.5.6. Check yourself

- The run ends with $R = 10^{-5}$ and a reconstruction that looks like a shape. Has the attack succeeded? *(Not certainly. At the true input $R = 0$, and in Table 14.4 $R = 1.3 \times 10^{-5}$ goes*

with an error below 1%, but a different input can also have small R. A loss that has stopped falling well above rounding error signals a stationary point that is not the input; restart from a new random guess.)

- Why does the attacker want the label before running DLG? *(With the label fixed, R depends on the input only. Searching jointly over a soft label adds a variable that interacts with every gradient entry through $p - e_y$, and Zhao et al. found that the joint search fails much more often.)*

14.6. Batches and averaging

14.6.1. Context

Clients rarely send the gradient of one example. They send the average over a batch, or the change in parameters after several local steps. Averaging is often said to protect the individual examples: the gradient now describes the batch, not anyone in it. This section measures that claim. Averaging does destroy the one-line formula of Equation 14.7, and it does make DLG harder, but three things survive: the span of the batch, every example that some unit "sees alone", and a search that still works for small batches.

14.6.2. Statement

Take a batch of B examples and a fully connected first layer, and write $\gamma_{1,i}$ for the backward signal of example i at that layer. Each claim below follows from the gradient being a sum of one outer product per example.

The gradient is a sum of B outer products, and its rows lie in the span of the batch. By Facts 1 and 3, averaging adds up the per-example outer products $\gamma_{1,i} x_i^\top$. Each of those has rows that are multiples of its own x_i, so every row of the sum is a weighted combination of the B inputs. It lies in their **span**, the set of all such combinations. And adding B rank-one matrices gives rank at most B:

$$\nabla_{W_1} \ell = \frac{1}{B} \sum_{i=1}^{B} \gamma_{1,i}\, x_i^\top, \qquad \operatorname{rank} \nabla_{W_1} \ell \le B, \qquad \text{every row} \in \operatorname{span}\{x_1, \dots, x_B\}. \tag{14.13}$$

Unit ratios are weighted averages. With one example, dividing row j by the bias entry cancelled a single scale. With a batch, row j is a sum of different inputs with different scales $\gamma_{1,ij}$, and the bias entry is the sum of those scales. The division gives each input a weight equal to its share of the total, so the result is a weighted average of the inputs. For a unit j with $(\nabla_{b_1} \ell)_j \neq 0$,

$$\frac{(\nabla_{W_1} \ell)_{j,:}}{(\nabla_{b_1} \ell)_j} = \sum_{i=1}^{B} \frac{\gamma_{1,ij}}{\sum_{i'} \gamma_{1,i'j}}\, x_i^\top, \tag{14.14}$$

which equals x_i exactly when only example i contributes, that is when $\gamma_{1,i'j} = 0$ for every $i' \neq i$. For ReLU this happens when unit j is switched on for example i only: unit j **isolates** example i.

How often an example is isolated. A unit isolates example i when it is on for i and off for every other example. Suppose each of the m ReLU units switches on for each example independently with probability $\frac{1}{2}$, like a fair coin. Then one unit isolates example i with probability 2^{-B}, the chance of one particular pattern of B coin flips. The example is missed only if all m units miss it, which has probability $(1-2^{-B})^m$. So each example of the batch is recovered exactly by some unit ratio with probability

$$P_{\text{iso}}(B, m) = 1 - (1 - 2^{-B})^m. \tag{14.15}$$

14.6.3. Derivation

1. **Sum of outer products.** By Fact 3 the batch gradient is the average of the per-example gradients, and by Fact 1 each of those is $\gamma_{1,i} x_i^\top$.
2. **Rank and span.** Stack the $x_i^\top$ as the rows of a matrix $X \in \mathbb{R}^{B \times d}$ and the $\gamma_{1,i}^\top$ as the rows of $\Gamma \in \mathbb{R}^{B \times m}$. Then the sum of outer products is a matrix product, $\nabla_{W_1} \ell = \frac{1}{B} \Gamma^\top X$. A product has rank at most that of either factor, and X has only B rows, so the rank is at most B. Row j is $\frac{1}{B} \sum_i \Gamma_{ij} x_i^\top$, a combination of the x_i, so it lies in their span.
3. **Ratios.** By step 1 and Fact 1, the bias gradient is $(\nabla_{b_1} \ell)_j = \frac{1}{B} \sum_i \gamma_{1,ij}$. Divide the j-th row by it. The factors $\frac{1}{B}$ cancel, and the weights $\gamma_{1,ij} / \sum_{i'} \gamma_{1,i'j}$ sum to 1 because they are each example's share of the same total. If only $\gamma_{1,ij}$ is nonzero, the weight on x_i is 1 and all the others are 0.
4. **One unit.** For ReLU, $\gamma_{1,i'j} = 0$ whenever unit j is off on $x_{i'}$, because the ReLU slope is 0 there (Fact 3). So unit j isolates example i if it is on for i (probability $\frac{1}{2}$) and off for each of the other $B-1$ (probability $\frac{1}{2}$ each, independently). Multiplying the B independent probabilities gives 2^{-B}. (An active unit also needs $(W_2^\top \gamma_{2,i})_j \neq 0$, which holds with probability 1 for random weights.)
5. **Many units.** The units are independent by assumption, so the probability that none of the m units isolates example i is the product of m factors $1 - 2^{-B}$, which is $(1-2^{-B})^m$. Subtracting from 1 gives Equation 14.15.
6. **When the independence assumption holds.** Suppose the first-layer bias is zero and the inputs are drawn from a distribution that is symmetric about zero, such as $\mathcal{N}(0, I)$. Unit j, whose weights are the row $(W_1)_{j,:}$, is on for x_i when $(W_1)_{j,:}\, x_i > 0$. Symmetry makes $(W_1)_{j,:}\, x_i$ equally likely to be positive or negative, and independent inputs make these signs independent across the batch. So each unit's on/off pattern over the batch is exactly a sequence of fair coin flips, and step 4 is exact. Different units look at the same inputs, though, so their patterns are not fully independent of each other, and step 5 is only approximate. Real data are not symmetric: images of the same kind are positively correlated, and Table 14.5 shows that this changes the answer substantially.

14.6.4. Interpretation

The formula is exponential in B and linear in m. A unit isolates a given example with probability 2^{-B}, so among m units the expected number that isolate it is $m2^{-B}$. With $m \gg 2^B$ almost every example is isolated; with $m \ll 2^B$ almost none is. To find the width that gives an even chance, set the miss probability $(1-2^{-B})^m$ to at most $\frac{1}{2}$ and take logs: $m \ln(1-2^{-B}) \leq -\ln 2$, so $m \geq \ln 2 / (-\ln(1-2^{-B}))$. At $B = 10$ this is $\ln 2 / (-\ln(1-2^{-10})) = 0.6931 / 0.000977 \approx 709.4$,

so you need $m \geq 710$ units. Real first layers have thousands of units, so batches of 10 are not safe from this attack.

Correlated data are easier for the attacker, not harder. With images, a unit tends to fire on many examples of a batch or on few: the number of examples it fires for is more spread out than the coin-flip model predicts (statisticians call this **overdispersion**), instead of concentrating around $B/2$. Units that fire on just one example are then much more common at large B, and isolation decays much more slowly than 2^{-B}. Exercise 5 in the exercise book works out one extreme model, in which each unit has its own firing rate ρ, drawn uniformly between 0 and 1, and fires on each example with that probability. Averaging the isolation probability $\rho(1-\rho)^{B-1}$ over ρ gives $1/(B(B+1))$ per unit, which shrinks only like $1/B^2$ instead of halving with each extra example.

The span leaks even when nothing is isolated. By Equation 14.13, the server learns the B-dimensional subspace that contains the batch. For $B \ll d$ that already rules out almost every input, since every example must be a combination of B known directions.

A malicious server does better still. The analysis above assumes random weights, as an honest server would send. A server that chooses θ can plant first-layer units that fire on rare inputs only ("trap weights", Boenisch et al. 2023), or that sort inputs into bins by a feature such as brightness (Fowl et al. 2022), so that most examples of even a large batch are isolated by construction.

DLG on batches has a harder search to do: it must untangle B inputs from one sum. In the experiments below it always recovers single examples, usually recovers pairs, and mostly fails beyond that, with the matching loss stuck well above zero. That is an optimization failure, not a shortage of information: at $B = 4$ there are $64 \cdot 4 = 256$ unknown pixels against 2,212 equations.

Finally, several local steps do not help either. If the client takes several SGD steps on its batch and sends the total change in parameters, every step's first-layer gradient is made of outer products with the same inputs x_i, and only the backward signals change from step to step. So for one example the change in W_1 is still a multiple of $x^\top$ in every row, still rank one, and Equation 14.7 still recovers x exactly (Exercise 6 in the exercise book).

14.6.5. Example: what a batch hides

Rank and isolation in one batch. A batch of 4 images through the 32-unit ReLU network gives a first-layer gradient whose singular values (the sizes of the matrix along its independent directions), relative to the largest, are 1.0, 0.84, 0.69, 0.039 and then 1.5×10^{-16}. Four directions are nonzero and the rest are rounding error: rank 4, as Equation 14.13 says. Every row lies in the span of the four images to within 4.6×10^{-16}. The unit ratios recover all 4 of the 4 images exactly. For comparison, Equation 14.15 with $B = 4$ has $1 - 2^{-4} = 15/16$ and predicts $1 - (15/16)^{32} = 1 - e^{32\ln(15/16)} = 1 - e^{-2.065} = 0.873$ per example under independence.

Isolation against batch size. Table 14.5 compares Equation 14.15 with simulation, 20 random networks and batches per cell (see Figure 14.4 for the full range).

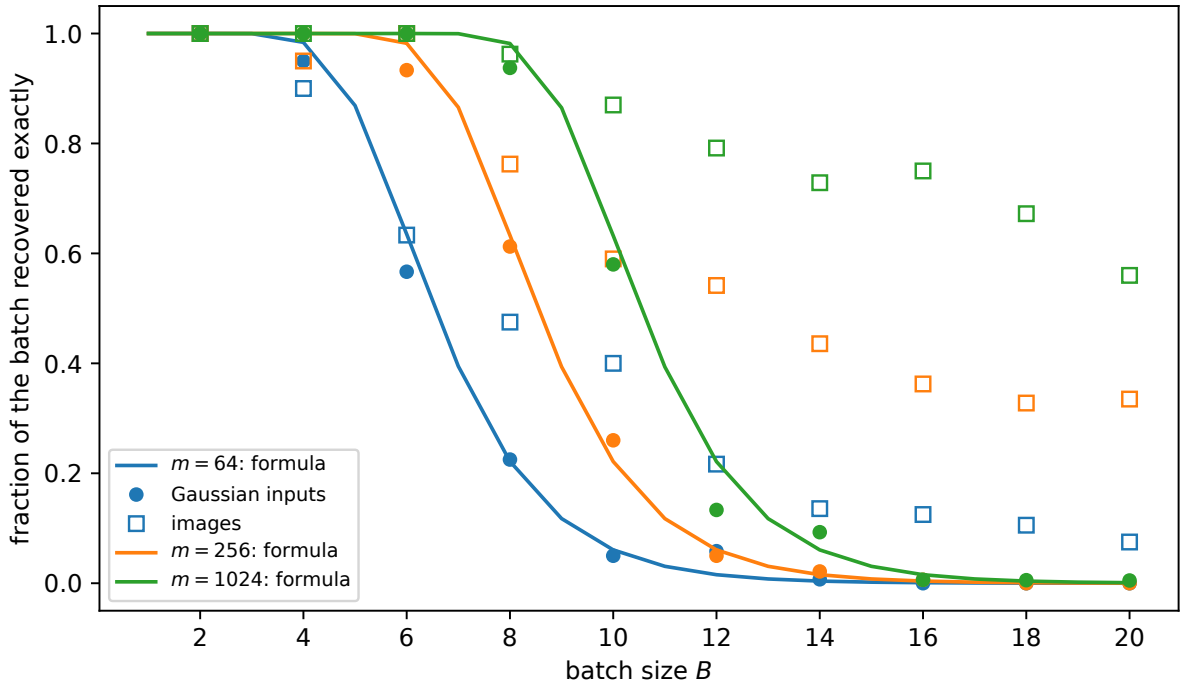

Figure 14.4.: Fraction of a batch recovered exactly by first-layer unit ratios, for ReLU networks with $m = 64$, 256 and 1024 hidden units. Lines: Equation 14.15. Filled circles: Gaussian inputs and zero first-layer bias, where each unit's on/off pattern is a sequence of fair coin flips. Open squares: the 8×8 images, which are correlated, so units fire on many or few of them and isolation decays much more slowly.

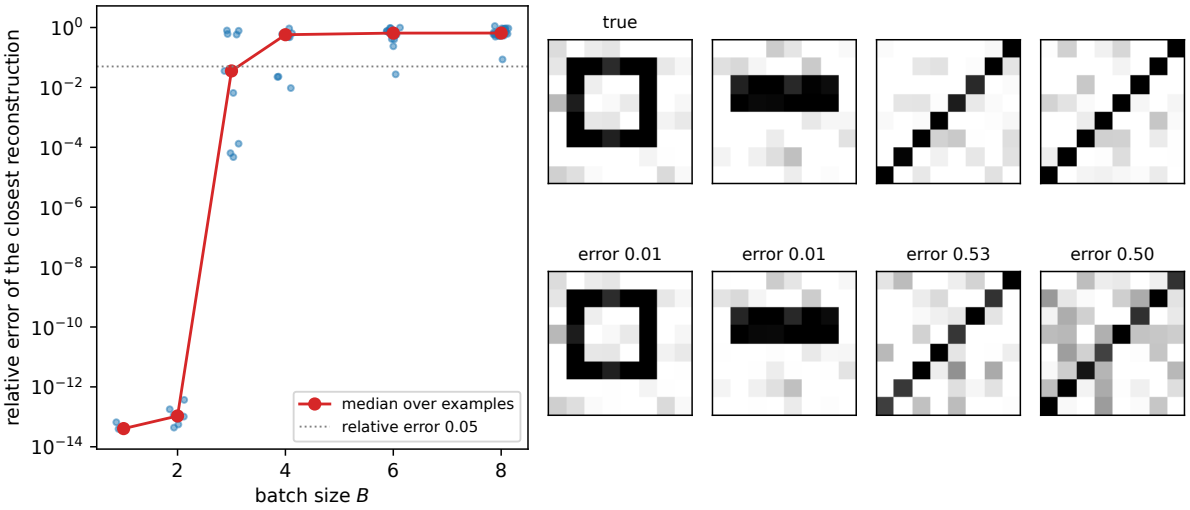

Figure 14.5.: Deep Leakage from Gradients against batch size, sigmoid network with 32 hidden units. Left: relative error of the closest reconstruction for every example (dots) and the median (red), on a log scale; the dotted line marks an error of 0.05. Right: a batch of 4, true images (top) and their closest reconstructions (bottom). Some examples are recovered and others are blends.

Table 14.5.: Fraction of batch examples recovered exactly from first-layer unit ratios of a random ReLU network, against Equation 14.15.

m	B	Equation 14.15	Gaussian inputs	Images
64	4	0.984	0.975	0.838
64	8	0.222	0.188	0.550
64	16	0.001	0.000	0.144
256	8	0.633	0.562	0.769
256	12	0.061	0.046	0.542
256	16	0.004	0.006	0.375
1024	12	0.221	0.196	0.850
1024	16	0.016	0.009	0.691

For Gaussian inputs the formula matches to within the simulation noise. It usually overestimates slightly (in seven of the eight rows), because units share inputs and so their on/off patterns are not fully independent (step 6 of the derivation). For images the formula is far too reassuring about privacy. At $B = 16$ it predicts that 1.6% of the batch is exposed in the 1024-unit network; 69.1% is.

At $B = 4$, by contrast, the images are recovered less often than the formula predicts (0.838 against 0.984 for $m = 64$). Overdispersion cuts both ways. The same spread that makes "on for exactly one image" more common at large B also makes "on for all four images" and "on for none" common at small B, and units like that isolate nothing.

DLG against batch size. Table 14.6 runs DLG on 6 random networks and batches for each batch size.

Table 14.6.: Deep Leakage from Gradients on batches, sigmoid network with 32 hidden units, 600 Adam steps, 6 trials per batch size.

B	Median relative error	Examples recovered (error < 0.05)	Median final matching loss
1	0.000	1.00	1.5×10^{-27}
2	0.000	0.67	1.3×10^{-27}
4	0.363	0.29	3.3×10^{-5}
8	0.711	0.00	7.7×10^{-5}

Batches of one and two are recovered to rounding error in most runs. From $B = 4$ the median run gets stuck: the matching loss stalls near 10^{-5}, many orders of magnitude above the 10^{-27} of a successful run, and the reconstructions are blends of the batch (Figure 14.5). Averaging has made the search harder, not the information smaller: there are still 2,212 equations, and on a ReLU network of the same width the closed-form isolation attack recovered all four images of a batch of 4 (above).

14.6.6. Check yourself

- A first layer has $m = 4096$ ReLU units and the batch size is 8. Under the independence model, what fraction of the batch is exposed? *(A unit isolates a given example with probability* $2^{-8} = 1/256$*, so the expected number of isolating units per example is* $4096/256 = 16$*, and* $P_{iso} = 1 - (1 - 1/256)^{4096} \approx 1 - e^{-16}$*: essentially the whole batch.)*
- Why does the span of the batch, revealed by Equation 14.13, matter if the attacker cannot tell which direction is which example? *(Each example is a combination of* B *known basis vectors, so any further search, such as DLG, has* B *unknowns per example instead of* d*: 4 instead of 64 here, and 4 instead of hundreds of thousands for real images.)*

14.7. Code: check every attack by computation

The script code/gradient_inversion.py computes every number in this chapter and draws every figure. The network, its forward and backward passes and the hand-written double backpropagation for DLG are small typed functions; the attacks call them, and the figures loop over them. From the repository root:

```
uv run python code/part02-attacks/gradient_inversion.py
```

It takes about half a minute. **Output** (seed 0), summarized in Table 14.7:

Table 14.7.: The script's output with the default seed.

Experiment	Result
Hand example (Table 14.2)	$p = (0.3441, 0.6559)$, $\gamma_1 = (-0.3279, 0.9838)$; both unit ratios give $(0.5, 1, 0.2)$; $\nabla_{b_2}\ell = (-0.6559, 0.6559)$, label 1 (the first class; index 0 in the script)
Exact recovery, one image, ReLU, $m = 32$	13 usable units of 32; largest relative error 6.7×10^{-17}; $s_2/s_1 = 9.5 \times 10^{-17}$; 2,212 gradient entries for 64 pixels
Labels, one example, 1,000 trials	Bias rule 1.000; weight rule 1.000
Label counts, all exact, 200 batches	Averaged guess: $B = 4$: 1.000, $B = 16$: 0.975, $B = 64$: 0.525. Uniform guess: 0.925, 0.095, 0.000
DLG, one image (Table 14.4)	Relative error 5.8×10^{-14} after 600 steps; matching loss 1.3×10^{-27}
Double backpropagation against finite differences	Largest gap 1.2×10^{-10}
DLG on batches (Table 14.6)	Recovered: $B = 1$: 1.00, $B = 2$: 0.67, $B = 4$: 0.29, $B = 8$: 0.00
Batch of 4, ReLU	Rank 4; rows in the span to 4.6×10^{-16}; 4 of 4 images isolated

Experiment	Result
Isolation (Table 14.5)	Formula matches Gaussian inputs; images exposed far more at large B
Width for isolation probability $\frac{1}{2}$ at $B = 10$	710

In the table, s_1 and s_2 are the two largest singular values of the first-layer gradient, so their ratio measures how far the gradient is from rank one. tests/test_gradient_inversion.py checks that the output still matches.

What to take from it. Three things stand out. First, the closed forms are exact: unit ratios and the bias rule for labels are right to rounding error, every time, whatever the network does above the first layer, because everything above only rescales the rows that the division removes. Second, search works when the closed form is missing: DLG recovers single images to about 13 digits, and the final matching loss tells the attacker whether it has succeeded. Third, batching is not a defence. It weakens DLG on this toy, but the label histogram, the span of the batch and every isolated example still come out exactly, and real data are isolated far more often than the independence model predicts.

14.9. Cheat sheet

Network $a = W_1 x + b_1$, $h = \sigma(a)$, $z = W_2 h + b_2$, $p = \mathrm{softmax}(z)$, $\ell = -\ln p_y$; backward signals $\gamma_2 = p - e_y$ and $\gamma_1 = (W_2^\top \gamma_2) \odot \sigma'(a)$. The client sends g, the gradient of its average loss over B examples. Table 14.8 collects the results.

Table 14.8.: Every result in this chapter.

Result	Formula	Needs	Fails when
Outer product (Fact 1)	$\nabla_W \ell = \gamma x^\top$, $\nabla_b \ell = \gamma$	A fully connected layer	—
Exact recovery, one example	$x = (\nabla_{W_1} \ell)_{j,:} / (\nabla_{b_1} \ell)_j$	First layer fully connected with bias	Convolutional first layer; batches (partly)
Label, one example	$y = \arg\min_k (\nabla_{b_2} \ell)_k$; or the non-positive row of $\nabla_{W_2} \ell$ when $h \geq 0$	Softmax and cross-entropy	p_y rounds to 1
Label counts, batch	$n_k = \sum_i p_{ik} - B(\nabla_{b_2} \ell)_k$	Last-layer bias; a guess of $\sum_i p_{ik}$	Large B with a poor guess of $\sum_i p_{ik}$
Deep Leakage from Gradients	$\min_{x'} \lVert G(x') - g \rVert^2$ by gradient descent	Twice-differentiable network; labels	Optimizer stuck (final $R \gg 0$), larger batches
Span of a batch	$\mathrm{rank}\, \nabla_{W_1} \ell \leq B$, rows in $\mathrm{span}\{x_i\}$	Fully connected first layer	—
Isolation, batch	$P_{\text{iso}} = 1 - (1 - 2^{-B})^m$ under independence	ReLU units, random weights	$m \ll 2^B$ for symmetric data; much slower decay for real data

Rules of thumb

- A gradient is a sum of outer products of backward signals with forward inputs. Any layer whose input you can isolate, you can read.
- One example, a fully connected layer with a bias: the input costs one division. The label costs one sign.
- When there is no closed form, match gradients. The final matching loss tells you whether it worked.
- Batching helps against search but not against structure. The label histogram and the span of the batch always leak, and examples isolated by a single unit leak exactly; with real data that is most of them for batches of 10 or more on wide layers.
- An honest server can already do all of this. A malicious server that chooses the weights can do it for large batches by design.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

15. Linkage and re-identification

15.1. Why this matters

A hospital wants to share its discharge records with researchers. It deletes the names, the addresses and the insurance numbers, and keeps what the research needs: postcode, date of birth, sex, diagnosis. Nobody's name is in the file. Is anyone in it identifiable?

Usually, yes. Most people are the only person with their combination of postcode, birth date and sex. Anyone who holds a second table with names and those same three columns, such as a voter roll, can join the two tables and put a name back on most rows. This is a **linkage attack**, and putting a name back on a "de-identified" record is **re-identification**. It needs no model, no gradients and no queries: only a release and some auxiliary data about the people in it. The other chapters of this part attack trained models. This one attacks the data itself, and it explains why removing names was never the same as anonymizing.

Before those questions comes a shortcut that fails for a simpler reason: replacing each name by a code, or pseudonym, such as a hash of an identifier. The chapter shows that a hash of a guessable identifier can be undone by trying every value, and that even a code nobody can undo ties a person's records together. The chapter then follows three questions, each building on the one before. The first is how many people are unique on a given set of attributes, and how you can predict that number without having the data. Once that is answered for tidy tables, the second question is what happens when the data are high-dimensional and sparse, like movie ratings or shopping baskets, so that no record matches the adversary's information exactly. The third is whether releasing only a sample helps, since a record that is unique in the sample need not be unique in the population.

15.1.1. The one idea: identifying information is measured in bits, and bits add up

Picking one person out of n takes $\log_2 n$ bits of information, because each bit halves the number of candidates and you need to halve n down to 1. That is 27.9 bits for the 248.7 million people in the United States in 1990, and 32.9 bits for 8 billion people. Each attribute you learn about someone carries some bits too: an attribute with v equally likely values is worth $\log_2 v$ bits. A sex is worth $\log_2 2 = 1$ bit, a birth month $\log_2 12 \approx 3.6$, and a birth date in a span of 80 years, one of $365 \times 80 = 29{,}200$ days, about $\log_2 29{,}200 = 14.8$. For independent attributes, the bits add: the chance of a given combination is the product of the chances of its values, and the logarithm turns that product into a sum. **Once the bits of the attributes you know exceed $\log_2 n$ by a few, almost everyone is unique.** Every result in this chapter makes that sentence precise: the expected fraction of unique people as a function of the bits (Section 15.5), the score that adds up bits from rare movie ratings (Section 15.6), and the correction for a sample (Section 15.7).

Table 15.1 lists the results and where each is used.

Table 15.1.: The results of this chapter and where each is used.

Result	Where it is used
Linkage success is the number of distinct quasi-identifier combinations over n	Scoring a release against an adversary who knows who is in it
Inverting a hashed identifier costs N hashes, $\log_2 N$ bits	Why hashing names, licence or phone numbers is not anonymization
Expected fraction unique, $\sum_c p_c(1-p_c)^{n-1}$	Predicting re-identification risk from a model of the population
Uniform cells: $e^{-n/K}$, a single curve in bits minus $\log_2 n$	The "33 bits" rule and its correction
Collision lower bound $(1-\sum_c p_c^2)^{n-1}$	A guaranteed uniqueness rate from marginals alone
Concentration of the fraction unique (McDiarmid)	Why one sample of the population is enough
Narayanan–Shmatikov score as a likelihood ratio	De-anonymizing sparse data with noisy auxiliary information
Eccentricity and its false-match rate	Deciding when the best match is the right one
Correctness of a match in a sample, $1/(1+\lambda(1-q))$ and $e^{-\lambda(1-q)}$	Why releasing a small sample does not protect the people in it

What you need. Every outside fact this chapter uses is restated where it is used; these links are for more detail. Entropy, the chain rule and the conversion between probabilities and bits are in Information theory. The binomial and Poisson distributions, and Poisson thinning (Exercise 2 in the exercise book of that chapter), are in Probability distributions. McDiarmid's inequality is in Concentration. The Neyman–Pearson lemma, the Bayesian view of a test, and why you should read a curve of true against false positive rates at small false positive rates are in Hypothesis testing. The birthday bound is in Cryptography basics. The vocabulary of adversaries, auxiliary knowledge and games is in Threat models.

Notation. A population has n people. Each person has a combination of attribute values, their **cell**. Under the model of the population, a person falls in cell c with probability p_c, independently of everyone else. There are K cells. A person is **unique** when nobody else is in their cell. U is the number of unique people. Logarithms are base 2 when the unit is bits and natural otherwise.

15.2. Toolkit: three facts every derivation uses

15.2.1. Fact 1 — Counting with indicators

To find how many people are unique on average, you do not need the distribution of U. Give each person a counter, an **indicator**, that is 1 if that person is unique and 0 otherwise. U is the sum of these counters, $U = \sum_{i=1}^{n} \mathbf{1}[\text{person } i \text{ is unique}]$. The average of a sum is the sum of the averages, and the average of a 0/1 counter is the probability that it is 1. So

$$\mathbb{E}U = \sum_{i=1}^{n} \Pr[\text{person } i \text{ is unique}]. \tag{15.1}$$

The rule "the average of a sum is the sum of the averages" is **linearity of expectation**, and it holds even when the terms depend on each other. Here they do: knowing that person 1 is unique changes the chance that person 2 is. Linearity does not care, because it only adds up how often each counter is 1, outcome by outcome. Walk through the smallest case to see it: $n = 3$ people, $K = 2$ equally likely cells A and B, so 8 equally likely outcomes (Table 15.2).

Table 15.2.: Three people, two equally likely cells: who is unique in each of the 8 outcomes.

Cells of (person 1, 2, 3)	`AAA`	`AAB`	`ABA`	`BAA`	`ABB`	`BAB`	`BBA`	`BBB`
Unique people	none	3	2	1	1	2	3	none
U	0	1	1	1	1	1	1	0

Directly, six of the eight outcomes have $U = 1$, so $\mathbb{E}U = 6/8 = 0.75$. Through the indicators, person 1 is unique when persons 2 and 3 are both in the other cell, which happens with probability $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$; the same holds for each person, so $\mathbb{E}U = 3 \times \frac{1}{4} = 0.75$. The two counts agree. This chapter uses the same move for the expected number of unique people, of sample uniques, and of false matches.

15.2.2. Fact 2 — $(1-p)^k$ is e^{-pk}, up to a factor you can bound

The question "does each of the other k people avoid my cell?" has the answer $(1-p)^k$ when each avoids it with probability $1-p$. Powers like this are awkward, and an exponential is easier to read: $(1-p)^k$ is close to e^{-pk} when p is small, because $1-p$ is close to e^{-p} for small p. The fact pins down how close, with bounds on both sides. For $0 \le p < 1$ and $k \ge 0$,

$$e^{-pk/(1-p)} \le (1-p)^k \le e^{-pk}. \tag{15.2}$$

To prove it, take logarithms, so that $(1-p)^k$ becomes $k\ln(1-p)$ and the claim becomes $-\frac{p}{1-p} \le \ln(1-p) \le -p$. Both sides come from one inequality, $\ln x \le x - 1$ for all $x > 0$, which holds because ln is concave and $x - 1$ is its tangent line at $x = 1$, and a concave curve lies below its tangents. With $x = 1 - p$ it gives the upper bound $\ln(1-p) \le -p$. With $x = \frac{1}{1-p}$ it gives $\ln \frac{1}{1-p} \le \frac{1}{1-p} - 1 = \frac{p}{1-p}$, and flipping the sign gives the lower bound $\ln(1-p) \ge -\frac{p}{1-p}$. The two bounds differ only by the factor $\frac{1}{1-p}$ in the exponent, which is close to 1 when p is small.

To see how tight this is, take $p = 10^{-4}$ and $k = 9999$. Then $pk = 0.9999$ and $pk/(1-p) = 0.9999/0.9999 = 1$, and $(1-p)^k = 0.36790$ sits between the lower bound $e^{-pk/(1-p)} = e^{-1} = 0.36788$ and the upper bound $e^{-pk} = e^{-0.9999} = 0.36792$. This is how the chapter turns "every one of the other $n-1$ people avoids my cell" into e^{-np}.

15.2.3. Fact 3 — Probabilities multiply, bits add

If attributes $A_1, \dots, A_k$ are independent, the probability of a cell is the product of the probabilities of its values, $p_c = \prod_j p_j(c_j)$, where $p_j(c_j)$ is the probability that attribute j takes the value c_j that the cell has. Three quantities that this chapter uses follow from that one product.

The **surprisal** of a cell, $\log_2(1/p_c)$, is the number of bits it takes to single out that cell: a cell with probability 2^{-10} has a surprisal of 10 bits. Since the logarithm of a product is the sum of the logarithms, surprisal adds up over attributes, $\log_2(1/p_c) = \sum_j \log_2(1/p_j(c_j))$.

The **entropy** is the average surprisal, $H = \sum_c p_c \log_2(1/p_c)$: how many bits a typical person's cell carries. Averaging the sum above term by term, it adds up too, $H(A_1, \dots, A_k) = \sum_j H(A_j)$. This is the chain rule of Information theory, which says that the entropy of a pair is the entropy of the first plus that of the second given the first, in the special case where knowing the first tells you nothing about the second.

The **collision probability** $\sum_c p_c^2$ is the chance that two independent people land in the same cell: both land in cell c with probability $p_c \cdot p_c$, and you add over cells. It multiplies over attributes, because two people share a cell exactly when they share the value of every attribute, and for independent attributes those agreements are independent events. In symbols, $\sum_c \prod_j p_j(c_j)^2 = \prod_j \sum_v p_j(v)^2$, which you can check by expanding the product of sums on the right: each term of the expansion picks one value for each attribute, that is, one cell.

Real attributes are not independent (age and number of children, ZIP code and income), and then the pair carries fewer bits than the sum of their separate bits, because part of what the second attribute says was already said by the first. The sum is therefore an upper bound on the joint entropy, and adding up bits overstates how identifying correlated attributes are.

15.3. Quasi-identifiers and the linkage attack

15.3.1. Context

Data protection practice sorts the columns of a table into three kinds. **Direct identifiers** name a person on their own: name, social security number, email address. **Sensitive attributes** are what the release is about and what must not be tied to a person: a diagnosis, a salary. **Quasi-identifiers** are everything in between: attributes that do not name anyone alone but that, combined, often single out one person, and that also appear in other datasets with names attached. ZIP code, birth date and sex are the classic example. Removing direct identifiers and keeping quasi-identifiers is the most common form of "de-identification", and the linkage attack is what breaks it. This section asks how often the attack names the right record.

15.3.2. Statement

The linkage attack. The release R holds records (quasi-identifiers, sensitive attribute). The adversary holds an auxiliary table with (name, quasi-identifiers), for example a voter roll. For each name, it finds the records of R with the same quasi-identifiers and picks one of them uniformly at random.

The game. In the language of Threat models, an attack is scored by a game. A challenger draws a target uniformly from the n people in R and gives the adversary the target's quasi-identifiers. The adversary wins if it outputs the target's record. Group the records of R into **equivalence classes**, sets of records with identical quasi-identifiers, with sizes $k_1, \dots, k_J$; there are J classes, one per distinct combination. A target alone in its class is found for sure, and a target in a class of k look-alikes is found one time in k. A class of k records is therefore hit k times as often as a single record but won only a $1/k$ share of those times, so each class contributes the same amount, one record's worth, to the wins. Averaging over the target gives the success probability of the linkage attack,

$$\Pr[\text{win}] = \frac{1}{n} \sum_{j=1}^{J} k_j \cdot \frac{1}{k_j} = \frac{J}{n} : \tag{15.3}$$

the number of distinct quasi-identifier combinations divided by the number of records. No adversary that sees only the quasi-identifiers can do better.

Sweeney's measurement. Sweeney (2000) estimated from 1990 census tables that 87% of the US population, 216 of 248 million people, were likely unique on {5-digit ZIP code, date of birth, sex}. On {city, date of birth, sex} the figure was 53%, and on {county, date of birth, sex} 18%.

15.3.3. Derivation

The idea is to fix the class the target falls in, find the best guess within it, and then average over classes.

1. **Condition on the target's class.** A target in a class of size k_j shares its quasi-identifiers with $k_j - 1$ other records. To an adversary who sees only quasi-identifiers, those records look the same as the target's. Picking one of the k_j at random wins with probability $1/k_j$.
2. **Show that nothing beats this.** Within a class, the target is equally likely to be any of the k_j records, because it was drawn uniformly and the records differ only in their sensitive attribute, which the adversary does not know. So every guess within the class wins with probability exactly $1/k_j$, and a guess outside the class never wins, since a record there has different quasi-identifiers from the target.
3. **Average over the target.** The target lands in class j with probability k_j/n, the share of records in that class. Weighting each class's win probability by how often the target lands in it gives $\Pr[\text{win}] = \sum_j \frac{k_j}{n} \cdot \frac{1}{k_j} = \frac{J}{n}$.

15.3.4. Interpretation

For this adversary, uniqueness is the whole story. A unique record is re-identified with certainty and a record in a class of 2 with probability $\frac{1}{2}$. Each unique record adds a full win and no class adds more, so the fraction of unique people is a lower bound on the success, and the success is at most 1. That is why the next section is about predicting uniqueness.

The game assumes the adversary knows the target is in the release, as a curious neighbour or an insurer with a list of patients might. Without that knowledge, a unique match in the release may

belong to someone else who happens to share the quasi-identifiers but is not in R. Whether that uncertainty protects anyone is the question of Section 15.7.

Re-identification is also not the only harm. If all records of a class share one diagnosis, the adversary learns the diagnosis without knowing which record is the target's. In the other direction, Equation 15.3 shows that a release in which every class has at least k records keeps the linkage success at most $1/k$: each class then contributes one win for at least k records, so $J \leq n/k$. That guarantee holds against this adversary only. Syntactic anonymity and how it breaks studies such releases and the attacks on the sensitive attribute that they leave open.

15.3.5. Example: one hospital release, one voter roll

Table 15.3 is a hospital release with names removed, and Table 15.4 part of a public voter roll.

Table 15.3.: A de-identified hospital release: no names, three quasi-identifiers, one sensitive attribute.

ZIP code	Birth date	Sex	Diagnosis
02138	1961-03-14	F	asthma
02138	1972-11-02	M	diabetes
02138	1972-11-02	M	hypertension
02139	1958-06-21	F	depression
02139	1990-01-01	F	migraine
02139	1990-01-01	F	asthma
02139	1990-01-01	F	fracture
02141	1983-09-30	M	pneumonia

Table 15.4.: Part of a voter roll: names with the same three quasi-identifiers.

Name	ZIP code	Birth date	Sex
Ana Silva	02138	1961-03-14	F
Ben Cole	02138	1972-11-02	M
Carla Diaz	02139	1958-06-21	F
Dan Eto	02141	1983-09-30	M

Joining on the three columns gives Ana's asthma, Carla's depression and Dan's pneumonia with certainty, because each of them matches exactly one record. Ben matches two records, so the adversary gets diabetes or hypertension and is right with probability $\frac{1}{2}$. The release has classes of sizes 1, 1, 1, 2 and 3, so $J = 5$ classes for $n = 8$ records, and Equation 15.3 gives a success of $5/8 = 0.625$ for a target drawn from the release.

This is, in miniature, how Sweeney re-identified the governor of Massachusetts in the late 1990s. The state's Group Insurance Commission had released hospital records of about 135,000 state employees and their families without names. Sweeney bought the Cambridge voter roll for twenty dollars. Six people on it shared the governor's birth date, three of them were men, and only one of those lived in his ZIP code. Barth-Jones (2012) later pointed out that the governor was an

easy target in one respect: his hospital stay had been in the news, so the adversary knew he was in the release, the assumption of the game above. For an ordinary person, whom nobody knows to be in the data, a unique match is less certain, which is the question Section 15.7 takes up.

In bits (Figure 15.1). Now count the bits of Sweeney's three attributes, treating each as uniform over its values, which gives an upper bound. There are about 40,000 ZIP codes, $365 \times 80 = 29{,}200$ birthdays in about 80 birth years, and two sexes, so the three attributes carry at most $\log_2 40{,}000 + \log_2 29{,}200 + 1 = 15.3 + 14.8 + 1.0 = 31.1$ bits, against $\log_2(248.7 \times 10^6) = 27.9$ bits needed to single out one American. The same count in cells: there are $K = 40{,}000 \times 29{,}200 \times 2 = 2.34 \times 10^9$ cells for $n = 248.7$ million people, so $n/K = 0.106$ people per cell. If everyone fell into a uniformly random cell, the next section shows that a fraction $e^{-n/K} = e^{-0.106} = 0.899$ would be unique. Sweeney's 87% is a little lower because people are not spread uniformly: ZIP codes range from a few residents to tens of thousands, and birth years are not equally common, so people crowd into the popular cells. Golle (2006) repeated the estimate with the 2000 census and found 63%. Both estimates have to model how birth dates spread within the age groups that census tables publish, and the answer is sensitive to that modelling.

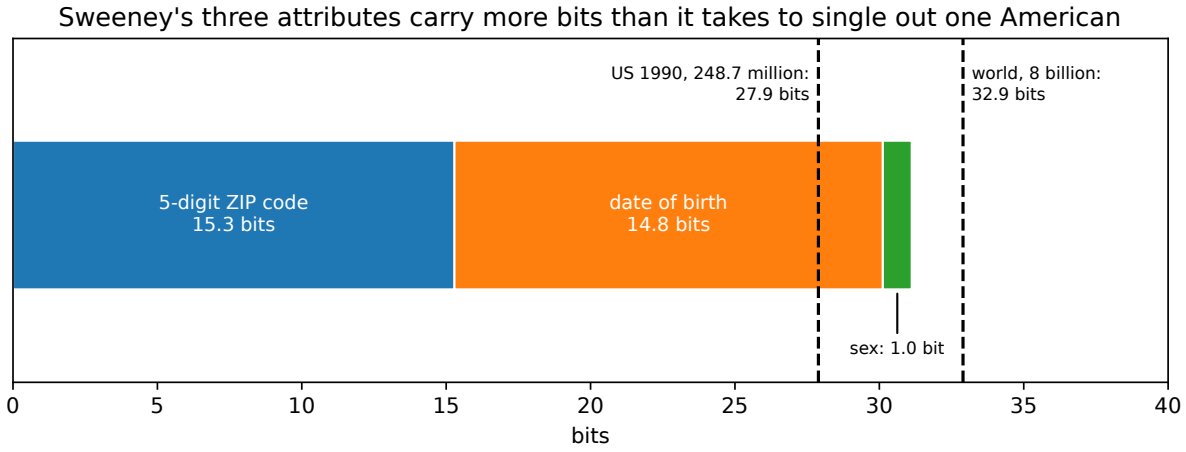

Figure 15.1.: The three classic quasi-identifiers, in bits, against the bits needed to single out one person in the US population of 1990 and in the world population. The bits are upper bounds that treat each attribute as uniform over its values.

15.3.6. Check yourself

- A release of 1,000 records has 900 distinct quasi-identifier combinations. What is the linkage success for a target drawn from the release, and what is the smallest possible number of unique records? *(0.9 by Equation 15.3. At least 800: with s singletons, the other $900 - s$ classes hold at least 2 records each, so $s + 2(900 - s) \leq 1000$, that is $s \geq 800$, attained with 100 pairs.)*
- Why does it not matter for Equation 15.3 what the sensitive attribute is? *(The adversary chooses only from the quasi-identifiers. The sensitive attribute is what it learns after winning, not what it uses to win.)*

15.4. Pseudonyms and hashed identifiers

15.4.1. Context

A common alternative to deleting an identifier is to replace it by a **pseudonym**, a code that stays the same for every record of one person. Analysts can then still follow that person through the data. A popular way to make the code is to apply a cryptographic hash function, such as the widely used MD5, to the identifier. A hash is easy to compute and hard to invert, and the same input always gives the same output. The hope is that the code hides who the person is while keeping their records together. This section shows that the code fails at the first goal, hiding who the person is, in two separate ways. A hash of an identifier drawn from a small set can be inverted by trying every member of the set. And even a pseudonym nobody can invert still ties all of a person's records together, so linking one of them to the person links them all.

15.4.2. Statement

Inverting a hash by enumeration. Suppose the format of the identifiers is public, so that the adversary can list every possible value, say N of them, and suppose the release replaces each identifier by its hash under a public function with no secret key. The adversary computes the hash of all N values and keeps a table from each hash back to its identifier. It can then look up the identifier behind every pseudonym in the release. It needs N hash computations, done once for the whole release. So the attack costs $N = 2^{\log_2 N}$ hashes, whatever the hash function. Hashing protects the identifier only as well as its $\log_2 N$ bits of guessing work do.

Linking through one record. Suppose instead that each person gets a random pseudonym, or a **keyed hash**, which mixes a secret key into the hash so that only the key holder can compute it. Then nobody else can invert the pseudonym. The adversary may know enough about one of a person's records to tie it to the person. It then learns that person's pseudonym, and with it every record carrying that pseudonym. As Section 15.5 will count, one record is usually enough when its quasi-identifiers carry more bits than $\log_2$ of the number of records in the release.

15.4.3. Derivation

1. **The hash is a fixed function.** With no secret key, the hash of an identifier x is $h(x)$ for a public function h that anyone can compute. So the set of possible pseudonyms is $\{h(x) : x \text{ in the set of identifiers}\}$, and the adversary can list it in full with N computations.
2. **Distinct identifiers almost surely get distinct pseudonyms.** A collision, two identifiers with the same hash, would make the lookup ambiguous. Suppose the hash behaves like a random function, which is what a cryptographic hash is designed for. Then, for a 128-bit hash such as MD5 and N in the millions, the birthday bound of Cryptography basics puts the chance of any collision below $N^2/2^{129}$, which is negligible. So each pseudonym in the release maps back to exactly one identifier.
3. **Being hard to invert does not help.** A cryptographic hash is hard to invert only in the sense that no attack does better than guessing inputs. That protects an unpredictable input, such as a long random password, but here guessing costs only N evaluations.

4. **A consistent pseudonym is a join key**, a column on which records can be matched. A pseudonym that is the same on every record of one person groups those records exactly. Learning the pseudonym of any one record therefore identifies the whole group, and the cost of learning it is the cost of re-identifying one record, which the other sections of this chapter measure.

15.4.4. Interpretation

Hashing protects only identifiers that are already hard to guess. Phone numbers, licence numbers and national identity numbers all come from sets of a few million to about ten billion values, between about 20 and 33 bits. A laptop hashes millions of values per second, so it lists any of these sets in seconds to hours. A secret key turns the hash into a keyed hash, which closes the enumeration attack as long as the key stays secret, but it does nothing against the second failure.

The second failure is the one that matters for any pseudonymized release. A pseudonym keeps the rows of one person together, which is the reason to use it, and that makes each person's set of rows one long record. As Section 15.6 will show for movie ratings, a long record of a person's actions is identifying, and a single known action can be enough to find it.

15.4.5. Example: the New York City taxi release

In 2014 a freedom-of-information request obtained every New York City taxi trip of 2013, and the requester published them. That is about 173 million trips, with pickup and drop-off times and places, fares and tips. Each taxi's medallion number, the permit that lets a cab operate, and each driver's licence number had been replaced by its MD5 hash. Readers of the data soon found one hashed licence that seemed to earn thousands of dollars a day. The chapter's script confirms that its code, `cfcd208495d565ef66e7dff9f98764da`, is the MD5 of the string "0". That string was the placeholder for a missing licence, so the code pooled the trips of many drivers. That match also showed that the codes were plain MD5 hashes with no key.

Vijay Pandurangan then inverted all the pseudonyms. Licence numbers have six digits, or seven digits starting with 5, about 2 million possibilities or 20.9 bits. Medallion numbers follow a few fixed patterns, about 22 million possibilities or 24.4 bits. He hashed every possibility in minutes and looked up each pseudonym. Public lists of licence holders then put a name on every driver's trips and income. The script repeats the attack in miniature. It hashes five secret six-digit identifiers, then hashes all 10^6 six-digit numbers, 19.9 bits' worth, and recovers all five.

Passengers had no pseudonym at all, yet they were exposed too, because each trip is itself a sparse record of the kind Section 15.6 studies. Describe a trip by its pickup minute and pickup place. The minute is one of the 525,600 minutes of the year, worth 19.0 bits. The place, on a grid of 100-metre squares over the city's roughly 780 km^2, is one of 78,000 squares, worth 16.3 bits. Call each pair of minute and square a cell. Together they carry at most 35.3 bits, more than the 27.4 bits that single out one trip among 173 million. So if trips spread evenly over the cells, a known pickup almost always picks out one trip, and busy times and places only add a few look-alikes (Exercise 8 in the exercise book works out how often under uniform cells). Anthony Tockar showed this in 2014 by matching photographs of celebrities getting into taxis to their trips, which revealed where they went and how much they tipped. With random driver pseudonyms,

the same move works from the driver's side. A passenger who knows who drove one trip finds that trip, learns the driver's pseudonym, and with it every trip and the year's income.

15.4.6. Check yourself

- A company replaces customers' 10-digit phone numbers by their SHA-256 hashes, without a key. How many hash computations does it take to invert them all? *(At most 10^{10}, about 33.2 bits of work, done once for the whole table. A modern computer does this in hours. The strength of SHA-256 does not matter, because the inputs are guessable.)*
- The company switches to random pseudonyms. Is the release now anonymous? *(No. Each customer's records still share one pseudonym. Anyone who links one record to a customer, through a known purchase or visit, learns the pseudonym and every other record with it.)*

15.5. How many people are unique? A birthday calculation

15.5.1. Context

A data custodian who wants to know the re-identification risk of a release can count unique records in it. But counting needs the data, and it says nothing about a new release or a different set of columns. A model of the population answers both. If each person falls in cell c with probability p_c, the expected fraction of unique people has a closed form. It is the birthday problem asked the other way round. The birthday problem, in Cryptography basics, asks whether *any* two of n people share a birthday; here you ask how many people share their cell with *nobody*.

15.5.2. Statement

Exact expected fraction. A person is unique when each of the other $n-1$ people lands outside their cell. If the person is in cell c, each other person avoids it with probability $1-p_c$, independently, so all of them avoid it with probability $(1-p_c)^{n-1}$. Averaging over the person's own cell, which is c with probability p_c, gives the expected fraction of unique people, for n people falling in cells independently with probabilities (p_c):

$$\frac{\mathbb{E}U}{n} = \sum_c p_c(1-p_c)^{n-1}. \tag{15.4}$$

Uniform cells. If all K cells are equally likely, every term has $p_c = 1/K$, and the formula becomes $(1-1/K)^{n-1} \approx e^{-n/K}$: the chance that nobody else lands in your cell when the average cell holds n/K people. Now count the cells in bits, $b = \log_2 K$, so that $K = 2^b$ and $n = 2^{\log_2 n}$. The average occupancy is $n/K = 2^{\log_2 n - b}$, and

$$\frac{\mathbb{E}U}{n} \approx \exp\left(-2^{\log_2 n - b}\right), \tag{15.5}$$

a single curve in $b - \log_2 n$, the bits beyond those needed to name one person. Solving $e^{-n/K} = f$ for the bits says how many you need for a fraction f of people to be unique: $b = \log_2 n + \log_2 \frac{1}{\ln(1/f)}$. That is half once b exceeds $\log_2 n$ by 0.53 bits, 90% at 3.25 bits more and 99% at 6.64 bits more.

A lower bound from the collision probability. The exact formula needs every p_c, and there can be billions of cells. A cruder question needs much less: how likely is a random person to share a cell with one other random person? That is the collision probability $\sum_c p_c^2$ of Fact 3. If you pretend every person's cell is as crowded as average in this sense, you get a guaranteed floor on uniqueness. For any (p_c),

$$\frac{\mathbb{E}U}{n} \geq \Big(1 - \sum_c p_c^2\Big)^{n-1}, \tag{15.6}$$

and for independent attributes $\sum_c p_c^2 = \prod_j \sum_v p_j(v)^2$ by Fact 3, so the bound needs only the per-attribute frequencies (the **marginals**).

Concentration. The expectation is an average over many imagined populations, but you have only one. Moving a single person to another cell changes the number of unique people by at most 2, so in a large population no one person can move the fraction much, and the fraction in the population you have is close to its expectation: for every $t > 0$,

$$\Pr\Big[\Big|\frac{U}{n} - \frac{\mathbb{E}U}{n}\Big| \geq t\Big] \leq 2e^{-nt^2/2}. \tag{15.7}$$

15.5.3. Derivation

The exact formula (Equation 15.4).

1. **Count with indicators.** By Fact 1, $\mathbb{E}U = \sum_i \Pr[\text{person } i \text{ is unique}]$. Every person draws their cell from the same probabilities (p_c), independently of the others, so nothing distinguishes person i from person j and every term of the sum is the same. It is enough to find it for one person.
2. **Condition on the person's own cell.** Call it c; it has probability p_c.
3. **Ask the others to stay away.** Given c, person i is unique if each of the other $n-1$ people lands outside c. They are independent and each avoids c with probability $1 - p_c$, so this has probability $(1-p_c)^{n-1}$.
4. **Average over the cell.** $\Pr[\text{person } i \text{ is unique}] = \sum_c p_c(1-p_c)^{n-1}$. Since all n terms are equal, $\mathbb{E}U$ is n times this; divide by n.

Uniform cells (Equation 15.5).

1. **Put $p_c = 1/K$ in Equation 15.4.** There are K terms, each $\frac{1}{K}(1-\frac{1}{K})^{n-1}$, so the sum is $(1-\frac{1}{K})^{n-1}$.
2. **Replace the power by an exponential.** Fact 2 with $p = 1/K$ and $k = n-1$ squeezes $(1-\frac{1}{K})^{n-1}$ between $e^{-(n-1)/K}$ and $e^{-(n-1)/(K-1)}$. These exponents differ by $\frac{n-1}{K(K-1)}$, of order n/K^2, and replacing $n-1$ by n changes the exponent by only $1/K$. So $(1-\frac{1}{K})^{n-1} \approx e^{-n/K}$ with relative error of order $1/K + n/K^2$, negligible for K in the thousands or more.
3. **Write the exponent in bits.** $n/K = 2^{\log_2 n}/2^b = 2^{\log_2 n - b}$.

4. **Find the bits for a target fraction.** Solve $e^{-n/K} = f$ for K: taking logarithms, $n/K = \ln(1/f)$, so $K = n/\ln(1/f)$ and $b = \log_2 n - \log_2 \ln(1/f)$. At $f = \frac{1}{2}$, $\ln 2 = 0.693$ and $-\log_2 0.693 = 0.53$. At $f = 0.9$, $\ln \frac{1}{0.9} = 0.105$ and $-\log_2 0.105 = 3.25$. At $f = 0.99$, $\ln \frac{1}{0.99} = 0.0101$ and $-\log_2 0.0101 = 6.64$.

The collision lower bound (Equation 15.6). The idea is that Equation 15.4 is an average of the function $(1-x)^{n-1}$ over the cell probabilities people find themselves in, and for a curve that bends upwards the average of the function is at least the function of the average.

1. **Write Equation 15.4 as an average.** Draw a person's cell Y, so $Y = c$ with probability p_c, and look at the probability p_Y of the cell they landed in. Then $\frac{\mathbb{E}U}{n} = \mathbb{E}[g(p_Y)]$ with $g(x) = (1-x)^{n-1}$.
2. **Check that g bends upwards.** g is convex on $[0,1]$, because its second derivative $g''(x) = (n-1)(n-2)(1-x)^{n-3}$ is never negative there.
3. **Apply Jensen's inequality.** For a convex function, the average of the function is at least the function of the average, $\mathbb{E}[g(X)] \geq g(\mathbb{E}X)$. The reason is that a convex curve lies above its tangent line at the point $\mathbb{E}X$; averaging the curve gives at least the average of the tangent line, which is the tangent's value at $\mathbb{E}X$, which is $g(\mathbb{E}X)$. So $\mathbb{E}[g(p_Y)] \geq g(\mathbb{E}[p_Y])$.
4. **Compute the inner average.** $\mathbb{E}[p_Y] = \sum_c p_c \cdot p_c = \sum_c p_c^2$, the collision probability. For independent attributes it factorizes by Fact 3.

Equality in step 3 holds when p_Y is constant, that is, when all cells with positive probability are equally likely, because then there is nothing to average. The bound is tight for uniform cells and loose when a few cells hold most of the people: those crowded cells push the collision probability up and the bound down, while the many people in rare cells are still unique.

Concentration (Equation 15.7). The tool is McDiarmid's inequality (Concentration). It applies to any function f of n independent inputs such that changing input i alone, with the others fixed, moves f by at most c_i. It says that f is unlikely to be far from its mean: $\Pr[f - \mathbb{E}f \geq t] \leq \exp(-2t^2/\sum_i c_i^2)$, and the same for the lower tail. So the work is to find c_i.

1. **Change one input.** U is a function of the n independent cells. Change one person's cell from u to u'; only cells u and u' change their counts, so only they can change U.
2. **Bound the change.** A cell with count k contributes $\mathbf{1}[k = 1]$ to U: it holds a unique person exactly when it holds one person. Cell u's count drops by one and its contribution changes by $\mathbf{1}[k_u - 1 = 1] - \mathbf{1}[k_u = 1] \in \{-1, 0, 1\}$. Cell u''s count rises by one, and its contribution likewise changes by -1, 0 or 1. So U changes by at most 2, and U/n by at most $c_i = 2/n$. (It can change by exactly 2: move a person out of a pair and into an empty cell, and both the person and their former partner become unique.)
3. **Apply McDiarmid.** With $c_i = 2/n$ for all n people, $\sum_i c_i^2 = n \cdot 4/n^2 = 4/n$, so each tail is at most $\exp(-2t^2/(4/n)) = e^{-nt^2/2}$. Adding the upper and lower tails gives the factor 2.

15.5.4. Interpretation

For uniform cells, the bits picture is exact. Equation 15.5 depends on n and K only through $b - \log_2 n$, so the curve is the same for a town and for the planet (Figure 15.2, right). The often-quoted "33 bits identify anyone" is the point $b = \log_2 n$, where the average cell holds one person and the curve is at e^{-1}. With 2^{33} uniform cells for 8 billion people, $n/K = 8 \times 10^9/2^{33} = 0.93$

and only a fraction $e^{-0.93} = 0.394$ is unique. 33 bits are enough to *give* everyone a distinct label, but random labels of 33 bits collide often; you need $32.9 + 6.64 = 39.5$ bits for 99% of the world to be unique.

Skew usually lowers uniqueness. When a few values are common (a big city, a common occupation), many people crowd into a few cells and are not unique, while many rare cells stay empty. In the census below, and for Sweeney's attributes, the uniform model with the same number of cells overstates uniqueness for this reason. This is not a theorem, though: with far fewer cells than people, a uniform spread leaves nobody unique, while a few rare cells would hold some uniques.

The entropy H gives a rule of thumb, not a bound. The rule replaces the real cells by 2^H equally likely cells, as if every cell carried the average surprisal, and gives $e^{-n2^{-H}}$. The collision bound is always below it (up to replacing n by $n-1$), because the collision probability is at least 2^{-H}. To see why, note that $\log_2 \sum_c p_c^2$ is the logarithm of an average of p_c (weighted by p_c), while $-H = \sum_c p_c \log_2 p_c$ is the average of the logarithm, and for the concave logarithm Jensen's inequality runs the other way: the log of an average is at least the average of the log. So $\log_2 \sum_c p_c^2 \geq -H$. The exact value can sit on either side of the entropy rule: in Table 15.5 it is above it with three and four attributes and below it with five or more.

If attributes are independent, the prediction needs only the marginals. In practice they are not, and a model of the joint distribution is needed. That is what Rocher, Hendrickx & de Montjoye (2019) fit, a **Gaussian copula**: a model that keeps each attribute's own frequencies and ties the attributes together through the correlations of a multivariate normal distribution. It is how Section 15.7 estimates risk from a sample.

Finally, one population is enough. Setting the right side of Equation 15.7 equal to a failure probability β and solving for t says that the fraction unique in the population you have is within $\sqrt{2\ln(2/\beta)/n}$ of its expectation with probability $1-\beta$. For $n = 10{,}000$ and $\beta = 0.05$ that is $\sqrt{2\ln 40/10^4} = 0.0272$. That is about five times the standard deviation of the fraction unique over the 20 simulated populations behind Table 15.5 (at most 0.0053, which the script prints next to each simulated mean), where a normal approximation would put 95% of populations within two standard deviations. McDiarmid is loose here because it charges every person the worst case, a change of 2 in U, while most changes move it by 0 or 1.

15.5.5. Example: a synthetic census

The script builds a population of $n = 10{,}000$ people with eight independent attributes, made up but shaped like real ones: sex (uniform), age in 16 five-year bands (flat, then thinning out), region (40 values with Zipf frequencies, so a few regions are large), birth month (uniform), marital status, number of children, occupation (20 values, Zipf) and blood group (real-world frequencies). It reveals them one at a time. Table 15.5 gives, for each step, the entropy H of the attributes known so far and the number of cells K, then the exact expected fraction unique from Equation 15.4, the average over 20 simulated populations, the collision lower bound of Equation 15.6, the entropy rule $e^{-n2^{-H}}$ and the uniform-cells value $e^{-n/K}$ for the same number of cells.

Table 15.5.: Fraction of 10,000 people who are unique as attributes are revealed: exact, simulated (mean of 20 populations), and three approximations. $\log_2 n = 13.29$ bits.

Attributes known	Bits H	Cells K	Exact	Simulated	Collision bound	Entropy rule	Uniform cells
sex, age band, region	9.31	1,280	0.0158	0.0160	0.0000	0.0000	0.0004
+ birth month	12.90	15,360	0.3328	0.3332	0.0834	0.2692	0.5215
+ marital status	14.60	61,440	0.5789	0.5797	0.4237	0.6690	0.8498
+ children	16.48	368,640	0.7939	0.7918	0.7443	0.8967	0.9732
+ occupation	20.39	7,372,800	0.9747	0.9737	0.9736	0.9928	0.9986
+ blood group	22.57	58,982,400	0.9925	0.9926	0.9924	0.9984	0.9998

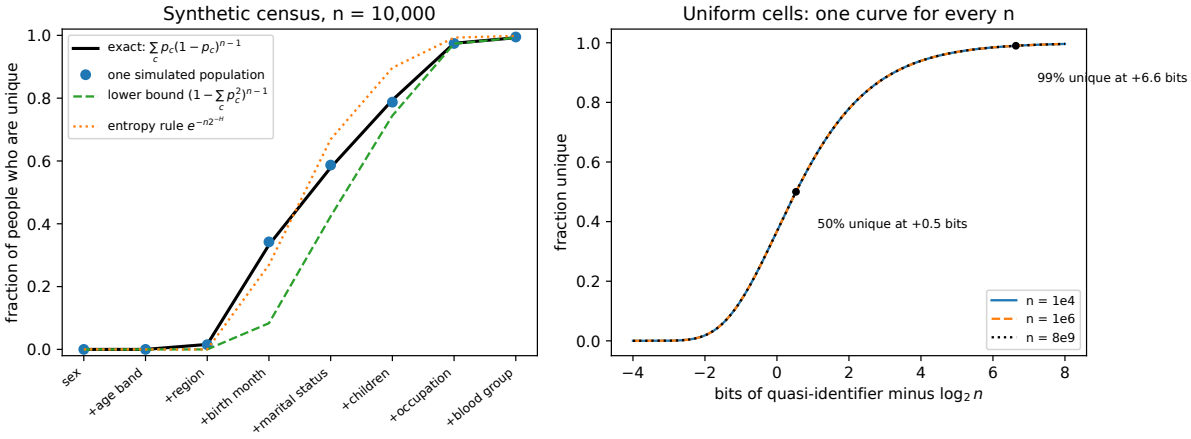

Figure 15.2.: Left: the fraction of people who are unique in the synthetic census as attributes are added, exact against one simulated population, with the collision lower bound and the entropy rule. Right: with uniform cells, the fraction unique depends only on the bits beyond $\log_2 n$; the curves for $n = 10^4$, 10^6 and 8×10^9 coincide.

Read the table along the bits column, against $\log_2 n = 13.29$. With 12.90 bits, just below it, a third of the people are unique. With 20.39 bits, $20.39 - 13.29 = 7.1$ bits beyond it, 97.5% are, close to the 99% that the uniform curve predicts at 6.64 bits beyond. Uniform cells overstate uniqueness at every step from four attributes on, by up to $0.8498 - 0.5789 = 0.27$ (with five attributes), because the attributes are skewed. The collision bound is loose with few attributes, where region and age band put most people in a few large cells, and becomes tight once most cells are nearly empty. Simulation and the exact formula agree to within 0.003.

15.5.6. Check yourself

- With $n = 1000$ people and $K = 1000$ equally likely cells, what fraction is unique, and how many bits beyond $\log_2 n$ is that? *($(1 - 0.001)^{999} = 0.368 \approx e^{-1}$, at zero bits beyond $\log_2 n$, since $K = n$.)*
- Why can the indicators "person i is unique" be dependent and still give $\mathbb{E}U = n \Pr[\text{person 1 is unique}]$? *(Linearity of expectation holds for any random variables, dependent or not. Dependence matters for the variance, which is why the concentration step needs McDiarmid rather than a sum of independent terms.)*

15.6. Sparse, high-dimensional data: the Netflix attack

15.6.1. Context

In 2006 Netflix released about 100 million movie ratings by 480,189 subscribers for a public competition. Names were replaced by random numbers, and some ratings and dates were perturbed. The data look nothing like a census table: each record is a set of (movie, rating, date) triples, 209 on average out of 17,770 movies. There are no quasi-identifier columns to join on, and the adversary's information about a person ("she watched these films around these dates and liked them") is partial and noisy. Narayanan & Shmatikov (2008) showed that this does not help. In a sparse, high-dimensional dataset, a handful of approximate facts about a person typically matches one record far better than any other. They then matched a small sample of Netflix records to public reviews on the Internet Movie Database, which carry names or pseudonyms. The stakes were real. Viewing histories are protected by US law, the Video Privacy Protection Act of 1988, and Narayanan and Shmatikov pointed out that ratings of a few films can suggest a person's political or religious views or sexual orientation. In 2009 a subscriber sued Netflix on these grounds in a class action that was later settled, and in 2010 Netflix cancelled a planned second competition after an inquiry by the Federal Trade Commission. This section explains why a scoring rule that favours rare items works, and when to trust its answer.

15.6.2. Statement

The scoring algorithm. The adversary has auxiliary information aux: a few items i (films) with approximate values aux_i (ratings). Since no record will match exactly, it scores how well each record r of the release agrees, item by item, and adds up the agreements. An agreement on a film that half the subscribers rated says little, while an agreement on an obscure film says a lot, so each item gets a weight w_i that is larger for rarer items:

$$\text{Score}(\text{aux}, r) = \sum_{i \in \text{aux}} w_i \, \text{Sim}(\text{aux}_i, r_i), \tag{15.8}$$

where r_i is the record's value for item i and $\text{Sim} \in [0, 1]$ measures agreement (here: 1 if r rated i within one star of aux_i, else 0). Narayanan and Shmatikov use $w_i = 1/\ln|\text{supp}(i)|$, where $|\text{supp}(i)|$, the **support** of item i, is the number of records that rated it.

The eccentricity test. The top-scoring record is the best guess, but the adversary also needs to know whether to trust it. A real match should stand out: its score should be well above the second-best one, measured against how spread out all the scores are. Let $s_1 \geq s_2$ be the two largest scores and σ the standard deviation of all scores. The adversary declares a match only if the gap, in units of σ, clears a threshold τ,

$$\frac{s_1 - s_2}{\sigma} \geq \tau, \tag{15.9}$$

and otherwise says "no match". Narayanan and Shmatikov used $\tau = 1.5$.

Their findings on Netflix. With 8 ratings, of which 2 may be completely wrong, and dates known to within 14 days, 99% of records are uniquely identified. With 2 ratings and dates within 3 days, 68% are.

The likelihood-ratio form of the score. The weighting can be derived rather than guessed. For each record, the adversary is weighing two explanations: "this record is the target" against "this record is someone unrelated". The standard way to weigh two explanations of the same observations is the **likelihood ratio**, the probability of what you observed under the first explanation divided by its probability under the second. Its logarithm is a sum over items when items behave independently, so it has exactly the form of Equation 15.8. To make this precise, suppose an unrelated record agrees with the auxiliary value of item i with probability s_i, independently across items, and the target's record agrees with probability $1 - \rho$, where ρ covers wrong or stale auxiliary information. Then ranking records by the likelihood ratio is ranking them by Equation 15.8 with

$$w_i = \ln \frac{1 - s_i}{s_i} + \ln \frac{1 - \rho}{\rho} \approx \ln \frac{1}{s_i} + \ln \frac{1 - \rho}{\rho}, \tag{15.10}$$

where the approximation uses $1 - s_i \approx 1$ for rare items. The record with the highest score is the most likely to be the target.

15.6.3. Derivation

The weights. The plan is to write the probability of a record's pattern of agreements under each explanation, take the log of the ratio, and collect the terms that differ from record to record.

1. **Record the agreements.** Write $a_i(r) = \mathrm{Sim}(\mathrm{aux}_i, r_i) \in \{0, 1\}$: 1 if record r agrees with the auxiliary information on item i.
2. **Write the probability of the pattern under each explanation.** If r is the target, each item agrees with probability $1 - \rho$ and disagrees with probability ρ, independently, so the pattern has probability $\Pr[a(r)] = \prod_i (1 - \rho)^{a_i} \rho^{1 - a_i}$ (the exponents pick the right factor for each item). If r is unrelated, each item agrees with probability s_i, so $\Pr[a(r)] = \prod_i s_i^{a_i} (1 - s_i)^{1 - a_i}$.
3. **Take the log of the ratio.** The logarithm turns the ratio of products into a sum over items: $\sum_i \left[a_i \ln \frac{1-\rho}{s_i} + (1 - a_i) \ln \frac{\rho}{1 - s_i} \right]$.

4. **Keep only what depends on the record.** Collect the terms with a_i: $\sum_i a_i\big[\ln\frac{1-\rho}{s_i} - \ln\frac{\rho}{1-s_i}\big] + \sum_i \ln\frac{\rho}{1-s_i}$. The last sum is the same for every record, so it does not change the ranking. The bracket, rearranged, is Equation 15.10: the log-likelihood ratio is the score with those weights, plus a constant.
5. **Why the likelihood ratio is the right thing to threshold.** For any single record, deciding between "target" and "unrelated" is a hypothesis test. The Neyman–Pearson lemma of Hypothesis testing says that, among all tests that wrongly accept an unrelated record with a given probability, the one that accepts when the likelihood ratio exceeds a threshold accepts the true target most often. The intuition: if you can afford only so many false accepts, spend them on the patterns that are most typical of the target relative to an unrelated record.

The best guess is the top score. Step 5 is about one record at a time. When the adversary knows the target is one of the n records and must pick one, Bayes' rule gives the answer. Suppose each record is equally likely a priori to be the target, and records are independent given who the target is.

1. **Write the probability of everything you see if t is the target.** Record t's pattern follows the target distribution and every other record's follows the unrelated one, so all the agreement patterns together have probability $P_1(a(t))\prod_{j\neq t} P_0(a(j))$, with P_1 and P_0 the two products of step 2 above.
2. **Turn it into a posterior.** Bayes' rule says the posterior probability of t is proportional to its prior times this probability, and the prior is the same for every t. Divide by $\prod_j P_0(a(j))$, which does not depend on t either: what remains is $P_1(a(t))/P_0(a(t)) = \mathrm{LR}(t)$, the likelihood ratio of record t. Normalizing so the probabilities sum to 1,

$$\Pr[\text{target} = t \mid \text{data}] = \frac{\mathrm{LR}(t)}{\sum_j \mathrm{LR}(j)}. \tag{15.11}$$

3. **Pick the most probable record.** The maximum a posteriori (MAP) guess is the record with the largest likelihood ratio, which is the top score.

Why rare items carry the attack. A false match is an unrelated record that happens to agree on every item the adversary knows. Take the clean case, $\rho \to 0$ and exact agreement required. An unrelated record agrees on all of a set I of items with probability $\prod_{i\in I} s_i$, and by Fact 1 the expected number of false matches among n records is n times that. Writing both factors as powers of 2 shows the bits:

$$n\prod_{i\in I} s_i = 2^{\log_2 n - \sum_{i\in I}\log_2(1/s_i)}. \tag{15.12}$$

Each item contributes $\log_2(1/s_i)$ bits, its surprisal, and the false matches vanish once the bits exceed $\log_2 n$: the same picture as in Section 15.5. A film that 1% of subscribers rated carries $\log_2 100 = 6.64$ bits; three of them carry $3 \times 6.64 = 19.9$ bits, more than the $\log_2 480{,}189 = 18.9$ bits needed to single out one Netflix subscriber.

15.6.4. Interpretation

Sparsity is the vulnerability. In a sparse dataset most items are rated by few people, so each item a person rated is worth many bits, and nobody's record is close to anyone else's. Narayanan and Shmatikov formalize this as most records having no near neighbour. A census table has few columns with few values each; a ratings matrix has thousands of columns, and a person's "row" is a long sequence of rare events.

Because the score adds up evidence rather than demanding a perfect match, noise in the auxiliary information costs little. With a wrong item, the target loses one term of the score, while unrelated records rarely gain one. The score needs a margin, not a perfect match.

The eccentricity test answers a different question from the score. The top score is the best guess *if the target is in the release*. If it may not be, the adversary also needs to decide whether to trust the guess, and the eccentricity asks whether the top score stands out from the crowd of scores. How often it stands out by chance depends on the shape of the score distribution, so τ has to be calibrated on records known not to be the target. It should be read at a small false positive rate, as for any attack, because a match is only useful if the adversary can be confident in it (Hypothesis testing). Equation 15.11 gives the principled version. Add one more explanation, "the target is not in the release", with prior $1 - \pi$, and give each record prior π/n. Under the new explanation every record is unrelated, so its likelihood, divided by $\prod_j P_0(a(j))$ as before, is 1. Bayes' rule then gives the posterior that record t is the target as $\pi \,\mathrm{LR}(t)/(\pi \sum_j \mathrm{LR}(j) + (1-\pi)n)$.

The weights matter less than the bits. Any weighting that favours rare items does about as well as any other; what decides success is whether the auxiliary information carries more bits than $\log_2 n$.

15.6.5. Example: a synthetic ratings matrix

The script draws a sparse matrix of 5,000 users and 4,000 items. Item popularity follows a Zipf law, the number of ratings per user is log-normal (median 30, mean 40.6), and ratings are 1 to 5 stars from a user bias, an item quality and noise. The result has 203,029 ratings and density 0.0102, close to Netflix's 0.0118. An item drawn from a random user's record carries a median of 5.83 bits, against $\log_2 5000 = 12.29$ bits needed. The auxiliary information about a target is m items from their record, with the rating off by one star half the time; in the noisy setting, a quarter of the items are replaced by random items drawn by popularity, which the target has almost never rated. Table 15.6 gives the fraction of 400 targets whose record gets the top score (ties broken at random), for three weightings. The first is equal weights. The second is the Narayanan–Shmatikov weights. The third is the likelihood-ratio weights of Equation 15.10 in their approximate form $\ln(1/s_i)$, which is close to the exact $\ln \frac{1-s_i}{s_i}$ because every item here is rated by a small fraction of users, with $s_i = |\mathrm{supp}(i)|/n$, the fraction of users who rated the item, and $\rho = \frac{1}{2}$, which makes $\ln \frac{1-\rho}{\rho} = \ln 1 = 0$ and so drops the constant term.

Table 15.6.: Re-identification rate in a synthetic ratings matrix with 5,000 users: the fraction of 400 targets whose record gets the top score, for three weightings of Equation 15.8.

Auxiliary information	Equal weights	$1/\ln\lvert\mathrm{supp}(i)\rvert$	$\ln(n/\lvert\mathrm{supp}(i)\rvert)$
2 items	0.428	0.440	0.402
4 items	0.936	0.941	0.924
8 items	1.000	1.000	1.000
8 items, 2 of them wrong	0.943	0.989	0.978

Read the table with the bits in mind. Two items carry about $2 \times 5.83 = 11.7$ bits, a little under $\log_2 n$, and re-identify about 43% of targets. Four items carry about $4 \times 5.83 = 23$ bits and re-identify 93%. With 8 items of which 2 are wrong, the rarity weightings re-identify 98–99% of targets, matching the 99% of Narayanan and Shmatikov for 8 ratings with 2 wrong. Equal weights fall to 94% because a wrong popular item helps many unrelated records. The two rarity weightings differ by less than two standard errors; the standard error of a rate near 0.98 over 400 targets is $\sqrt{0.98 \times 0.02/400}$, which is 0.007 at these rates.

Figure 15.3 (left and centre) shows what the eccentricity measures. When the target is in the release, its record scores far above every other. When the target is not, the top score is just the high end of a long tail.

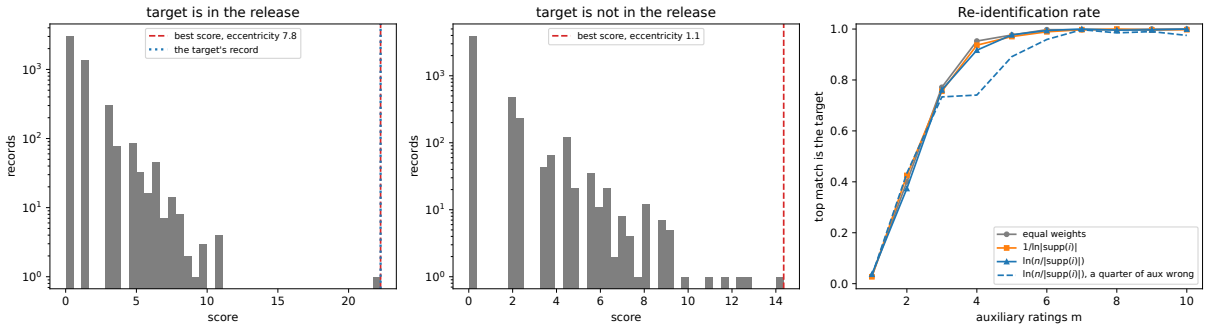

Figure 15.3.: Left and centre: the scores of all 5,000 records for one target's auxiliary information (8 items, 2 wrong), on a log scale. When the target is in the release its record stands far out; when it is not, the best score is the edge of the crowd. Right: re-identification rate against the number of auxiliary items, for three weightings, and for the likelihood-ratio weights when a quarter of the items, rounded down, are wrong.

To test the eccentricity rule, the script also scores 400 outsiders, people drawn from the same model who are not in the release, so that any match it declares for them is false. With 8 items, 2 of them wrong, and $\tau = 1.5$, 94.8% of insiders are correctly re-identified, but 26.3% of outsiders are also "matched" to someone. The median eccentricity is 7.32 for insiders and 0.72 for outsiders, but the outsiders' distribution has a long tail. Holding the false-match rate to 1% means raising τ until only 1% of outsiders clear it, which happens at $\tau = 4.83$, and that threshold still re-identifies 73.0% of insiders. Figure 15.4 shows the whole trade-off, the true positive rate (insiders matched) against the false positive rate (outsiders matched) as τ varies, with false positives on a log axis.

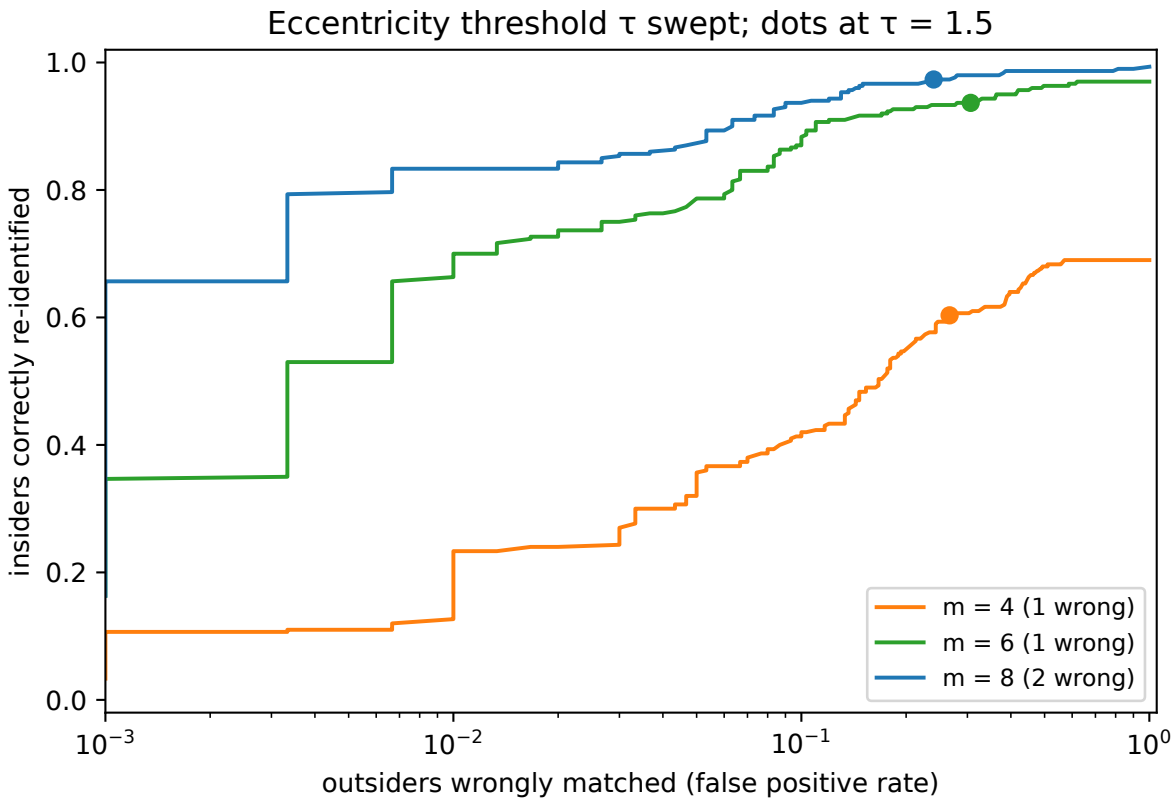

Figure 15.4.: True against false positive rates of the eccentricity test as the threshold τ is swept, for 4, 6 and 8 auxiliary items with 1, 1 and 2 of them wrong. The dots mark $\tau = 1.5$. A false positive rate of 0 is drawn at the left edge.

15.6.6. Check yourself

- Why do the likelihood-ratio weights in Equation 15.10 contain a term in ρ that is the same for every item, and what does it do? *(It is the evidence from agreeing at all, independent of rarity. When the auxiliary information is reliable (ρ small), every agreement counts a lot and a record that misses one item is heavily penalized relative to one that matches all of them.)*
- A record agrees with 3 auxiliary items, each rated by 1% of 480,189 users. How many unrelated records would you expect to agree with all three, if agreements were independent? *($480{,}189 \times 10^{-6} = 0.48$, since each unrelated record agrees on all three with probability $0.01^3 = 10^{-6}$: about half a false match, so three such items are close to, but not quite, enough.)*

15.7. Does releasing a sample protect?

15.7.1. Context

Statistical agencies and companies often release a sample: 1% of a census, 5% of the patients. The argument is plausible deniability. A record that is unique in the sample need not be unique in the population: the person you have in mind may share their attributes with someone who was not sampled, so a match is not proof. Rocher, Hendrickx & de Montjoye (2019) measured how much this argument is worth. They fitted a Gaussian copula model (each attribute's own frequencies, tied together by the correlations of a multivariate normal) to a sample and used it to estimate, for each record, how likely it is to be unique in the population and so how likely a match is to be correct. Their model predicted that 99.98% of Americans would be correctly re-identified in any dataset with 15 demographic attributes, and that releasing a sample does little to change that. This section derives the two probabilities that matter and checks them.

15.7.2. Statement

Each of n people is in the release independently with probability q, the **sampling rate**. Consider a cell with probability p, and let $\lambda = (n-1)p$ be the expected number of *other* people in it. There are two ways to attack, depending on which side the adversary starts from.

From a person to the release. The adversary knows a target's cell and finds exactly one record in that cell in the release. There are two ways that can happen. Either the target was sampled and none of the others in the cell were, and the match is right. Or the target was not sampled and exactly one of the others was, and the match is wrong. If the cell holds J others, the wrong story is J times as likely as the right one, because swapping who was sampled between the target and any one of the others leaves the probability unchanged. How many others should you expect? The release shows no second record in the cell, so the others who are there were all left out of the sample, and each of the $n-1$ others is in the cell and unsampled with probability about $p(1-q)$. So the cell is expected to hold about $\lambda(1-q)$ others, not λ, and the wrong story is about $\lambda(1-q)$ times as likely as the right one. A match is correct with probability "right over right plus wrong":

$$\kappa = \Pr[\text{correct} \mid \text{one match}] = \frac{1}{1 + \frac{(n-1)p(1-q)}{1-pq}} \approx \frac{1}{1+\lambda(1-q)}. \tag{15.13}$$

From a record to the population. The adversary takes a record that is alone in its cell in the release and looks the cell up in a register of the whole population, such as a voter roll. The record is identified if it is alone in its cell in the population too. Knowing the record is alone in the sample already tells you that nobody else in the cell was sampled. What remains is whether anyone in the cell was left out of the sample. Each of the $n-1$ others is in the cell but unsampled with probability about $p(1-q)$, so about $\lambda(1-q)$ people are expected to hide there, and the chance that nobody does is

$$\xi = \Pr[\text{population-unique} \mid \text{sample-unique}] = \left(\frac{1-p}{1-pq}\right)^{n-1} \approx e^{-\lambda(1-q)}. \tag{15.14}$$

The whole release. Averaged over the release, the fraction of sample-unique records that are unique in the population is the expected number of records that are unique in both, divided by the expected number of sample-unique records:

$$\frac{\sum_c p_c(1-p_c)^{n-1}}{\sum_c p_c(1-p_c q)^{n-1}}, \tag{15.15}$$

which equals the population uniqueness rate Equation 15.4 as $q \to 0$ and rises to 1 at $q = 1$.

15.7.3. Derivation

From a person (Equation 15.13). The plan is to compute the two stories, "right match" and "wrong match", given the number of others in the cell, and then average over that number.

1. **Name the crowd.** Let J be the number of other people in the target's cell. Each of the $n-1$ others is in it with probability p, independently, so $J \sim \mathrm{Bin}(n-1, p)$.
2. **The right match.** Given J, "exactly one match and it is the target" means the target is sampled and none of the J others are: probability $q(1-q)^J$.
3. **The wrong match.** Given J, "exactly one match and it is someone else" means the target is not sampled and exactly one of the J others is. There are J choices of which other, each sampled with probability q while the remaining $J-1$ are not: probability $(1-q)\cdot Jq(1-q)^{J-1} = Jq(1-q)^J$.
4. **Form the conditional probability.** The probability of a correct match given one match is the right story over the sum of both, each averaged over J. The common factor q cancels, leaving $\Pr[\text{correct} \mid \text{one match}] = \dfrac{\mathbb{E}[(1-q)^J]}{\mathbb{E}[(1+J)(1-q)^J]}$.
5. **Compute the first average.** The **probability generating function** of J is $\mathbb{E}[z^J]$. For a binomial it is $(1-p+pz)^{n-1}$, because z^J is a product of one factor per other person, z if they are in the cell and 1 if not, and each factor averages to $1-p+pz$ independently. At $z = 1-q$: $\mathbb{E}[(1-q)^J] = (1-pq)^{n-1}$.

6. **Compute the second average.** Differentiating z^J in z and multiplying by z gives Jz^J, so $\mathbb{E}[Jz^J] = z\frac{d}{dz}(1-p+pz)^{n-1} = (n-1)pz(1-p+pz)^{n-2}$. At $z = 1-q$: $\mathbb{E}[J(1-q)^J] = (n-1)p(1-q)(1-pq)^{n-2}$.
7. **Simplify.** Divide numerator and denominator of step 4 by $(1-pq)^{n-1}$ to get Equation 15.13. For small p, $1-pq \approx 1$ and $(n-1)p = \lambda$, which gives the approximation.

From a record (Equation 15.14).

1. **Sort the others into three groups.** Each other person is, independently, in the cell and sampled (probability pq), in the cell and not sampled ($p(1-q)$), or outside the cell ($1-p$).
2. **Condition on sample-uniqueness.** "The record is sample-unique" says that no other person is in the first group. Because each person's group is independent of the others', this condition acts on each person separately: it rules out the first group and rescales the other two by $1-pq$, their total probability. So, given it, each other person is outside the cell with probability $\frac{1-p}{1-pq}$, still independently.
3. **Ask for population-uniqueness.** Population-unique means all $n-1$ others are outside the cell: probability $\left(\frac{1-p}{1-pq}\right)^{n-1}$. The ratio $\frac{1-p}{1-pq}$ is $1 - \frac{p(1-q)}{1-pq}$, close to $1-p(1-q)$ for small p, so by Fact 2 the whole power is about $e^{-(n-1)(p-pq)} = e^{-\lambda(1-q)}$.

The whole release (Equation 15.15).

1. **Count the records unique in both.** By Fact 1, the expected number of records that are sample-unique and population-unique is $\sum_i \Pr[i \text{ sampled and population-unique}]$. Population-unique implies sample-unique, and sampling is independent of the cells, so each term is q times the probability of being population-unique, which is the per-person term of Equation 15.4. The total is $nq\sum_c p_c(1-p_c)^{n-1}$.
2. **Count the sample-unique records.** Their expected number is $nq\sum_c p_c(1-p_cq)^{n-1}$: person i is sampled, and each other person is either outside i's cell or not sampled, which fails only with probability p_cq.
3. **Divide.** The factor nq cancels. Each cell's term in the numerator is its term in the denominator times $\left(\frac{1-p_c}{1-p_cq}\right)^{n-1}$, its ξ from Equation 15.14, so the ratio is an average of ξ over cells weighted by how often each is sample-unique. As $q \to 0$ the denominator tends to $\sum_c p_c = 1$, leaving the population uniqueness rate. At $q = 1$ the two sums are equal and the ratio is 1.

15.7.4. Interpretation

Sampling only helps when the cell is crowded. In both formulas, sampling enters only through the factor $1-q$, which multiplies λ. For rare combinations, $\lambda \ll 1$, both are close to 1 whatever q is. Because $1-q \le 1$, both are at least their values at $q = 0$: $\kappa \ge 1/(1+\lambda)$ and $\xi \ge e^{-\lambda}$ for every sampling rate. Below a few percent, shrinking the sample further barely changes anything, because $1-q$ is already close to 1.

Matching from a person is more forgiving than matching from a record: $\kappa \ge \xi$, since $1/(1+x) \ge e^{-x}$ (which is $e^x \ge 1+x$, the exponential lying above its tangent line at 0). A person-to-release match can be right even when the target is not unique in the population: the others in the cell may simply not have been sampled.

At small sampling rates, a sample unique is a population unique at the population rate. By Equation 15.15, a 1% sample gives plausible deniability exactly to the people who were not unique in the population anyway. With enough attributes, that is almost nobody.

Finally, the adversary can tell which matches to trust. λ depends on the cell, and the sample is a good sample of the population, so the adversary can estimate p from it and compute κ or ξ for each record. Rocher et al. showed this with a copula model; the script does it with the product of the marginals estimated from a 1% sample.

15.7.5. Example: a 1% sample of a synthetic census

For a single cell, Table 15.7 gives both probabilities in their Poisson forms, the approximations on the right of Equation 15.13 and Equation 15.14, for three values of λ. For instance, with $\lambda = 0.1$ and $q = 0.01$, $\kappa = 1/(1 + 0.1 \times 0.99) = 1/1.099 = 0.910$.

Table 15.7.: Probability that a match in a sample is correct: from a person to the release (κ) and from a sample-unique record to the population (ξ), for three crowding levels and two sampling rates.

λ (expected others in the cell)	κ, $q = 0.01$	κ, $q = 0.5$	ξ, $q = 0.01$	ξ, $q = 0.5$
0.1	0.910	0.952	0.906	0.951
0.5	0.669	0.800	0.610	0.779
2	0.336	0.500	0.138	0.368

Going from a 50% to a 1% sample lowers κ by $0.952 - 0.910 = 0.04$ for a rare cell and by $0.500 - 0.336 = 0.16$ for a crowded one.

The script then draws a population of $n = 100{,}000$ with the first seven attributes of Table 15.5; 82.8% of its people are unique. Equation 15.15 gives 0.8301 of sample uniques being population-unique at $q = 0.01$ (simulated: 0.8334 over 19,951 sample uniques in 20 samples), 0.8493 at $q = 0.1$ and 0.9235 at $q = 0.5$. As the formula predicts, the 1% value sits just above the population rate of 0.828. A 1% sample leaves 83% of its unique records identifiable against a population register.

The adversary's own estimate works too. From one 1% sample with 993 sample-unique records, it estimates each attribute's frequencies, multiplies them to get an estimate $\hat{p}$ of each record's cell probability, and computes ξ by Equation 15.14 with n and q, which are public. Its mean prediction is 0.817 against an actual 0.824. The predictions also sort the records well. The 415 records it rates above 0.95 average a prediction of 0.980 and are population-unique 99.3% of the time; the 119 it rates below 0.5 average 0.284 and are unique 30.3% of the time. Figure 15.5 shows both experiments.

15.7.6. Check yourself

- A combination is expected to be shared by $\lambda = 0.05$ other people. What is κ for a 1% sample, and for a full release? *($1/(1 + 0.05 \times 0.99) = 0.953$ and $1/(1 + 0) = 1$.)*

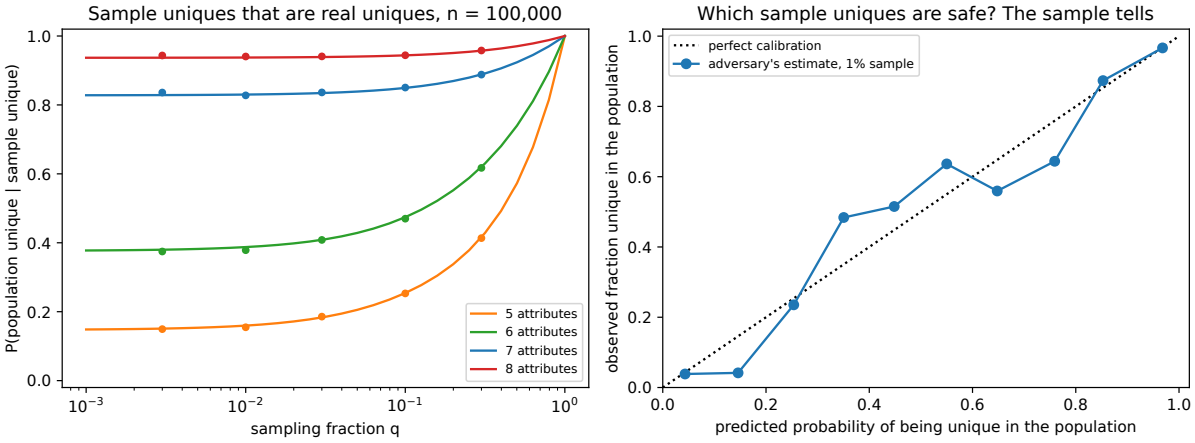

Figure 15.5.: Left: the fraction of sample-unique records that are unique in a population of 100,000, against the sampling rate, for 5 to 8 attributes; lines are Equation 15.15, dots are simulations. As $q \to 0$ each curve levels off at the population's uniqueness rate. Right: the adversary's predicted probability that a sample-unique record is unique in the population, estimated from a 1% sample, against the observed fraction, in bins of width 0.1.

- Why does Equation 15.15 tend to the population uniqueness rate, not to 0, as $q \to 0$? *(A tiny sample has almost no collisions, so nearly every sampled record is sample-unique. The fraction of them that are population-unique is then just the fraction of the population that is unique.)*

15.8. Code: check every formula by simulation

The script code/linkage.py computes every number in this chapter and draws every figure. The uniqueness formulas are computed by summing over all cells (grouped by probability, so even 59 million cells are summed quickly) and checked against simulated populations. The ratings experiment is a scaled-down Netflix: a NumPy matrix of 5,000 users, scored with Equation 15.8. From the repository root:

```
uv run python code/part02-attacks/linkage.py
```

Output (seed 0), summarized in Table 15.8:

Table 15.8.: The script's output with the default seed.

Experiment	Result
Bits	$\log_2(8 \times 10^9) = 32.9$; $\log_2(248.7 \times 10^6) = 27.9$; ZIP 15.3 + birth date 14.8 + sex 1.0 = 31.1 bits

Experiment	Result
Sweeney, uniform cells	$K = 2.34 \times 10^9$; $n/K = 0.106$; fraction unique 0.899
World, uniform cells	33 bits: fraction unique 0.394. Bits needed for 50%, 90%, 99%: 33.4, 36.1, 39.5
Toy release	Classes of sizes 1, 1, 1, 2, 3: linkage success 0.625
Hashed identifiers	MD5 of "0": `cfcd2084…`. All 10^6 six-digit identifiers (19.9 bits) hashed, 5 of 5 inverted. Taxi: 173 million trips (27.4 bits), licences 20.9 bits, medallions 24.4 bits; pickup minute 19.0 + pickup square 16.3 = 35.3 bits; phone numbers 33.2 bits
Synthetic census, $n = 10^4$	Table 15.5; McDiarmid 95% half-width 0.0272
Synthetic ratings, 5,000 users	203,029 ratings, density 0.0102; median bits per item 5.83; rates in Table 15.6
Eccentricity, 8 items, 2 wrong	$\tau = 1.5$: insiders 0.948, outsiders 0.263. $\tau = 4.83$: insiders 0.730, outsiders 0.010
Sampling, $n = 10^5$, 7 attributes	Population unique 0.828. Sample uniques that are unique: 0.8301 ($q = 0.01$; simulated 0.8334), 0.8493 ($q = 0.1$), 0.9235 ($q = 0.5$)
κ and ξ	Table 15.7
Adversary's estimate of ξ, 1% sample	Mean predicted 0.817, actual 0.824; above 0.95: predicted 0.980, actual 0.993; below 0.5: predicted 0.284, actual 0.303

tests/test_linkage.py checks that the output still matches.

What to take from it. First, a hash of a guessable identifier is only a lookup table away from the identifier: one pass over a million hashes inverts every six-digit identifier. Second, the formulas are right: every simulated fraction agrees with its exact expectation to within 0.004. Third, the bits beyond $\log_2 n$ decide uniqueness. A few bits short, a minority is unique; seven bits beyond, almost everyone is, in a census table and in a ratings matrix alike. Fourth, the shortcuts err in known directions. For real, skewed attributes the uniform model usually overstates uniqueness (in the census, at every step from four attributes on) and the collision bound understates it, so compute the exact sum; it needs only a model of the population. Fifth, the decision rule needs calibration. Picking the top score is nearly always right when the target is in the data, but the popular threshold $\tau = 1.5$ matches a quarter of outsiders in this toy, so choose τ from the false positive rate you can accept. Last, sampling is not a defence. It protects the people in crowded cells, who were not at much risk, and the adversary can tell who they are.

15.10. Cheat sheet

n people, cells c with probabilities p_c, K cells, U the number of unique people, q the sampling rate, λ the expected number of others in the target's cell. Table 15.9 collects the results.

Table 15.9.: Every result in this chapter.

Result	Formula	Note
Linkage success	J/n, J = number of distinct quasi-identifier combinations	Target known to be in the release; at most $1/k$ if all classes have $\geq k$ records
Expected fraction unique	$\sum_c p_c(1-p_c)^{n-1}$	Exact for independent people
Uniform cells	$(1-1/K)^{n-1} \approx \exp(-2^{\log_2 n - b})$	50% at $b = \log_2 n + 0.53$; 99% at $\log_2 n + 6.64$

Result	Formula	Note
Collision bound	$\geq (1-\sum_c p_c^2)^{n-1}$; $\sum_c p_c^2 = \prod_j \sum_v p_j(v)^2$	Jensen; tight for uniform cells
Concentration	$\Pr[\lvert U/n - \mathbb{E}U/n\rvert \geq t] \leq 2e^{-nt^2/2}$	McDiarmid with $c_i = 2/n$
Netflix score	$\sum_{i \in \text{aux}} w_i \operatorname{Sim}(\text{aux}_i, r_i)$	$w_i \approx \ln(1/s_i) + \ln \frac{1-\rho}{\rho}$ is the log-likelihood ratio
Eccentricity	$(s_1 - s_2)/\sigma \geq \tau$	Calibrate τ on outsiders at a small false positive rate
Hashed identifier	N hash computations invert every pseudonym; a key stops this, not linkage	A consistent pseudonym is a join key
Expected false matches	$n \prod_{i \in I} s_i = 2^{\log_2 n - \sum_i \log_2(1/s_i)}$	Each item is worth its surprisal in bits
Correct match, person to release	$\kappa \approx 1/(1+\lambda(1-q))$	$\geq 1/(1+\lambda)$ for every q
Sample-unique is population-unique	$\xi \approx e^{-\lambda(1-q)}$	$\geq e^{-\lambda}$ for every q
Sample uniques that are real	$\sum_c p_c(1-p_c)^{n-1} / \sum_c p_c(1-p_c q)^{n-1}$	Population uniqueness rate as $q \to 0$

Rules of thumb

- $\log_2 n$ bits name one person: 33 for the world, 28 for the US, 13 for a town of 10,000. About 7 bits more make 99% of people unique.
- Add up the bits of the attributes an adversary might know. If the sum exceeds $\log_2 n$, assume most people are unique; if attributes are correlated, the true sum is lower.
- In sparse data every rare item is worth $\log_2(1/s_i)$ bits, so a handful of facts is enough, noise or not.
- Hashing an identifier from a set of N values hides at most $\log_2 N$ bits, about 20 to 33 for licence, phone or identity numbers, which is at most 2^{33} hash computations.
- Removing names, replacing them by pseudonyms, releasing a sample, or perturbing a few values does not anonymize a dataset. The defence has to hold whatever auxiliary data exist. The next chapter tests the classic attempts, k-anonymity and its successors, against that requirement.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

16. Syntactic anonymity and how it breaks

16.1. Why this matters

Linkage and re-identification showed that deleting names does not anonymize a table. The columns that remain, such as age, ZIP code and sex, are **quasi-identifiers**: none of them names anyone, but together they single out most people, and anyone who holds a list of names with the same columns (a voter roll, say) can join the two tables and put a name back on most rows. Between 1998 and 2008, data custodians and researchers answered with a family of definitions that constrain the released table itself. **k-anonymity** hides every record in a crowd of at least k that look alike. **l-diversity** asks each crowd to hold several different sensitive values. **t-closeness** asks each crowd to look like the whole table. They are called **syntactic** because each one is a property of the published table that you can check by reading it, with no reference to how the table was produced or to what else the adversary knows.

These definitions are not history. Statistics offices, hospital data-sharing agreements, regulators' guidance and anonymization tools such as ARX still use them. You need to know what they promise and exactly where the promise ends, for two reasons. You will meet them in practice, and their failures are the specification of the definition the next part introduces.

The definitions form a chain, each proposed in answer to an attack on the one before it. Removing names falls to **linkage**, and k-anonymity caps linkage at $1/k$ (Section 16.3). But k-anonymity only stops the adversary from picking out the target's record; it does not stop the adversary from learning the target's diagnosis. If every record in the target's crowd has the same diagnosis (**homogeneity**), or if the adversary can rule out the other diagnoses from what it already knows about the target (**background knowledge**), the diagnosis leaks with no record picked out. l-diversity answers these two attacks (Section 16.4). A crowd can be diverse and still move the adversary's belief a long way, though: half the crowd may have a disease that is rare in the population (**skewness**), or all its different diagnoses may be diseases of the same organ (**similarity**). t-closeness answers these (Section 16.5). Finally, **composition** defeats all three at once: two releases, each satisfying the definition, intersect to reveal what neither reveals alone (Section 16.6).

16.1.1. The one idea: a syntactic definition fixes the adversary's knowledge

Each definition is a property of one table, and it protects against an adversary whose knowledge is fixed in advance. For k-anonymity the adversary knows the quasi-identifiers and nothing else. For l-diversity it knows the quasi-identifiers plus a few facts about the target. For t-closeness it knows the quasi-identifiers plus the table's overall distribution. Each attack in this chapter gives the adversary one more piece of knowledge that the definition did not anticipate, and the guarantee then says nothing. A second release, the most ordinary auxiliary information there is,

breaks all three definitions. A definition that survives has to hold whatever the adversary knows, and has to say what happens when releases are combined.

Table 16.1 lists the results and where each is used.

Table 16.1.: The results of this chapter and where each is used.

Result	Where it is used
The posterior within a class is the class's frequency	Every attack on the sensitive attribute
k-anonymity caps linkage success at $1/k$	What k-anonymity does guarantee
Uniform cells: a fraction $\Pr[\text{Poisson}(n/K) \le k-2]$ violates k-anonymity	How coarse the quasi-identifiers must be, in bits
Recursive (c, ℓ)-diversity caps the posterior at $c/(1+c)$ after $\ell - 2$ values are ruled out	What l-diversity guarantees against background knowledge
t-closeness in total variation moves every event by at most t	What t-closeness guarantees, and why rare values escape it
Probability that two releases pin down a value	The composition attack

What this chapter uses from elsewhere. Every idea below is restated where it is used, and these links are for more detail. The linkage game, Equation 15.3, and the uniform-cells model are in Linkage and re-identification. The imputation baseline, the best guess of a sensitive attribute from the population alone, is in Attribute inference and model inversion. Total variation is in Divergences, the Poisson approximation to the binomial in Probability distributions, and entropy in Information theory.

Notation. A table has n records. Each has quasi-identifiers and one **sensitive attribute** S, such as a diagnosis, with m possible values. A **generalization** replaces each quasi-identifier by a coarser value: an age by a range, a ZIP code by a prefix. An **equivalence class** E is a set of records with the same generalized quasi-identifiers; $|E|$ is its number of records. Within a class, $n_E(v)$ is the number of records with $S = v$, and $P_E(v) = n_E(v)/|E|$ is the fraction of the class with that value, the class's distribution. $P(v)$ is the same fraction over the whole table. **Suppression** deletes records.

16.2. Toolkit: three facts every derivation uses

16.2.1. Fact 1 — Within a class, the posterior is the frequency

The adversary's **posterior** is its belief about the target's sensitive value after it has seen the release. Here is the situation. The adversary knows the target's quasi-identifiers and knows the target is in the release, so it can find the target's class E. But all records in E show the same generalized quasi-identifiers, so it cannot tell which one is the target's. If it knows nothing else, it has no reason to favour any record, and each of the $|E|$ records is equally likely to be the target's.

(This is step 2 of the derivation of Equation 15.3: the target was drawn at random, and the records of a class differ only in the sensitive attribute, which the adversary does not know.) The chance that the target has value v is then the number of records with v divided by the number of records:

$$\Pr[S_{\text{target}} = v \mid \text{release}] = \frac{n_E(v)}{|E|} = P_E(v). \tag{16.1}$$

Background knowledge works by elimination. If the adversary also knows that the target's value is not in some set B of values, the records with values in B cannot be the target's. It crosses them out and spreads its belief evenly over the records that are left. The number left is $|E|$ minus the records with values in B, so for a value v not in B,

$$\Pr[S_{\text{target}} = v \mid \text{release}, S_{\text{target}} \notin B] = \frac{n_E(v)}{|E| - \sum_{u \in B} n_E(u)}. \tag{16.2}$$

For example, take a class of three records with the diagnoses cancer, cancer, flu. Two of the three records say cancer, so the adversary's posterior is $\frac{2}{3}$ for cancer and $\frac{1}{3}$ for flu. If it knows that the target did not have flu, the flu record is crossed out, two records remain and both say cancer, so cancer has posterior $\frac{2}{2} = 1$. Every attack on the sensitive attribute in this chapter is this calculation.

16.2.2. Fact 2 — Total variation bounds every event

To say that a class "looks like the whole table" you need a distance between two distributions P and Q on the same values. The **total variation (TV)** distance is half the total absolute difference between the two probability tables, and it equals the largest difference in probability that any single question about the value can show:

$$\text{TV}(P, Q) = \frac{1}{2} \sum_{v} |P(v) - Q(v)| = \max_{A} |P(A) - Q(A)|, \tag{16.3}$$

where the maximum is over all sets of values A, and $P(A)$ is the probability that the value lands in A (Divergences).

The equality has a short reason. $P(A) - Q(A) = \sum_{v \in A} (P(v) - Q(v))$, which is largest when A holds exactly the values where $P(v) > Q(v)$, so the maximum is attained by $A = \{v : P(v) > Q(v)\}$ and equals the total excess of P over Q. Both distributions sum to 1, so the total excess of P over Q equals the total excess of Q over P, and each is half the sum of all absolute differences. (Taking A to be the values where Q is larger gives the same number with the sign flipped, which is why the absolute value does no harm.) This is what t-closeness relies on: a bound on the distance is a bound on every question the adversary can ask.

16.2.3. Fact 3 — The number of others in your cell is nearly Poisson

Fact 3 is the tool for counting how many people share your quasi-identifiers. Model the generalized quasi-identifiers as K cells, and suppose the n people fall into them independently, each cell equally likely. Fix yourself. Each of the other $n-1$ people lands in your cell with probability $1/K$, independently, so the number of *other* people in your cell is $\text{Bin}(n-1, 1/K)$. When there are many

trials, each with a small chance, the binomial is close to the **Poisson** distribution with the same mean, $\Pr[N = j] \approx e^{-\lambda}\lambda^j/j!$ (Probability distributions). Here the mean is $\lambda = (n-1)/K \approx n/K$, the average number of people per cell. Your class then has $1 + \text{Poisson}(\lambda)$ members: you plus the others. This is how the chapter counts how many records violate k-anonymity at a given coarseness.

16.3. k-anonymity

16.3.1. Context

Sweeney and Samarati proposed the first answer to the linkage attack in 1998: make sure that no combination of quasi-identifiers in the release singles out fewer than k people. A custodian gets there by generalizing (age 37 becomes 35–39, ZIP code 02139 becomes 021**) and by suppressing the few records that still stand out. The question is what this buys, and what it costs.

16.3.2. Statement

Definition. A release is **k-anonymous** if every equivalence class has at least k records.

What it guarantees. Recall the linkage game: a target is drawn uniformly from the release, the adversary is given the target's quasi-identifiers, and it wins if it picks out the target's record. Equation 15.3 says the best it can do is J/n, where J is the number of classes. The reason is that in a class of size $|E|$ the best guess is a random record of the class, right with probability $1/|E|$, and the target lands in that class with probability $|E|/n$, so each class contributes $1/n$ and the J classes contribute J/n. When every class has at least k records there cannot be many classes, and

$$\Pr[\text{win}] = \frac{J}{n} \le \frac{1}{k}. \tag{16.4}$$

What it costs, for uniform cells. Coarse quasi-identifiers protect more but say less, so the question is how coarse they must be. Suppose the generalized quasi-identifiers split the population into K equally likely cells. A record violates k-anonymity when its cell holds fewer than k people, and by Fact 3 the expected fraction of such records is

$$\Pr[\text{Poisson}(n/K) \le k-2]. \tag{16.5}$$

Keeping that fraction below a target α needs enough people per cell, $n/K \ge \lambda_k$, where λ_k is the mean at which the fraction is exactly α: $\Pr[\text{Poisson}(\lambda_k) \le k-2] = \alpha$. A quasi-identifier with K equally likely values carries $\log_2 K$ bits of information about a person, so in bits the quasi-identifiers may carry at most $b = \log_2 K = \log_2 n - \log_2 \lambda_k$.

16.3.3. Derivation

The cap on linkage (Equation 16.4). The idea is that n records cannot fill more than n/k classes of at least k each.

1. **Count records by class.** The J classes split the n records between them, each record in exactly one class, so $n = \sum_j |E_j|$.
2. **Use the definition.** Every class has at least k records, so the sum is at least Jk: $n \geq Jk$, that is $J/n \leq 1/k$.
3. **Read off the linkage success.** Equation 15.3 says the linkage success is J/n, so it is at most $1/k$.

The cost (Equation 16.5). The idea is to compute the chance that one person's class is too small, then note that this chance is also the expected fraction of such people.

1. **Size of a person's class.** A person's class is their cell. By Fact 3 it holds the person plus N others, with N approximately Poisson(n/K).
2. **When it is too small.** The class is smaller than k when $1 + N \leq k - 1$, that is $N \leq k - 2$, which has probability $\Pr[\text{Poisson}(n/K) \leq k - 2]$.
3. **From one person to the fraction.** The expected number of people in small classes is the sum, over people, of each one's chance of being in one (linearity of expectation: the expected count of events is the sum of their probabilities). Every person has the same chance, so the sum is n times it, and the expected fraction is that chance.
4. **Solve for the coarseness.** As λ grows, the Poisson count moves up and the chance of a small count, the CDF (cumulative distribution function) at $k - 2$, falls. So "at most α" is the same as $\lambda \geq \lambda_k$. Put $K = n/\lambda$ and take $\log_2$: $\log_2 K = \log_2 n - \log_2 \lambda$, largest at $\lambda = \lambda_k$.

16.3.4. Interpretation

The guarantee is about names only. Equation 16.4 bounds the chance of picking out the target's *record*. It says nothing about the sensitive attribute, which is the whole point of the release, and the next two sections attack exactly that gap.

k-anonymity is the mirror image of uniqueness, and the bits make the comparison exact. In the same uniform-cells model, a person is unique when nobody else is in their cell, which by Fact 3 has probability $\Pr[\text{Poisson}(n/K) = 0] = e^{-n/K}$. For 99% of people to be unique you need $e^{-n/K} = 0.99$, so $n/K = \ln(1/0.99) \approx 0.01$ and $K \approx 100n$, which is $\log_2 n + \log_2 100 = \log_2 n + 6.64$ bits (Section 15.5). At the other end, Table 16.2 shows that 2-anonymity for 99% of records needs the quasi-identifiers to carry at most $\log_2 n - 2.20$ bits. The window between "almost everyone is unique" and "almost everyone is hidden" is $6.64 + 2.20 = 8.84$, about 9 bits wide, and every attribute you publish uses some of it.

k costs more than $\log_2 k$ bits. You might expect that hiding everyone in a class of k needs k people per cell, that is $\log_2 k$ bits fewer than $\log_2 n$. But cells vary in size around their mean, and the unlucky small cells are the ones that violate the definition, so you need λ_k people per cell *on average*, and λ_k is larger than k. The margin is largest for small k. For $k = 2$ a person violates the definition when $N = 0$, which has probability $e^{-\lambda}$; setting $e^{-\lambda} = 0.01$ gives $\lambda_2 = \ln 100 = 4.61$, more than twice k.

Which columns are quasi-identifiers is a judgment, and in sparse data everything is one. Section 15.6 showed that a handful of rare movie ratings single out a subscriber. Making a ratings matrix k-anonymous means generalizing thousands of columns until little is left (Aggarwal, 2005).

Finally, the guarantee assumes the adversary knows no more than the quasi-identifiers. A neighbour who knows that the target's record is the only one in the class with a given diagnosis needs no linkage at all.

16.3.5. Example: a k-anonymous hospital table

Table 16.2 applies Equation 16.5 to a population of $n = 10{,}000$ ($\log_2 n = 13.29$ bits) with $\alpha = 1\%$. For each k it finds λ_k, then subtracts $\log_2 \lambda_k$ from $\log_2 n$. For $k = 2$, $\lambda_2 = 4.61$ from the calculation above, $\log_2 4.61 = 2.20$, and $13.29 - 2.20 = 11.08$ bits are allowed.

Table 16.2.: Uniform cells, $n = 10{,}000$: how many bits of quasi-identifier k-anonymity allows if at most 1% of records may fall in classes smaller than k.

k	People per cell λ_k	Bits allowed	Below $\log_2 n$ by	$\log_2 k$
2	4.61	11.08	2.20	1.00
5	10.05	9.96	3.33	2.32
10	17.40	9.17	4.12	3.32
20	30.58	8.35	4.93	4.32
50	66.74	7.23	6.06	5.64

The last two columns compare the true cost with the naive $\log_2 k$. The gap is about 1.2 bits at $k = 2$ ($2.20 - 1.00$) and shrinks to about 0.4 bits at $k = 50$ ($6.06 - 5.64$), because a Poisson count with a large mean varies little relative to its mean. Figure 16.1 draws the whole curve for each k.

Real tables are not uniform, so real anonymizers search for a generalization that works on the data. The script builds a synthetic hospital table of $n = 10{,}000$ patients with three quasi-identifiers: age in years (0 to 89), a five-digit ZIP code (800 values, a few areas far more common than the rest) and sex. The sensitive attribute is one of eight diagnoses, and it depends on age: asthma peaks in childhood, fractures around 18, depression around 40, diabetes, hypertension and cancer later in life, while flu is equally common at every age and HIV is rare (1.0% of records). With exact quasi-identifiers, the linkage success is 0.933: by Equation 15.3, the 10,000 patients fall into $0.933 \times 10{,}000 = 9{,}330$ distinct combinations of age, ZIP code and sex, so most of them are alone in theirs.

The script anonymizes the table with **Mondrian** (LeFevre, DeWitt & Ramakrishnan, 2006). Start with the whole table as one box. Split a box at the median of the quasi-identifier with the widest range (relative to its full range), as long as both halves still have at least k records. Stop when no split is allowed. Each final box is a class, published as a range per quasi-identifier. Mondrian recodes locally: a busy ZIP area gets narrow age ranges and a quiet one wide ranges. Because it keeps splitting until a split would leave fewer than k on one side, its classes stay close to size k, much closer than those of a single global generalization of each column. Table 16.3 gives the result.

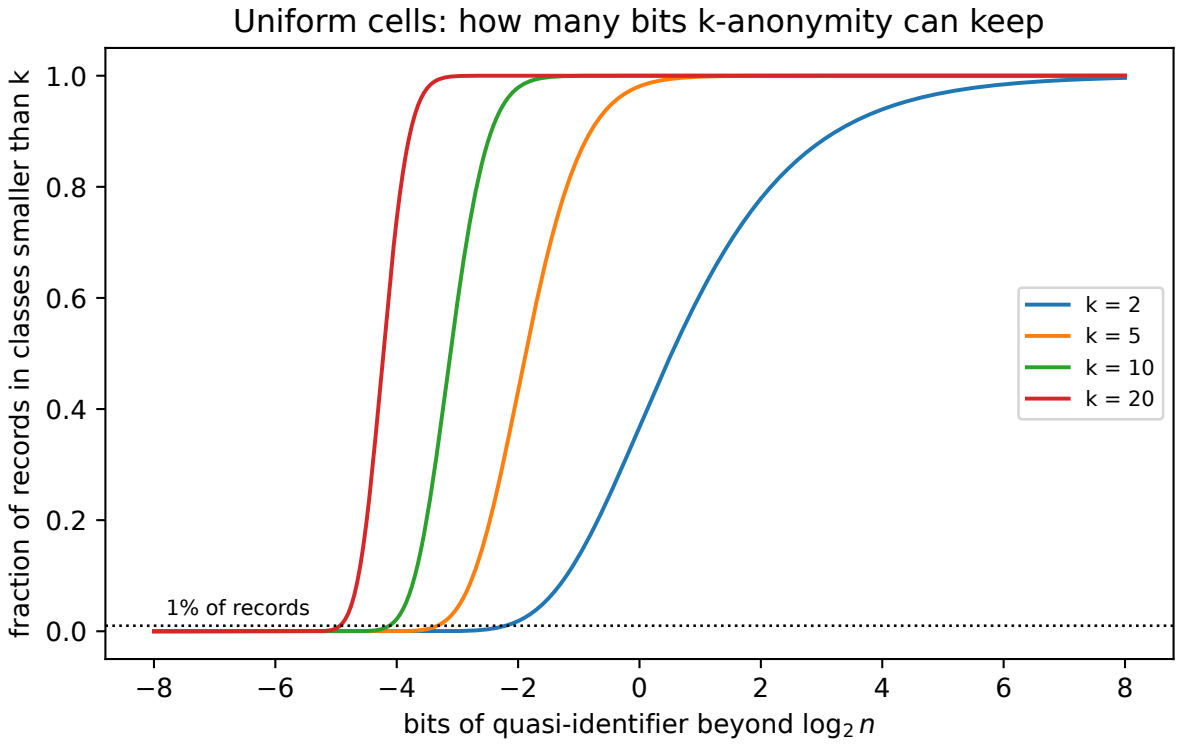

Figure 16.1.: The fraction of records in classes smaller than k, against the bits of quasi-identifier beyond $\log_2 n$, for uniform cells. Each curve is a Poisson CDF; the dotted line is 1% of records.

Table 16.3.: Mondrian k-anonymization of a synthetic hospital table of 10,000 patients. Mean width is the average, over records and quasi-identifiers, of the class's range as a fraction of the full range. Certain disclosure is the fraction of records in a class with a single diagnosis. Guess accuracy is the fraction of records whose diagnosis is the most common one in their class.

k	Classes	Sizes	Mean width	Linkage J/n	Certain disclosure	Guess accuracy
2	4,091	2–5	0.005	0.4091	0.2797	0.675
5	1,542	5–11	0.016	0.1542	0.0232	0.593
10	748	10–20	0.028	0.0748	0.0000	0.562
20	366	20–41	0.043	0.0366	0.0000	0.540
50	129	50–99	0.075	0.0129	0.0000	0.506

The linkage success sits between $1/(2k)$ and $1/k$ for every k (Figure 16.2, left). J/n is one over the average class size. No class is smaller than k, so the upper bound $1/k$ is guaranteed. The lower bound is not: Mondrian can leave classes larger than $2k$ (up to 41 records at $k = 20$), but they are rare enough that the average size stays below $2k$ in every row. At $k = 2$, for instance, 0.4091 lies between 0.25 and 0.5. The cost in precision is small. At $k = 5$ the average range covers 1.6% of each quasi-identifier's span.

The last two columns are about the diagnosis, and the next section explains them.

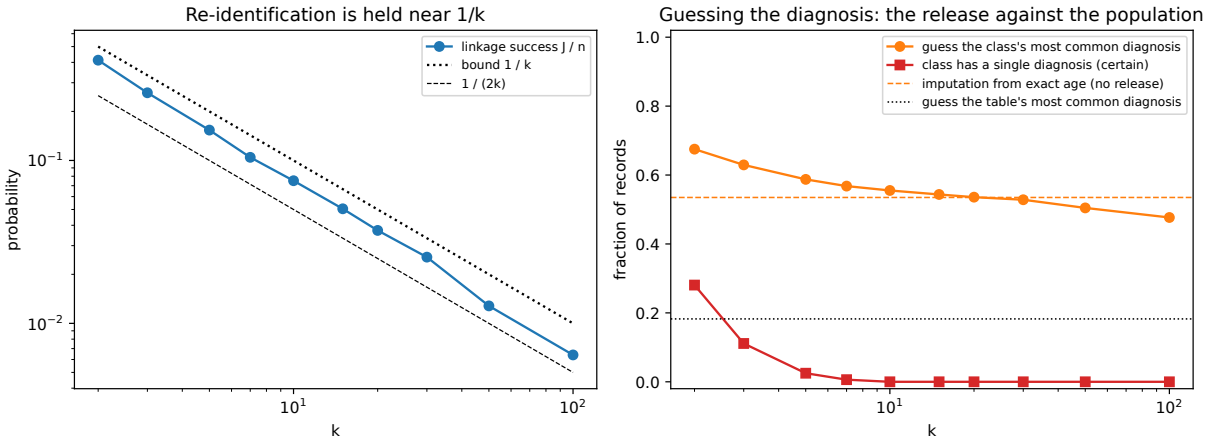

Figure 16.2.: Left: the linkage success of Mondrian releases of the synthetic hospital table against k, between $1/(2k)$ and the bound $1/k$. Right: how often the diagnosis is the most common one in the record's class, and how often the class holds a single diagnosis, against two baselines that use no release.

16.3.6. Check yourself

- A k-anonymous release of 1,000 records has 120 classes. What is the largest k it can satisfy, and what is the linkage success? *(At most* $\lfloor 1000/120 \rfloor = 8$*, since* $Jk \le n$*. The success is* $120/1000 = 0.12$*, below* $1/8 = 0.125$*.)*

- Why does 2-anonymity need about 4.6 people per cell on average, not 2? *(The number of others in your cell is roughly Poisson. With a mean of 1, a fraction $e^{-1} = 0.37$ of people would have nobody else in their cell. To get that down to 1% you need $e^{-\lambda} = 0.01$, that is $\lambda = 4.61$.)*

16.4. Homogeneity, background knowledge and l-diversity

16.4.1. Context

Machanavajjhala, Kifer, Gehrke & Venkitasubramaniam (2006) pointed out that k-anonymity hides who a record belongs to but not what it says. Table 16.4 is a 3-anonymous release.

Table 16.4.: A 3-anonymous release with three classes of three records.

ZIP code	Age	Diagnosis
130**	< 30	heart disease
130**	< 30	heart disease
130**	< 30	heart disease
148**	4*	cancer
148**	4*	flu
148**	4*	heart disease
130**	3*	cancer
130**	3*	cancer
130**	3*	flu

Alice is 26 and lives in ZIP code 13053. Her class is the first, and every record in it says heart disease. By Fact 1 her posterior for heart disease is the fraction of her class that has it, $\frac{3}{3} = 1$. This is the **homogeneity attack**: no re-identification, full disclosure. Bob is 35, lives in 13068, and is in the third class, where two of three records say cancer, so his posterior for cancer is $\frac{2}{3}$. His neighbour saw him at work through the whole flu season and rules out flu; crossing out the flu record leaves two cancer records, and cancer then has posterior 1. This is the **background knowledge attack**. The question is what condition on the classes stops both.

16.4.2. Statement

Both attacks work because one value dominates the class, either from the start or after a few values are ruled out. l-diversity asks for enough different values in each class, and its three versions differ in how they measure "enough". Sort a class's value counts from largest to smallest as $r_1 \geq r_2 \geq ... \geq r_m$, so r_1 is the count of the most common value. A class is

- **distinct ℓ-diverse** if it holds at least ℓ different values;
- **entropy ℓ-diverse** if the entropy of P_E is at least $\log_2 \ell$. The entropy $H(P_E) = -\sum_v P_E(v) \log_2 P_E(v)$ measures in bits how spread out the values are; ℓ equally common values have entropy exactly $\log_2 \ell$, so the condition says the class is at least as spread out as ℓ equal values;

- **recursive (c, ℓ)-diverse** if $r_1 < c\,(r_\ell + r_{\ell+1} + \cdots + r_m)$: the most common value is less than c times the total of all but the $\ell - 1$ most common. The right-hand side is the "tail" that is left after the $\ell - 1$ biggest values are set aside, and the condition says the top value cannot swamp that tail.

A release is ℓ-diverse if every class is.

What recursive diversity guarantees. The tail is what survives the background knowledge attack. An adversary who rules out $\ell - 2$ values can at worst remove some of the big values, and the remaining ones still include a tail at least as large as the original one. Since the top value is less than c times that tail, it holds less than c parts out of $c + 1$. Precisely: if a class is recursive (c, ℓ)-diverse, then after the adversary rules out any $\ell - 2$ values that are not the target's, every remaining value v has

$$\Pr[S_{\text{target}} = v \mid \text{release}, \text{background}] < \frac{c}{1 + c}. \tag{16.6}$$

For distinct ℓ-diversity, the corresponding statement is weaker: the adversary needs to rule out $\ell - 1$ values to be certain, but one value can still hold all but $\ell - 1$ of the records.

16.4.3. Derivation

The plan is to compare the class after elimination with the original class: its top count cannot be larger, and its tail cannot be smaller, so the defining inequality survives.

1. **What is left.** Rule out a set B of $\ell - 2$ values. The remaining $m - \ell + 2$ values keep their original counts. Call the largest of them r'_1, and the total of the other $m - \ell + 1$ remaining values T'.
2. **The top does not grow.** Ruling out values removes records but never adds any, so r'_1 is one of the original counts, and no original count exceeds r_1: $r'_1 \le r_1$.
3. **The tail does not shrink below the original tail.** T' is a sum of $m - \ell + 1$ of the original counts. The smallest such sum you could possibly get is that of the $m - \ell + 1$ smallest counts, which is $r_\ell + \cdots + r_m$. So $T' \ge r_\ell + \cdots + r_m$.
4. **Combine with the definition.** Chain the three inequalities: $r'_1 \le r_1 < c\,(r_\ell + \cdots + r_m) \le c\,T'$.
5. **Turn counts into a posterior.** By Fact 1, after elimination the posterior of a remaining value is its count over the total count left, $r'_1 + T'$, so it is at most $r'_1/(r'_1 + T')$. The map $x \mapsto x/(x + T')$ increases in x (a larger share of a pie whose other part is fixed), so with $r'_1 < cT'$ this is below $cT'/(cT' + T') = c/(1 + c)$.

16.4.4. Interpretation

l-diversity protects against certainty, not against likelihood. The bound $c/(1 + c)$ is $\frac{1}{2}$ at $c = 1$, $\frac{2}{3}$ at $c = 2$ and $\frac{3}{4}$ at $c = 3$, so even recursive diversity lets the adversary be fairly sure. Distinct and entropy ℓ-diversity do not even give that, because neither limits the share of the top value directly: an entropy 3-diverse class over 8 values can have one value in 73% of its records, since the other 27% spread over seven values add enough entropy (Exercise 2 in the exercise book).

The adversary's knowledge is assumed, not bounded. The guarantee covers an adversary who rules out up to $\ell - 2$ values. One who rules out more, or who knows something softer ("probably not flu"), is not covered.

A posterior also has to be read against what the adversary would believe with no release. A posterior of 0.6 for one diagnosis is not a leak if the population already gives 0.6 to people of the target's age. The right comparison is the **imputation baseline** of Attribute inference and model inversion: the most likely value of the sensitive attribute given the target's own quasi-identifiers, under the true population distribution, computed with no release at all. Whatever the release teaches beyond that is about the individual; up to it, it is about the population.

Some tables cannot be made diverse at all. The table's distribution P is the average of its classes' distributions P_E, each weighted by the class's share of the records. Entropy is **concave**: mixing distributions can only make the result more spread out, so the entropy of an average is at least the average of the entropies. If every class had entropy at least $\log_2 \ell$, the table would too. So a table dominated by one value, with entropy below $\log_2 \ell$, has no entropy ℓ-diverse partition.

16.4.5. Example: homogeneity in the toy and in the hospital table

In Table 16.4 the three classes hold 1, 3 and 2 different values, so they are distinct 1-, 3- and 2-diverse. Their entropy versions are $\ell = 2^{H(P_E)}$, the number of equally common values with the same entropy. The first class has one value, entropy 0 and $\ell = 1.00$. The second has three equally common values and $\ell = 3.00$. The third, $\frac{2}{3}$ cancer and $\frac{1}{3}$ flu, has entropy $\frac{2}{3}\log_2 \frac{3}{2} + \frac{1}{3}\log_2 3 = 0.918$ bits and $\ell = 2^{0.918} = 1.89$: two values, but unevenly spread, so worth fewer than two. The release as a whole is only 1-diverse, because of Alice's class.

In the hospital table, the "certain disclosure" column of Table 16.3 counts the patients in homogeneous classes. At $k = 2$ it is 28.0% of all patients. At $k = 5$ it is 2.3%, or 232 patients whose diagnosis the release states outright. The population never gives that certainty: at no age does the population law give any diagnosis more than 0.705.

The guess accuracy column needs the baselines of Figure 16.2 (right). Guessing the most common diagnosis of the whole table is right for 18.5% of patients. Imputation, which guesses the most likely diagnosis for each patient's exact age under the population law, is right for 53.6%, with no release at all. A 5-anonymous release is right for 59.3%. So most of what the release teaches the adversary is the age–diagnosis pattern, which any useful study of this table would report. The excess over imputation, $0.593 - 0.536 = 0.057$ at $k = 5$, comes from the small classes, and it is down to $0.540 - 0.536 = 0.004$ at $k = 20$.

Table 16.5 adds diversity to $k = 5$.

Table 16.5.: Mondrian with l-diversity on the same hospital table: each split is allowed only if both halves satisfy the criterion.

Criterion	Classes	Sizes	Mean width	Linkage J/n	Certain disclosure	Guess accuracy
$k = 5$	1,542	5–11	0.016	0.1542	0.0232	0.593

Criterion	Classes	Sizes	Mean width	Linkage J/n	Certain disclosure	Guess accuracy
$k = 5$, distinct $\ell = 3$	1,132	5–33	0.022	0.1132	0.0000	0.574
$k = 5$, recursive $(c = 2, \ell = 3)$	389	5–641	0.113	0.0389	0.0000	0.417

Distinct 3-diversity removes the certain disclosures for little cost. Recursive $(2, 3)$-diversity forces some classes to cover hundreds of patients and pushes the guess accuracy below imputation. The reason is that diagnosis depends on age: to keep any diagnosis from dominating a class, Mondrian must mix ages, and that erases the pattern the data were released to show.

16.4.6. Check yourself

- Is the class {cancer, cancer, cancer, flu, asthma} recursive $(2, 3)$-diverse? *(No. The sorted counts are $r_1 = 3$, $r_2 = 1$, $r_3 = 1$, and the tail beyond the two most common values is $r_3 = 1$, so the condition is $3 < 2 \times 1$, which fails. It is distinct 3-diverse.)*
- Why does the derivation of Equation 16.6 allow only $\ell - 2$ ruled-out values, not $\ell - 1$? *(If the class has exactly ℓ values, ruling out $\ell - 1$ of them leaves one, with posterior 1, whatever c is. With $\ell - 2$ ruled out, at least two values remain, and step 3 of the derivation still finds the original tail among them.)*

16.5. Skewness, similarity and t-closeness

16.5.1. Context

Li, Li & Venkatasubramanian (2007) found two attacks that l-diversity does not see. In the **skewness attack**, 1% of the table has HIV, and a class that is half HIV, half not, is 2-diverse by every definition, yet by Fact 1 it raises the adversary's belief that a member has HIV from 1% to 50%, fifty-fold. In the **similarity attack**, a class holds three different diagnoses, gastric ulcer, gastritis and stomach cancer, so it is 3-diverse, and the adversary still learns that the target has a stomach disease. Both say that diversity is the wrong yardstick: what matters is how far a class's distribution is from what the adversary would believe anyway, which is the distribution of the whole table.

16.5.2. Statement

Definition. A release is **t-close** if every class's distribution is within distance t of the whole table's: $d(P_E, P) \le t$, for a chosen distance d between distributions.

With total variation as the distance, the guarantee is that no question about the target's value gets an answer more than t away from the answer the whole table gives. By Fact 2, the total variation is the largest such gap, so for every class and every set of values A,

$$|P_E(A) - P(A)| \le t. \tag{16.7}$$

In particular, guessing the most common value of the target's class is right with probability at most $\max_v P(v) + t$: the best guess from the table alone, plus t.

With the earth mover's distance (EMD), the choice of Li et al., values that are similar are close, which is what the similarity attack needs. Think of each distribution as piles of sand on the values. The EMD is the least work needed to reshape one set of piles into the other, where moving a unit of sand between two values costs their distance apart. For m ordered values (salary bands, age groups), numbered 1 to m and placed at ground distance $|i-j|/(m-1)$ so that the two ends are distance 1 apart, the work comes out as a sum over the gaps between neighbouring values of how much sand must cross each one:

$$\mathrm{EMD}(P_E, P) = \frac{1}{m-1} \sum_{i=1}^{m-1} \Big| \sum_{j \le i} (P_E(j) - P(j)) \Big|. \tag{16.8}$$

16.5.3. Derivation

Total variation (Equation 16.7). The idea is that the adversary's belief is the class distribution, so a bound on how far the class is from the table is a bound on how far the adversary's belief moves.

1. **A distance bound is an event bound.** By Fact 2, $\mathrm{TV}(P_E, P) = \max_A |P_E(A) - P(A)|$, so a bound t on the distance is a bound t on every event.
2. **The adversary's belief is the class distribution.** By Fact 1, the adversary's belief about a target in class E is P_E. So every question it can ask about the target's value, "is it in A?", gets an answer within t of the answer from the table as a whole.
3. **Apply it to the best guess.** Take $A = \{v\}$ for the class's most common value: $P_E(v) \le P(v) + t \le \max_u P(u) + t$.

Earth mover's distance on ordered values (Equation 16.8). The idea is that on a line, sand can only get from one side of a gap to the other by crossing it, so you can count the work gap by gap.

1. **What EMD is.** EMD is the least total cost of moving the mass of P_E until it becomes P, where moving mass f from value i to j costs $f|i-j|/(m-1)$. A move from i to j crosses each of the $|i-j|$ gaps between them once, so its cost is $1/(m-1)$ per unit per gap crossed.
2. **How much must cross each gap.** Look at the gap between values i and $i+1$. The values up to i hold $\sum_{j \le i} P_E(j)$ under the class and must end up holding $\sum_{j \le i} P(j)$. The difference, $\sum_{j \le i}(P_E(j) - P(j))$, is their excess (or shortfall), and that net mass has to cross the gap, rightwards if positive and leftwards if negative. Any plan moves at least this much across the gap.
3. **A plan that does no more.** A plan that only moves mass between neighbours and never in both directions across the same gap moves exactly the net amount across each gap. So the least cost is $1/(m-1)$ times the sum, over the $m-1$ gaps, of the absolute net mass crossing it, which is Equation 16.8.

16.5.4. Interpretation

The bound is additive, and rare values need a ratio. Equation 16.7 lets a 1% value rise to $1\% + t$. At $t = 0.15$ that is 16%, a sixteen-fold increase for the people who most need protection. A difference of 0.15 looks small next to a common value such as 40%, and enormous next to 1%. A guarantee for rare values has to bound the *ratio* of the adversary's beliefs with and without the release, not their difference. That is the shape of the definition in the next part.

t-closeness also fights the purpose of the release. If age predicts diagnosis, a class of similar ages has a different diagnosis distribution from the whole table, so it is not t-close for small t. Making every class t-close means mixing ages until the pattern is gone. But the pattern is a fact about the population, the kind of finding any study is published to report, not a secret about any one patient. Attribute inference and model inversion draws the same line between population inference and individual leakage.

The choice of distance is a choice of what is "similar". EMD with a ground distance from a hierarchy of diagnoses treats gastritis and gastric ulcer as close, so a class full of stomach diseases is far from the table and fails. Total variation treats every pair of values as equally different, so it would not see the similarity attack.

16.5.5. Example: toy, skew and hospital

In Table 16.4, the table has four heart disease, three cancer and two flu records, so its distribution is $\frac{4}{9}$ heart disease, $\frac{3}{9}$ cancer, $\frac{2}{9}$ flu. Each class's total variation from it is the total excess of the class over the table (Fact 2). Alice's class is all heart disease, an excess of $1 - \frac{4}{9} = \frac{5}{9} = 0.556$. The second class is $\frac{1}{3} = \frac{3}{9}$ of each, an excess of $\frac{3}{9} - \frac{2}{9} = \frac{1}{9} = 0.111$ on flu only. Bob's class, $\frac{6}{9}$ cancer and $\frac{3}{9}$ flu, has excesses $\frac{3}{9}$ and $\frac{1}{9}$, together $\frac{4}{9} = 0.444$. So the release is t-close only for $t \geq 0.556$.

For the skewness attack (Figure 16.3), the class that is 50% HIV is at total variation $0.50 - 0.01 = 0.49$ from a table with 1% HIV (the excess on HIV). A class with 10% HIV is at $0.10 - 0.01 = 0.09$, which passes $t = 0.1$, and still makes HIV ten times as likely for its members.

Table 16.6 adds t-closeness in total variation to $k = 5$ on the hospital table.

Table 16.6.: Mondrian with t-closeness (total variation) on the hospital table. The table's most common diagnosis has frequency 0.185.

Criterion	Classes	Sizes	Mean width	Largest TV	Guess accuracy	Bound $\max_v P(v)+t$
$k = 5$	1,542	5–11	0.016	0.937	0.593	—
$k = 5$, $t = 0.3$	495	6–60	0.291	0.300	0.275	0.485
$k = 5$, $t = 0.15$	136	14–304	0.324	0.149	0.222	0.335

The bound column is $0.185 + t$: $0.185 + 0.3 = 0.485$ and $0.185 + 0.15 = 0.335$. The guess accuracy respects this bound of Equation 16.7. But the classes now span about 30% of each quasi-identifier's

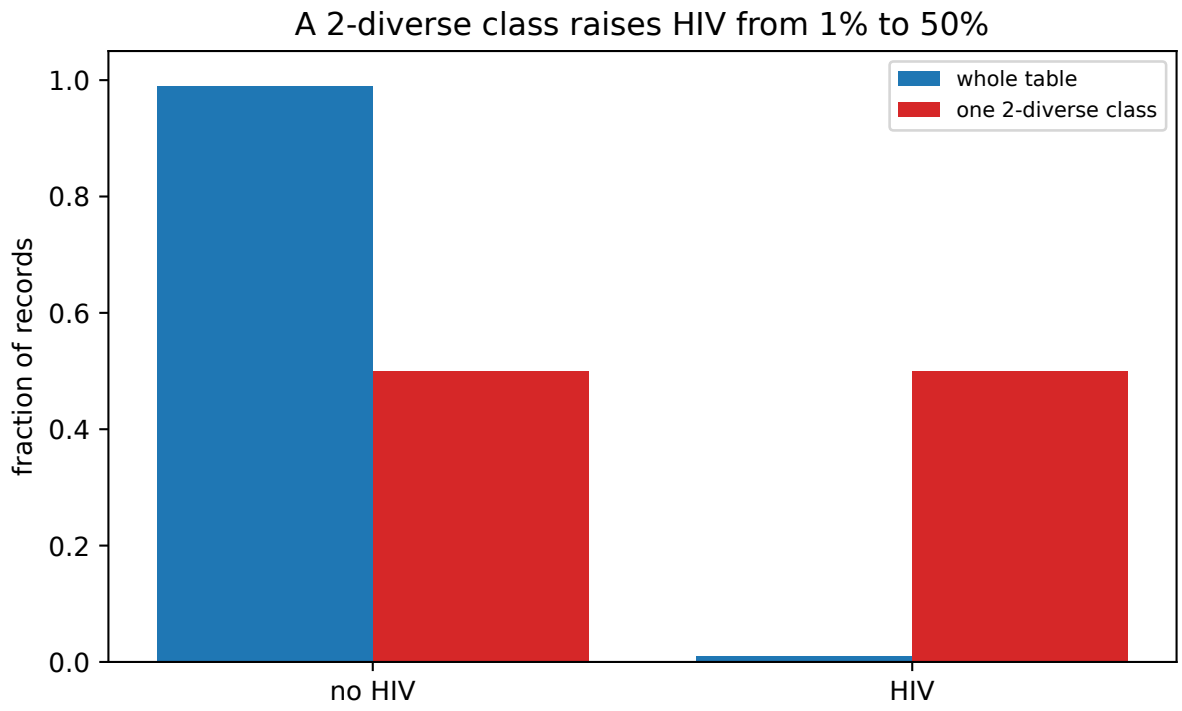

Figure 16.3.: The skewness attack: a table in which 1% of patients have HIV, and a class of it that is half HIV. The class is 2-diverse but at total variation 0.49 from the table.

range, and the release is worse than no release for learning about the population: its guess accuracy of 0.222 to 0.275 is far below the 0.536 that imputation from age achieves.

16.5.6. Check yourself

- A table has 2% cancer. A release is 0.05-close in total variation. What is the largest possible frequency of cancer in a class? *(0.07, from* $0.02 + 0.05$ *by Equation 16.7: 3.5 times the base rate, within the definition.)*
- Salaries take the 9 ordered values 3k to 11k, uniformly in the table. A class holds {3k, 4k, 5k}. Is the EMD to the table larger or smaller than for a class {6k, 8k, 11k}? *(Larger: 0.375 against 0.167. The first class is bunched at the low end, so mass has to travel far to spread out; the second is already spread out; Exercise 3 in the exercise book computes both.)*

16.6. The composition attack

16.6.1. Context

Every definition so far is about one release. Ganta, Kasiviswanathan & Smith (2008) asked what happens when there are two. Two hospitals in the same city publish their patient tables, each one properly k-anonymous, or ℓ-diverse, with no coordination. A patient treated at both

appears in a class of each. The adversary takes the diagnoses of the target's class in one release, those of the class in the other, and intersects: the true diagnosis is in both. Neither hospital did anything wrong, and each release satisfies its definition, yet the combination can reveal the diagnosis outright.

16.6.2. Statement

The attack. For a target in both releases, with class E_A in release A and E_B in release B, the candidate values are those that appear in both classes,

$$\{v : n_{E_A}(v) > 0\} \cap \{v : n_{E_B}(v) > 0\}, \tag{16.9}$$

and the true value is always among them, because the target's own record carries it in each class. The diagnosis is **pinned down** when one candidate is left.

How often, in a model. To see how often this happens, model the classes as random. Suppose the target's class has k_A records in one release and k_B in the other, and the other members' values are independent draws from the population distribution p, with p_v the probability of value v. Given that the target's true value is v, let A_v be the set of values other than v that appear among the $k_A - 1$ other members of the class in release A, and B_v the same for the $k_B - 1$ others in release B. These are the wrong values each release leaves open. The target is pinned exactly when no wrong value is left open by both, that is when A_v and B_v share nothing. So the probability is an average, over the true value v and over what release A leaves open, of the chance that every other member of the second class avoids those values. Writing $p(S) = \sum_{u \in S} p_u$ for the probability of a set of values,

$$\Pr[\text{pinned}] = \sum_v p_v \, \mathbb{E}[(1 - p(A_v))^{k_B - 1}], \qquad \Pr[A_v = S] = \sum_{T \subseteq S} (-1)^{|S| - |T|} \big(p_v + p(T)\big)^{k_A - 1}, \tag{16.10}$$

where the expectation is over the random set A_v, whose distribution is the second formula. A simpler lower bound counts, for each wrong value, the chance that both classes contain it, and subtracts the total from 1:

$$\Pr[\text{pinned}] \geq 1 - \sum_v p_v \sum_{u \neq v} \big(1 - (1 - p_u)^{k_A - 1}\big)\big(1 - (1 - p_u)^{k_B - 1}\big). \tag{16.11}$$

16.6.3. Derivation

The exact probability (Equation 16.10). The idea is to fix the true value and what the first class contains, compute the chance that the second class avoids it, and then average.

1. **Condition on the true value.** The target's true value is v with probability p_v. Everything below is for a fixed v, and the outer sum $\sum_v p_v(\cdot)$ averages over it.
2. **When the value is pinned.** The candidates are v itself together with the wrong values that appear in both classes, $\{v\} \cup (A_v \cap B_v)$. So the value is pinned exactly when A_v and B_v are disjoint.

3. **Fix what the first class leaves open.** Condition on $A_v = S$ for a particular set S. The $k_B - 1$ others in the second class are independent draws, and each avoids S with probability $1 - p(S)$. So $\Pr[B_v \cap S = \varnothing] = (1 - p(S))^{k_B - 1}$. Averaging over the possible sets S, weighted by $\Pr[A_v = S]$, gives the expectation in Equation 16.10.
4. **The distribution of the first class's set.** $A_v = S$ means two things: every one of the $k_A - 1$ draws lands in $S \cup \{v\}$, and each value of S is hit at least once. The first part is easy: "all draws land in $T \cup \{v\}$" has probability $(p_v + p(T))^{k_A - 1}$ for any set T. The second part is handled by **inclusion–exclusion**: start from "all draws land in $S \cup \{v\}$", subtract the cases where some value of S is missed (all draws land in a smaller set), add back the cases subtracted twice, and so on. The sets $T \subseteq S$ are the values not missed, and the sign $(-1)^{|S|-|T|}$ alternates with the number missed, which gives the alternating sum.

For a single wrong value, $S = \{u\}$, the sum has two terms: $\Pr[A_v = \{u\}] = (p_v + p_u)^{k_A - 1} - p_v^{k_A - 1}$, the probability that every draw is v or u, minus the probability that every draw is v (in which case u was never hit).

The lower bound (Equation 16.11). The idea is that the target fails to be pinned only if some wrong value turns up in both classes, and the chance of "some" is at most the sum of the chances of each.

1. **When it fails.** Given v, the value is not pinned when some $u \neq v$ is in both A_v and B_v.
2. **The chance for one wrong value.** u is missing from the first class when all $k_A - 1$ others avoid it, which has probability $(1 - p_u)^{k_A - 1}$, so $\Pr[u \in A_v] = 1 - (1 - p_u)^{k_A - 1}$, and likewise for B_v. The two classes are drawn independently, so the probability that u is in both is the product.
3. **Add over wrong values.** The expected number of wrong values in both sets is the sum of these products, by linearity of expectation (the expected count of events is the sum of their probabilities; Fact 1 of Linkage and re-identification). The chance that there is at least one is at most this expected number, because a count that is at least 1 whenever the event happens has expectation at least the event's probability (the union bound). Subtract from 1 and average over v.

16.6.4. Interpretation

None of the three definitions composes. Each is a condition on one table, and the intersection of two tables is not a table that either custodian checked. Ganta et al. showed the attack on k-anonymous and on ℓ-diverse releases. A custodian who checks only its own table cannot account for releases it does not know about.

That points to what is wanted instead. A definition that composes says: if release A leaks at most this much and release B at most that much, together they leak at most a known function of the two. It must also hold whatever the adversary knows, since another release is just auxiliary information. The next part starts from these two requirements.

The model understates the risk. It draws the other members of a class from the whole population. In real releases a class collects similar people (similar ages, here) who are more likely to share a diagnosis, so each class contains fewer distinct wrong values and the intersection is smaller than the model predicts.

The union bound is useful only for small classes. It charges every wrong value separately, so it is accurate when two wrong values rarely turn up in both classes at once. At $k = 2$ each class has a single other member, so it holds at most one wrong value, two wrong values can never turn up together, and the bound is exact. At $k = 5$ the expected number of shared wrong values exceeds 1, the bound is negative, and Equation 16.10 is needed.

16.6.5. Example: two hospitals

In the model, with p the population's diagnosis distribution, from which the hospital table is drawn, the probability that two releases pin down the diagnosis is 0.8734 for classes of 2, 0.1615 for classes of 5, 0.0288 for classes of 7 and 0.0015 for classes of 10. It falls fast because a larger class contains more wrong values, and each one is another chance for the two classes to share one. Simulation agrees to within 0.001 (Figure 16.4, left). The union bound gives 0.8734 at $k = 2$ and is negative from $k = 5$ on.

The script then runs the attack. A city has 15,000 people drawn from the model of the hospital table. Two hospitals each treat a random 10,000 of them, so 6,649 people are treated at both. Each hospital publishes a 5-anonymous Mondrian release of its own patients. Table 16.7 gives what the adversary learns about the 6,649.

Table 16.7.: The composition attack on two independent hospital releases, for the 6,649 people treated at both. "Pinned" is the fraction left with a single possible diagnosis.

Releases	Pinned by A alone	Pinned by B alone	Pinned by A and B	Mean candidates, A alone	Mean candidates, A and B
$k = 5$	0.0289	0.0262	0.0985	2.79	2.38
$k = 5$, distinct $\ell = 3$	0.0000	0.0000	0.0027	3.22	2.92

Two 5-anonymous releases pin down the diagnosis of 9.9% of the shared patients, more than three times either release alone (0.0985 against 0.0289 and 0.0262). For comparison, in the single-table release of Table 16.3 at $k = 5$ a patient's class has 6.8 records on average over patients, and the model at $k = 7$ predicts only 2.9%: real classes, which group patients of similar age, are more alike than random draws, as the interpretation above said. With distinct 3-diversity, no single release pins anyone down, and the two together pin down 18 patients (0.27% of 6,649).

16.6.6. Check yourself

- Two releases are each 3-diverse in the distinct sense, over 8 possible values. If each class's two other values were chosen uniformly at random from the 7 wrong ones, how likely is the intersection to pin down the truth? *($\binom{5}{2}/\binom{7}{2} = 10/21 = 0.476$: the second class must avoid both of the first class's wrong values, so its two wrong values must come from the other 5. Exercise 4 in the exercise book derives it.)*

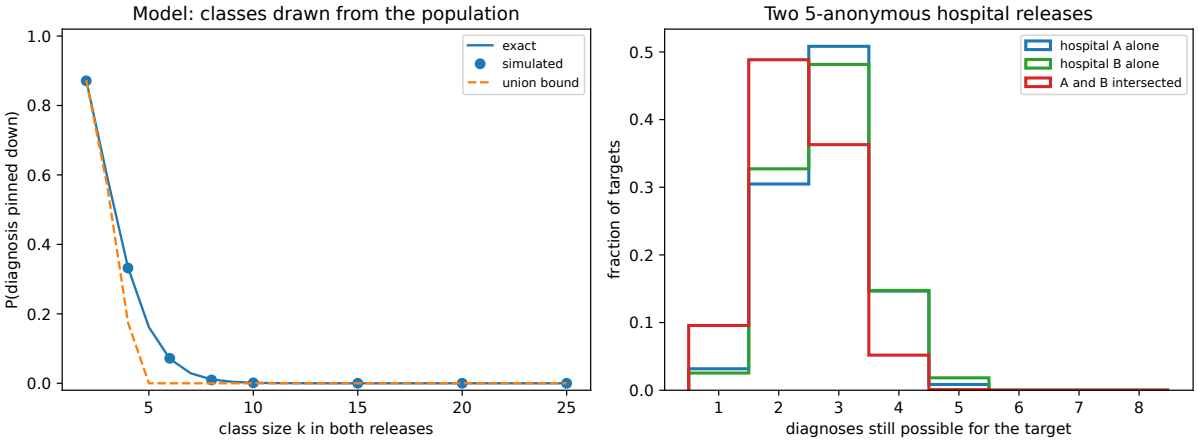

Figure 16.4.: Left: the probability that two releases pin down the diagnosis, against the class size, when the other members of each class are drawn from the population: exact (Equation 16.10), simulated, and the union bound (Equation 16.11). Right: the number of diagnoses still possible for a patient treated at both hospitals, from either 5-anonymous release alone and from their intersection.

- Why can't the second hospital prevent the attack by checking its own release more carefully? *(The attack needs only that the two classes share no wrong value. The second hospital would need to know the first hospital's classes, and every other release the patient appears in.)*

16.7. Code: anonymize, then attack

The script code/syntactic_anonymity.py computes every number in this chapter and draws every figure. It implements Mondrian with any criterion on a class (k-anonymity, distinct and recursive l-diversity, t-closeness in total variation), the uniform-cells calculation, the attacks on the sensitive attribute, and the composition attack, exactly by inclusion–exclusion, by simulation and on two synthetic hospital releases. From the repository root:

```
uv run python code/part02-attacks/syntactic_anonymity.py
```

Output (seed 0), summarized in Table 16.8:

Table 16.8.: The script's output with the default seed.

Experiment	Result
Toy release	Posteriors 1 (homogeneous class), $\frac{2}{3}$ cancer (Bob), 1 after ruling out flu; entropy $\ell = 1.00$, 3.00, 1.89; TV to the table 0.556, 0.111, 0.444
Recursive (c, ℓ) bound	$c/(1+c) = 0.500$, 0.667, 0.750 for $c = 1$, 2, 3
Skewness	50% HIV against 1%: TV 0.49, ratio 50. 10% HIV: TV 0.09, ratio 10

Experiment	Result
Uniform cells, $n = 10^4$	Table 16.2
Hospital table, $n = 10^4$	Exact quasi-identifiers: linkage 0.933. Baselines: most common diagnosis 0.185, imputation from age 0.536, largest population posterior 0.705
Mondrian	Table 16.3, Table 16.5, Table 16.6
Two hospitals	Table 16.7
Composition model	Pinned: 0.8734 ($k = 2$), 0.1615 ($k = 5$), 0.0288 ($k = 7$), 0.0015 ($k = 10$); simulation within 0.001

tests/test_syntactic_anonymity.py checks that the output still matches.

In practice, a census extract would be k-anonymized with ARX, a free anonymization tool that implements these criteria, and then linked back to a public table. The script's Mondrian release plays the part of ARX, and its linkage column is that measurement: the re-identification rate against an adversary holding everyone's quasi-identifiers, the strongest auxiliary table there can be.

What to take from it. k-anonymity does what it says: linkage success stays below $1/k$, and Mondrian keeps it above $1/(2k)$ at little cost in precision. But what it says is not enough, because small classes state diagnoses outright, for 2.3% of patients at $k = 5$. Even where nothing is stated outright, most of what an anonymized table teaches is about the population, so measure attribute disclosure against imputation, not against guessing the most common value. Each fix costs utility: recursive diversity and t-closeness remove the certain disclosures by erasing the age–diagnosis pattern the data exist to show. And two releases are worse than one, under every definition here. The composition attack more than triples the pinned diagnoses, and it is the attack that a better definition has to survive.

16.9. Cheat sheet

n records, classes E of size $|E|$, J classes, P_E the class's distribution of the sensitive attribute and P the table's, $r_1 \geq r_2 \geq ...$ a class's sorted counts. Table 16.9 collects the results.

Table 16.9.: Every result in this chapter.

Result	Formula	Note
Posterior in a class	$P_E(v) = n_E(v)/\|E\|$	Ruling out values renormalizes over the rest
k-anonymity	Every $\|E\| \geq k$; linkage $J/n \leq 1/k$	Says nothing about the sensitive attribute
Uniform cells	Fraction in classes $< k$: $\Pr[\text{Poisson}(n/K) \leq k-2]$	99% 2-anonymous at $\log_2 n - 2.20$ bits
Distinct, entropy l-diversity	$\geq \ell$ values; $H(P_E) \geq \log_2 \ell$	Neither caps the top value's share near $1/\ell$
Recursive (c, ℓ)-diversity	$r_1 < c(r_\ell + \cdots + r_m)$	Posterior $< c/(1+c)$ after ruling out $\ell - 2$ values
t-closeness (TV)	$\|P_E(A) - P(A)\| \leq t$ for every A	Additive: a 1% value may rise to $1\% + t$
EMD, ordered values	$\frac{1}{m-1}\sum_i \|\sum_{j \leq i}(P_E(j) - P(j))\|$	Similar values are close
Composition	Candidates \$= \$ values of E_A $\cap$ values of E_B	Pinned: Equation 16.10; no syntactic definition prevents it

Rules of thumb

- k-anonymity protects names, not attributes. Ask what a class's sensitive values reveal, not just how big it is.

- Measure attribute disclosure against imputation from the population, or you will count the study's findings as leaks.
- A rare sensitive value needs a bound on the ratio of beliefs, not on their difference.
- Assume another release exists. A guarantee that is only about one table is not a guarantee about a person.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

17. Reconstruction attacks

17.1. Why this matters

A hospital keeps one sensitive bit per patient: whether they tested positive. It never releases the bits. It only answers counting questions: "how many of patients 3, 17, 42, … tested positive?" To be safe, it adds a little noise to every answer. Is that enough? The answer, due to Dinur and Nissim (2003), is a hard no unless the noise is large. If every answer is within $o(\sqrt{n})$ of the truth, where n is the number of patients, an attacker who asks a number of random questions only slightly larger than n can recover almost every bit by solving a linear program. If the attacker may ask all 2^n questions, an error of $o(n)$ is already too small. (Here $o(\sqrt{n})$ means an amount that grows more slowly than $\sqrt{n}$, so that its ratio to $\sqrt{n}$ goes to 0 as n grows; $O(\cdot)$, used below, means "at most a constant times".) A table of aggregates is a system of equations whose unknowns are the people in it, and enough equations determine the unknowns.

This is the **reconstruction game** of Threat models and privacy games. In that game the secret is the whole dataset (or one column of it), and the adversary is scored by the fraction of entries it recovers, compared with the baseline of guessing from the population, which for fair bits is $\frac{1}{2}$. That chapter showed that one exact count of n fair bits lets the adversary recover only about $\frac{1}{2} + 1/\sqrt{2\pi n}$ of them: knowing the total tells you which value is the majority, and nothing about who holds it. This chapter shows what happens with many counts.

The one idea that organizes the chapter is this. **Every answer is a linear equation in the secret bits, and the error of the answers is the only thing standing between the attacker and the solution.** To hide a wrong guess, the curator's error has to be as large as the amount by which that guess changes the answers. For a random query that amount is about $\sqrt{n}$ when the guess is wrong on a constant fraction of the bits, and for the query aimed at exactly the wrong bits it is about n; errors well below those scales cannot hide the solution. Errors that are independent from answer to answer, and do not grow with the number of queries, are averaged away by asking more. Dwork and Roth call this the **Fundamental Law of Information Recovery**: overly accurate answers to too many questions destroy privacy.

Table 17.1 lists the results and where they are used.

Table 17.1.: The results of this chapter and where each is used.

Result	Where it is used
Exponential attack: error E on all 2^n subset sums leaves at most $4E$ wrong bits	Why per-answer error must be of order n when queries are unlimited
Anti-concentration of a random subset sum (Paley–Zygmund)	The step that makes a random query informative about every bad candidate

Result	Where it is used
Linear-programming decoder: error $o(\sqrt{n})$ on $O(n \log n)$ random queries leaves $o(n)$ wrong bits	The Dinur–Nissim attack; the $\sqrt{n}$ threshold
Least squares under worst-case and random error	The attack you would actually run; how noise and the number of queries trade off
Sampling curator, via Hoeffding and the union bound	Error of order $\sqrt{n \ln m}$ can stop reconstruction, yet still be far from private
Information bound, via Fano	No attack can succeed with much fewer than $n/\ln n$ queries
Least squares against a deployed query system	Why noise that does not grow with the number of queries fails, whatever the query language allows
Census block reconstruction by constraint search	Why publishing many overlapping tables reveals the microdata

How to read this chapter. Read the toolkit, then the exponential attack, which is short and exact. The linear-programming section is the heart of the chapter; on a first pass read its statement, the lemma and the figure, and come back for the union-bound steps. The least-squares section is what the script runs. The Fundamental Law section puts the results together with two converses. The last two sections leave the theory: one replays a published attack on a commercial query system, and the other shows the same idea on real-looking census tables.

The concentration tools (Hoeffding's inequality, the union bound) are in Concentration inequalities. Entropy, mutual information, the data processing inequality (DPI) and Fano's inequality are in Information theory. Each is restated below where it is used. No privacy definition is used: Part 3 introduces the one that defends against these attacks, and Lower bounds reads this chapter's results as lower bounds on the error any defence must add.

Conventions. The secret database is a bit vector $d = (d_1, \dots, d_n) \in \{0,1\}^n$, one bit per person. A **subset-sum query** is a set $S \subseteq [n] = \{1, \dots, n\}$ of people, and it asks how many of them have bit 1. It is written as its 0/1 indicator vector f, with $f_i = 1$ when person i is in S; its true answer is $\sum_{i \in S} d_i = \langle f, d \rangle$. The attacker asks m queries, the rows of an $m \times n$ matrix A. The **curator** (the party holding d) returns $a = Ad + e$, where e is its error, one entry per query. "Error at most E" means $|e_j| \le E$ for every query j. γ is a fraction of wrong bits, β a failure probability and σ the standard deviation of random noise. We write ln for the natural logarithm and $\log_2$ for the logarithm in base 2. Threat models and privacy games wrote m for the number of bits; here n is the number of bits and m the number of queries.

17.2. Toolkit: three facts every derivation uses

17.2.1. Fact 1 — Subset sums are inner products

A subset sum adds up the bits of the people in the subset, so it is the inner product of the subset's indicator vector with the database: $\langle f, d \rangle = \sum_i f_i d_i$, which is linear in d. Stacking m

queries as the rows of A gives $a = Ad + e$: a linear system with n unknowns (the bits) and m equations, each off by its error. Table 17.2 shows a few of the $2^4 = 16$ subset sums of the database $d = (1, 0, 1, 1)$.

Table 17.2.: Six subset sums of $d = (1, 0, 1, 1)$. Each is a linear equation in the four secret bits.

Subset S	$\{1\}$	$\{2\}$	$\{1,2\}$	$\{3,4\}$	$\{2,3,4\}$	$\{1,2,3,4\}$
Indicator f	1000	0100	1100	0011	0111	1111
$\langle f, d\rangle$	1	0	1	2	2	3

With exact answers there is nothing to attack. The singletons $\{1\}, \dots, \{4\}$ alone reveal d exactly, one bit per answer, and any n queries whose indicator vectors are linearly independent do the same, because Gaussian elimination solves the system. Everything interesting in this chapter is about answers with error.

Linearity also tells you how an attacker rules out a wrong guess. If the attacker considers a candidate database c, the answers c would produce differ from the true ones by $\langle f, c\rangle - \langle f, d\rangle = \langle f, c - d\rangle$, the subset sum of the difference vector $c - d$. If, for some query, that difference is larger than the curator's error could explain, the candidate is ruled out. Every attack below is a way of finding such a query for every bad candidate.

17.2.2. Fact 2 — Moments of a random-sign sum

A random query includes each person with probability $\frac{1}{2}$, so its answer behaves like a sum of terms that are switched on or off by fair coins. The cleanest form of such a sum uses signs instead of on/off switches. Let $s_1, \dots, s_n$ be independent fair signs ($+1$ or -1 with probability $\frac{1}{2}$ each) and $X = \sum_i s_i a_i$ for fixed numbers a_i. The sum is centred at 0, and its spread is set by $\sum_i a_i^2$, because the variances of independent terms add. What the later proofs need is that X has no heavy tails: its fourth moment is at most 3 times the square of its second moment, the same ratio as for a normal variable. In symbols,

$$\mathbb{E}X = 0, \qquad \mathbb{E}X^2 = \sum_i a_i^2, \qquad \mathbb{E}X^4 = 3\Big(\sum_i a_i^2\Big)^2 - 2\sum_i a_i^4 \le 3\Big(\sum_i a_i^2\Big)^2. \tag{17.1}$$

The proof is a count of which terms survive when you take expectations. Expand $X^4 = \sum_{i,j,k,l} s_i s_j s_k s_l a_i a_j a_k a_l$. A term in which some index appears an odd number of times (once or three times) contains a factor $\mathbb{E}s_i = 0$ or $\mathbb{E}s_i^3 = 0$, and vanishes, because the signs are independent and $s_i^3 = s_i$ has mean 0. Two kinds of terms survive. If all four indices are equal, $s_i^4 = 1$, and these terms add up to $\sum_i a_i^4$. If the indices form two distinct pairs, each $s_i^2 = 1$; the pairs can be matched as $i = j \neq k = l$ or in two other ways, so these terms add up to $3\sum_{i \neq k} a_i^2 a_k^2 = 3((\sum_i a_i^2)^2 - \sum_i a_i^4)$. Adding the two kinds gives the formula, and dropping the negative term $-2\sum_i a_i^4$ gives the bound. The second moment is the same computation with two indices: only the terms with $i = j$ survive. The mean is 0, and every odd moment is 0, because flipping all the signs turns X into $-X$ without changing its distribution.

A concrete case. Take $a = (1, 1, 1)$. Of the eight sign patterns, two give $X = \pm 3$ (all signs equal) and six give $X = \pm 1$, so $\mathbb{E}X^4 = (2 \cdot 81 + 6 \cdot 1)/8 = 21$. The formula gives $3 \cdot 9 - 2 \cdot 3 = 21$, and the bound $3 \cdot 9 = 27$.

This is how the fact is used. A random subset has $f_i = (1 + s_i)/2$: the person is in when the sign is $+1$ and out when it is -1. So a random subset sum $\sum_i q_i z_i$ is the constant $\frac{1}{2}\sum_i z_i$ plus half a random-sign sum, and its fourth moment is at most 3 times its squared second moment. That ratio is what Fact 3 needs.

17.2.3. Fact 3 — Paley–Zygmund: a variable with a light fourth moment is not concentrated near 0

Markov's inequality (Concentration inequalities) says that a non-negative variable is rarely *far above* its mean. The attacks need the opposite: that a variable is not too often *far below* its mean, so that a random query does not usually give a tiny answer. That cannot hold for every variable. A variable that is 0 most of the time and huge once in a while has a large mean and is still usually 0. What rules this out is a second moment that is not much larger than the squared mean, since a rare huge value makes $\mathbb{E}[W^2]$ enormous. The **Paley–Zygmund inequality** makes this precise. For a random variable $W \geq 0$ with finite second moment and $0 \leq \lambda < 1$,

$$\Pr\left[W > \lambda\,\mathbb{E}W\right] \geq (1-\lambda)^2 \frac{(\mathbb{E}W)^2}{\mathbb{E}[W^2]}. \tag{17.2}$$

A lower bound on how often a variable is not close to zero is called **anti-concentration**.

The proof splits the mean $\mathbb{E}W$ into the part that comes from the event $B = \{W > \lambda\,\mathbb{E}W\}$ and the part that comes from its complement: $\mathbb{E}W = \mathbb{E}[W\mathbf{1}[B^c]] + \mathbb{E}[W\mathbf{1}[B]]$. On the complement $W \leq \lambda\,\mathbb{E}W$, so the first part is at most $\lambda\,\mathbb{E}W$. For the second part, use the Cauchy–Schwarz inequality $\mathbb{E}[UV] \leq \sqrt{\mathbb{E}[U^2]\,\mathbb{E}[V^2]}$ with $U = W$ and $V = \mathbf{1}[B]$; since $\mathbf{1}[B]^2 = \mathbf{1}[B]$ has mean $\Pr[B]$, this gives $\mathbb{E}[W\mathbf{1}[B]] \leq \sqrt{\mathbb{E}[W^2]\Pr[B]}$. Together, $\mathbb{E}W \leq \lambda\,\mathbb{E}W + \sqrt{\mathbb{E}[W^2]\Pr[B]}$, that is, $(1-\lambda)\mathbb{E}W \leq \sqrt{\mathbb{E}[W^2]\Pr[B]}$. Squaring both sides and dividing by $\mathbb{E}[W^2]$ gives Equation 17.2.

The linear-programming decoder uses this with W the square of a random subset sum: it needs a random query to move a bad candidate's answer by a lot with constant probability, and Fact 2 supplies the light fourth moment.

17.3. The exponential attack

17.3.1. Context

Start with the strongest attacker: it may ask every one of the 2^n subset sums. How large must the curator's error be before the attacker cannot pin d down? The answer is linear in n, and the proof is three lines.

17.3.2. Statement

The attacker cannot know d, but it can throw away every candidate that contradicts an answer. Call a candidate $c \in \{0,1\}^n$ **consistent** if each of its subset sums is within E of the published answer, $\left|a_S - \sum_{i \in S} c_i\right| \le E$ for every S; the true d is always consistent. The attacker outputs any consistent candidate. The reason it cannot be far from d is that the bits where c is wrong form two subsets, the ones it missed and the ones it invented, and the attacker has asked about both. On each of them c and d disagree by the size of the subset, while both have to be within E of the same answer, so each subset has at most $2E$ people. The number of wrong bits, the **Hamming distance** between c and d, therefore satisfies

$$\operatorname{dist}(c,d) = \#\{i : c_i \neq d_i\} \le 4E. \tag{17.3}$$

The bound is tight: if d has at least $\lfloor 2E \rfloor$ ones and $\lfloor 2E \rfloor$ zeros, some curator with error at most E makes a candidate at distance $2\lfloor 2E \rfloor$ consistent.

So a curator with error $E = o(n)$ is **blatantly non-private** in the sense of Dinur and Nissim: the attacker recovers all but $o(n)$ of the bits.

17.3.3. Derivation

1. **A consistent candidate exists**, because d itself is one: the true answers are within E of d's sums by assumption.
2. **Count the ones that the candidate missed.** Let $S_0 = \{i : d_i = 1, c_i = 0\}$. On S_0, d sums to $|S_0|$ and c sums to 0. Both sums are within E of the one answer a_{S_0}, so by the triangle inequality they are within $2E$ of each other: $|S_0| = |S_0| - 0 \le 2E$.
3. **Count the zeros that the candidate invented.** Let $S_1 = \{i : d_i = 0, c_i = 1\}$. Now c sums to $|S_1|$ and d to 0 on S_1, and the same argument gives $|S_1| \le 2E$.
4. **Add.** Every disagreement is in S_0 or in S_1, so $\operatorname{dist}(c,d) = |S_0| + |S_1| \le 4E$.

Tightness. To show a curator can really be this misleading, build a bad candidate and a curator that covers for it. Let $k = \lfloor 2E \rfloor$ and let c flip k of the ones of d to 0 and k of the zeros to 1, so c is at distance $2k$. For any S, $\sum_S (c_i - d_i)$ is the number of flipped zeros in S minus the number of flipped ones in S, so it lies in $[-k, k]$: the two databases' sums are never more than k apart. A curator that answers the midpoint $a_S = \frac{1}{2}\left(\sum_S c_i + \sum_S d_i\right)$ is then within $k/2 \le E$ of both, so its error is at most E and c is consistent.

17.3.4. Interpretation

The proof uses only two queries, S_0 and S_1: the people the candidate got wrong in each direction. Small, well-aimed subsets do all the work. But the attacker does not know which people it got wrong, so it does not know these two subsets in advance, and that is why it needs all 2^n answers.

This is not an efficient attack. The attacker checks 2^n candidates against 2^n answers. The next section replaces "all subsets" by a few times n random ones and "check every candidate" by a linear program. The price is that a random subset cannot aim at the wrong bits the way S_0 and S_1 do, so the error must be $o(\sqrt{n})$ instead of $o(n)$.

The bound is a worst case over curators. It holds for every curator, including one that picks its errors to fool this attacker. A specific curator can be much weaker than the bound suggests. One that rounds every answer to a multiple of 4 has error at most 2, but its rounding is a known function of the true sum, and an attacker who simulates the rounding on each candidate recovers d exactly (Exercise 1 in the exercise book).

17.3.5. Example: ten people, all 1024 subsets

The script draws $d = (1, 1, 1, 0, 0, 0, 0, 0, 0, 1)$, with four ones, and checks all 2^{10} candidates against all 2^{10} subsets. It needs a test for whether a candidate c can be made consistent by *some* curator with error at most E. The tightness argument gives it: if every subset sum of $c - d$ is at most $2E$ in absolute value, the midpoint curator has error at most E and keeps c; if some subset sum of $c - d$ exceeds $2E$, no single answer can be within E of both c's sum and d's, so no curator keeps c. The script counts the candidates that pass the test (Table 17.3).

Table 17.3.: The exponential attack on $n = 10$ bits. Every surviving candidate is within $4E$ of d, and the bound is attained.

Error E	0	0.5	1	1.5	2
Candidates that survive	1	35	242	630	912
Largest distance to d	0	2	4	6	8
Bound $4E$	0	2	4	6	8

The bound is attained at every E, as the tightness argument predicts: that argument needs $\lfloor 2E \rfloor$ ones and $\lfloor 2E \rfloor$ zeros to flip, at most 4 of each here, and d has four ones and six zeros. At $E = 2$, 912 of the 1024 candidates survive, so the attacker learns little: the bound $4E = 8$ is close to $n = 10$, and a guarantee of at most 8 wrong bits out of 10 says almost nothing. Figure 17.1 draws both rows over a finer grid of E, for another random database of ten bits, so its counts can differ from those of Table 17.3.

17.3.6. Check yourself

- Why does the derivation not need the curator's errors to be random? *(It only uses $|e_S| \le E$ for the two subsets S_0 and S_1. The errors can be chosen by an adversarial curator, even after seeing the attacker's candidate.)*
- With $n = 10^6$ people and every subset sum answered with error at most 1000, how many bits can the attacker get wrong? *(At most $4E = 4000$, or 0.4% of the bits, although each answer has error up to 1000.)*

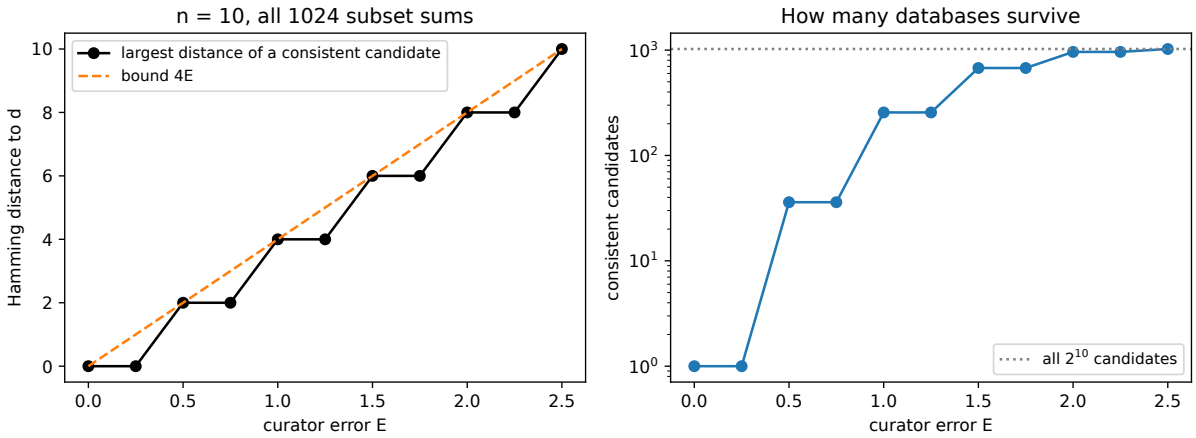

Figure 17.1.: The exponential attack on ten bits. Left: the largest Hamming distance between the true database and a candidate that some curator with error E can make consistent with all 1024 subset sums, against the bound $4E$. Right: the number of surviving candidates (log scale); at $E = 0$ only d survives.

17.4. The linear-programming decoder

17.4.1. Context

Asking 2^n questions is not realistic. Dinur and Nissim showed that a number of *random* subsets only a polylogarithmic factor above n suffices, with an efficient decoder: their proof asks $n(\ln n)^2$ of them, and the version proved below needs $O(n \log n)$. Instead of checking every bit vector, the decoder lets each unknown be any number between 0 and 1, finds a fractional vector consistent with the answers by linear programming (LP), and rounds it. A linear program finds a point that satisfies a list of linear inequalities, and it can be solved in time polynomial in the number of unknowns and inequalities.

The price is that the error must now be $o(\sqrt{n})$ instead of $o(n)$, and the reason is that a random query cannot aim at the wrong coordinates. Suppose a candidate differs from d by a vector with k entries of constant size. A random subset picks up each of those entries with probability $\frac{1}{2}$, so its sum of the difference behaves like a sum of k coin-flip terms, which fluctuates by about $\sqrt{k}$, not k. An error below $\sqrt{k}$ cannot hide that fluctuation. The key step is to show that the sum does fluctuate this much with constant probability, whatever the signs of the entries, and that is where the anti-concentration of Fact 3 comes in.

17.4.2. Statement

Let the m queries be independent uniformly random subsets (each person included with probability $\frac{1}{2}$). The true d satisfies every answer to within E, so the set of vectors that do so is not empty. The **linear-programming decoder** searches that set, after relaxing each bit to the interval $[0, 1]$ so that the search becomes a linear program. It solves the feasibility problem

$$\text{find } c \in [0,1]^n \text{ with } \left|\langle f_j, c\rangle - a_j\right| \le E \text{ for } j = 1, \dots, m, \tag{17.4}$$

which is a linear program: each absolute value is two linear inequalities, which makes $2m$ of them, and each $0 \le c_i \le 1$ is a box constraint, one per person. The decoder then rounds each c_i to the nearest bit.

The analysis rests on one lemma about a single random query. Think of z as the difference between a bad candidate and d. If z has many coordinates of at least a constant size (here $\frac{1}{3}$, the size left after a rounding step in the proof), then a random subset sum of z lands far from 0 with probability at least a constant, whatever the signs of the coordinates. "Far" means on the scale $\sqrt{\gamma n}$, the square root of the number of large coordinates, as the coin-flip picture above predicts.

Lemma (one random query catches a bad difference). Let $z \in \mathbb{R}^n$ have at least γn coordinates with $|z_i| \ge \frac{1}{3}$, and let f be a uniformly random subset. Then

$$\Pr\left[|\langle f, z\rangle| > \frac{\sqrt{\gamma n}}{12}\right] \ge \frac{3}{16}. \tag{17.5}$$

The theorem turns this into a guarantee for the decoder. A bad candidate survives the linear program only if every one of the m queries fails to catch it. Each query catches it with probability at least $\frac{3}{16}$, so it survives all m independent queries with probability at most $(13/16)^m$, which shrinks exponentially in m. There are many bad candidates, but after rounding them to a grid there are only finitely many, about $(n+1)^n$. Taking m large enough that $(n+1)^n(13/16)^m$ falls below a chosen failure probability β makes every bad candidate fail at once.

Theorem (Dinur–Nissim, in the form proved here). Fix d, γ and a failure probability β. If the curator's error is at most E with $2E + \frac{1}{2} \le \sqrt{\gamma n}/12$, and

$$m \ge \frac{n \ln(n+1) + \ln(1/\beta)}{\ln(16/13)}, \tag{17.6}$$

then with probability at least $1 - \beta$ over the queries, every solution of the linear program rounds to a vector with at most γn wrong bits, whatever errors the curator chose.

In words: error $o(\sqrt{n})$ on $O(n \log n)$ random subset sums lets the attacker recover all but $o(n)$ bits in polynomial time.

17.4.3. Derivation

The lemma. The plan is to apply Paley–Zygmund (Equation 17.2) to $W = Y^2$, where $Y = \langle f, z\rangle$ is the random subset sum. That needs the second and fourth moments of Y, and Fact 2 provides them once Y is written as a constant plus a random-sign sum. So write the random subset as $f_i = (1 + s_i)/2$ with independent fair signs s_i.

1. **Split the sum into a constant and a random-sign part.** $Y = \langle f, z\rangle = \mu + X$, with the constant $\mu = \frac{1}{2}\sum_i z_i$ and $X = \frac{1}{2}\sum_i s_i z_i$, a random-sign sum with coefficients $a_i = z_i/2$.
2. **Compute the second moment.** By Fact 2, $\mathbb{E}X = 0$, and the variance of the random-sign part, written τ^2 so that τ is its standard deviation, is $\tau^2 := \mathbb{E}X^2 = \sum_i a_i^2 = \frac{1}{4}\sum_i z_i^2$. Expanding $(\mu + X)^2$, the cross term $2\mu\,\mathbb{E}X$ vanishes, so $\mathbb{E}Y^2 = \mu^2 + \tau^2$.

3. **Bound the fourth moment by 3 times the squared second moment.** Expand $(\mu+X)^4 = \mu^4+4\mu^3X+6\mu^2X^2+4\mu X^3+X^4$. The terms with $\mathbb{E}X$ and $\mathbb{E}X^3$ vanish, since odd moments of a random-sign sum are 0. Fact 2 gives $\mathbb{E}X^4 \le 3(\sum_i a_i^2)^2 = \frac{3}{16}(\sum_i z_i^2)^2 = 3\tau^4$. So
$$\mathbb{E}Y^4 = \mu^4 + 6\mu^2\tau^2 + \mathbb{E}X^4 \le \mu^4 + 6\mu^2\tau^2 + 3\tau^4 \le 3(\mu^2+\tau^2)^2, \tag{17.7}$$
where the last step holds because $3(\mu^2+\tau^2)^2 = 3\mu^4 + 6\mu^2\tau^2 + 3\tau^4$ is larger by $2\mu^4 \ge 0$.
4. **Apply Paley–Zygmund** (Equation 17.2) with $W = Y^2$, whose mean is $\mu^2+\tau^2$. Step 3 says $(\mathbb{E}Y^2)^2/\mathbb{E}Y^4 \ge \frac{1}{3}$, so $\Pr[Y^2 > \lambda(\mu^2+\tau^2)] \ge (1-\lambda)^2(\mathbb{E}Y^2)^2/\mathbb{E}Y^4 \ge (1-\lambda)^2/3$.
5. **Drop the mean.** Since $\mu^2+\tau^2 \ge \tau^2$, the event $Y^2 > \lambda(\mu^2+\tau^2)$ implies $Y^2 > \lambda\tau^2$, that is $|Y| > \sqrt{\lambda}\,\tau$. So $\Pr[|Y| > \sqrt{\lambda}\,\tau] \ge (1-\lambda)^2/3$. A non-zero mean only helps: it pushes Y away from 0.
6. **Use the large coordinates to bound τ from below.** At least γn coordinates have $z_i^2 \ge \frac{1}{9}$, and the others contribute $z_i^2 \ge 0$, so $\tau^2 = \frac{1}{4}\sum_i z_i^2 \ge \frac{1}{4}\cdot\frac{\gamma n}{9}$ and $\tau \ge \sqrt{\gamma n}/6$.
7. **Choose $\lambda = \frac{1}{4}$.** Then $\sqrt{\lambda}\,\tau \ge \frac{1}{2}\cdot\sqrt{\gamma n}/6 = \sqrt{\gamma n}/12$, and the probability is at least $(3/4)^2/3 = (9/16)/3 = 3/16$. This gives Equation 17.5.

The theorem. The idea is to show that a solution with many wrong bits would give a difference vector that no random query catches, and that, with enough queries, no such vector exists.

1. **Consistent candidates differ from d by little on every query.** Both c and d are within E of every answer, so by the triangle inequality $|\langle f_j, c-d\rangle| \le 2E$ for all j, as in the exponential attack.
2. **A wrong bit is a large coordinate.** Rounding c_i gives the wrong bit only if c_i is on the far side of $\frac{1}{2}$ from d_i, that is, if $|c_i - d_i| \ge \frac{1}{2}$. So if the rounding has more than γn wrong bits, $z = c-d$ has more than γn coordinates of size at least $\frac{1}{2}$.
3. **Move to a finite set.** The linear program can return any point of the cube, and the union bound below needs a finite list of candidates. Round each c_i to the nearest multiple of $1/n$, giving c'. Each coordinate moves by at most $\frac{1}{2n}$, and a subset sum adds at most n coordinates, so $|\langle f, c-c'\rangle| \le n\cdot\frac{1}{2n} = \frac{1}{2}$ for every subset f. Hence $z' = c'-d$ satisfies $|\langle f_j, z'\rangle| \le 2E+\frac{1}{2}$ for all j, and still has more than γn coordinates of size at least $\frac{1}{2}-\frac{1}{2n} \ge \frac{1}{3}$ (for $n \ge 3$, since $\frac{1}{2}-\frac{1}{6} = \frac{1}{3}$).
4. **One grid point survives all queries only with small probability.** Fix one grid point c' whose z' has more than γn large coordinates. By the lemma (Equation 17.5), each random query has $|\langle f_j, z'\rangle| > \sqrt{\gamma n}/12$ with probability at least $\frac{3}{16}$, and by the assumption $2E+\frac{1}{2} \le \sqrt{\gamma n}/12$ such a query violates the bound of step 3. So each query lets z' pass with probability at most $1-\frac{3}{16} = \frac{13}{16}$. The queries are independent, so z' passes all m of them with probability at most $(13/16)^m$.
5. **Union bound over the grid.** The union bound (Concentration inequalities, Fact 2) says that the probability that at least one of several events happens is at most the sum of their probabilities. Each coordinate of a grid point takes one of the $n+1$ values $0, \frac{1}{n}, \dots, 1$, so there are at most $(n+1)^n$ grid points, and the probability that *some* bad grid point passes every query is at most $(n+1)^n(13/16)^m$. Taking logarithms, this is at most β exactly when $n\ln(n+1) - m\ln(16/13) \le \ln\beta$, that is, when $m\ln(16/13) \ge n\ln(n+1) + \ln(1/\beta)$, which is Equation 17.6.
6. **Conclude.** Outside that event, no bad grid point passes, so by step 3 no linear-program solution with more than γn wrong bits exists. The event depends only on the queries, not on the curator's errors, so the guarantee holds for every curator at once.

17.4.4. Interpretation

The threshold is $\sqrt{n}$ because a random query cannot aim at the wrong coordinates. Its inner product with a difference vector that has k coordinates of constant size fluctuates on the scale $\sqrt{k}$, as step 2 of the lemma computes. An error below that scale cannot hide $k = \gamma n$ wrong bits. An error of order $\sqrt{n}$ can, and Section 17.6 constructs a curator that does.

Among difference vectors, the balanced ones are the hard case. If the wrong coordinates of z all have the same sign, $\langle f, z\rangle$ has a large mean and escapes any small band almost surely. If they cancel, the mean is near 0 and only the fluctuation helps. Step 5 of the lemma covers both cases, because it drops the mean and relies on the fluctuation alone. Figure 17.2 shows the two cases.

The constants are poor, but the scaling is right. The theorem asks for E below about $\sqrt{\gamma n}/24$, which is what $2E + \frac{1}{2} \le \sqrt{\gamma n}/12$ gives after dividing by 2, and for $m \approx 33n$ at $n = 1000$ (the example below). The union bound over $(n+1)^n$ grid points costs the $\ln(n+1)$ factor. Sharper analyses need only $m = O(n)$ queries. Dwork, McSherry and Talwar (2007) go further with a variant of the decoder: instead of requiring every answer to be within E, which a single wildly wrong answer makes impossible, it minimizes the total absolute error $\|Ac - a\|_1$, and it tolerates a constant fraction of answers with arbitrarily large error. In practice, the least-squares decoder of the next section with $m = 4n$ already works at errors of about $0.2\sqrt{n}$.

Random queries are not essential either. Dinur and Nissim's queries were random to make the proof work, and real attacks use whatever queries the system answers. Cohen and Nissim (2020) ran a linear-programming reconstruction against Diffix, a commercial query system built to resist exactly this attack, and recovered every secret bit they targeted. Section 17.7 replays their attack.

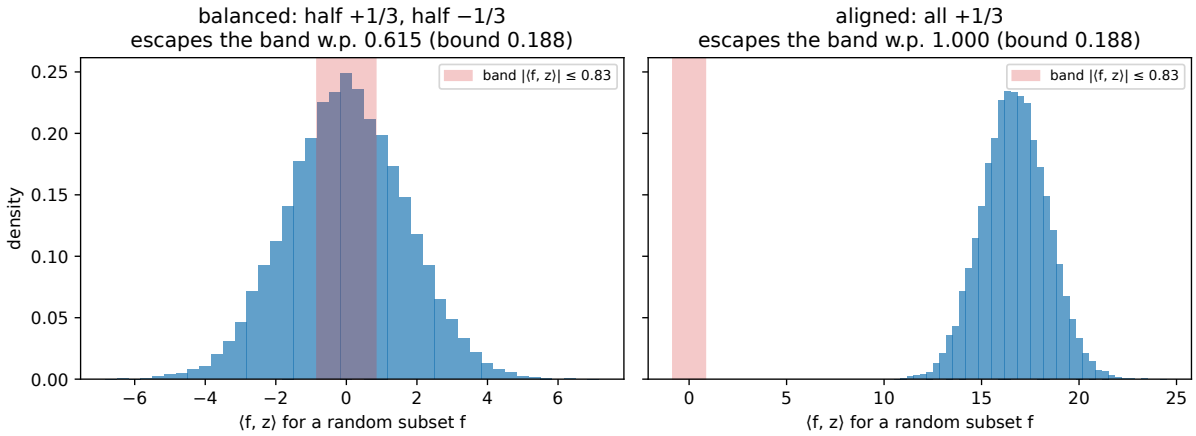

Figure 17.2.: A random subset sum of a difference vector z with $\gamma n = 100$ entries of size $\frac{1}{3}$ ($n = 1000$), over 20 000 random subsets, against the band $|\langle f, z\rangle| \le \sqrt{\gamma n}/12 = 0.83$ (red). Left: half the entries $+\frac{1}{3}$ and half $-\frac{1}{3}$, so the sum is centred at 0, yet it still leaves the band most of the time. Right: all entries $+\frac{1}{3}$, so the sum is centred far from the band. The lemma guarantees at least $\frac{3}{16} = 0.1875$ in both cases.

17.4.5. Example: what the theorem promises at $n = 1000$

Take $n = 1000$ people and target $\gamma = 0.1$, so at most $0.1 \times 1000 = 100$ wrong bits. The lemma's threshold is $\sqrt{\gamma n}/12 = \sqrt{100}/12 = 0.8333$. The script estimates the escape probability, the chance that a random subset sum lands outside the band ± 0.8333, over 100 000 random subsets for the two difference vectors of Figure 17.2: 0.6161 for the balanced one and 1.0000 for the aligned one, against the guaranteed 0.1875. The lemma is far from tight for both.

The theorem's condition $2E + \frac{1}{2} \le \sqrt{\gamma n}/12$ then allows an error of $E \le \sqrt{\gamma n}/24 - \frac{1}{4} = 0.4167 - 0.25 = 0.1667$. With failure probability $\beta = 0.01$, so that $\ln(1/\beta) = \ln 100$, Equation 17.6 asks for

$$m \ge \frac{1000 \ln 1001 + \ln 100}{\ln(16/13)} = 33\,295.04, \tag{17.8}$$

so at least 33 296 queries, about $33n$. Both constants are far from what the attack needs in practice, but they come with a complete proof.

17.4.6. Check yourself

- Why does the derivation round the linear program's solution to a grid before using the union bound? *(The solution can be any point in the cube, an infinite set. The union bound needs a finite list of candidates; the grid of step $1/n$ has $(n+1)^n$ points and moves every answer by at most $\frac{1}{2}$.)*
- If the curator could see the queries before choosing d, would the theorem still hold? *(The proof fixes d before the queries. With d chosen after the queries, add a union bound over the 2^n databases: the count of bad grid points grows to at most $2^n(n+1)^n$, which only adds $n \ln 2$ to the numerator of Equation 17.6.)*

17.5. Least squares under worst-case and random error

17.5.1. Context

The linear program needs a solver and a value of E. A simpler decoder needs neither. **Least squares** picks the vector whose answers come closest to the published ones, measured by the sum of squared differences, $\hat{x} = \arg\min_x \|Ax - a\|^2$. Setting the gradient $2A^\top(Ax - a)$ to zero gives the closed form $\hat{x} = (A^\top A)^{-1} A^\top a$. The decoder clips each coordinate to $[0, 1]$ and rounds it. Because $\hat{x}$ is a linear function of the answers, its error is a linear function of the curator's error, so you can analyse it exactly in two cases: errors chosen by an adversary, and independent random noise.

17.5.2. Statement

How much least squares amplifies the curator's error depends on how much A can shrink a vector. The **smallest singular value** $s_{\min}(A)$ is the smallest length $\|Ax\|$ over unit vectors x: the factor by which A shrinks the direction it shrinks most. Assume $m \ge n$ and that A has full column rank, so that $s_{\min}(A) > 0$.

Worst-case error. The decoder's error vector has length at most $\|e\|/s_{\min}(A)$, because undoing A can stretch a vector by at most $1/s_{\min}$. Each wrong bit is off by at least $\frac{1}{2}$, so it uses up at least $\frac{1}{4}$ of the squared length. If $|e_j| \le E$ for every j, so that $\|e\|^2 \le mE^2$, the least-squares decoder therefore gets at most

$$\frac{4\|e\|^2}{s_{\min}(A)^2} \le \frac{4mE^2}{s_{\min}(A)^2} \tag{17.9}$$

bits wrong. For random subsets, $s_{\min}(A) \approx \frac{1}{2}(\sqrt{m} - \sqrt{n})$, so $s_{\min}^2 \approx \frac{m}{4}(1 - \sqrt{n/m})^2$ and the bound becomes $16E^2/(1 - \sqrt{n/m})^2$; at $m = 4n$, $1 - \sqrt{1/4} = \frac{1}{2}$ and it is $64E^2$. So, if the cited asymptotics already hold at this size (the script checks them), error $E = o(\sqrt{n})$ gives $o(n)$ wrong bits with only $m = 4n$ queries. Section H.2 in the appendices proves a version with worse constants: $s_{\min}(A) \ge \sqrt{m}/14$ once m is of order $n \ln n$, so at most $784E^2$ bits are wrong with $m = O(n \log n)$ queries.

Random error. Now let the curator's errors be independent $\mathcal{N}(0, \sigma^2)$, normal with mean 0 and standard deviation σ. Each coordinate of the decoder's error is then also normal, and, as the derivation shows, its variance is about $\frac{4\sigma^2}{m-n}$: the noise σ^2 divided by roughly the number of equations beyond the n needed to determine d, times 4 because a random query includes each person only half the time. A bit is recovered when its error does not push it across $\frac{1}{2}$. Write Φ for the standard normal cumulative distribution function, so $\Phi(t)$ is the probability that a standard normal variable is below t. Each coordinate of $\hat{x} - d$ is approximately $\mathcal{N}(0, \frac{4\sigma^2}{m-n})$, and the expected fraction of bits recovered is approximately

$$\Phi\left(\frac{\sqrt{m-n}}{4\sigma}\right). \tag{17.10}$$

The argument of Φ is the distance $\frac{1}{2}$ to the wrong side, measured in standard deviations $2\sigma/\sqrt{m-n}$.

17.5.3. Derivation

Worst case.

1. **The decoder's error is linear in the curator's.** Substituting $a = Ad + e$, $\hat{x} = (A^\top A)^{-1} A^\top (Ad + e) = d + A^+ e$, with $A^+ = (A^\top A)^{-1} A^\top$ the pseudo-inverse. The d comes back exactly, because $(A^\top A)^{-1} A^\top A = I$.
2. **Bound its size.** Write A in its singular value decomposition, $A = U \operatorname{diag}(s_1, \dots, s_n) V^\top$ with U and V having orthonormal columns. Then $A^+ = V \operatorname{diag}(1/s_1, \dots, 1/s_n) U^\top$, whose largest singular value is $1/s_{\min}(A)$. So $\|\hat{x} - d\| = \|A^+ e\| \le \|e\|/s_{\min}(A)$.
3. **Clipping only helps.** Each d_i is in $[0, 1]$, and moving $\hat{x}_i$ to the nearest point of $[0, 1]$ cannot move it away from d_i.
4. **Count the wrong bits.** A wrong bit has $|\hat{x}_i - d_i| \ge \frac{1}{2}$, so it contributes at least $\frac{1}{4}$ to $\|\hat{x} - d\|^2$. Hence the number of wrong bits is at most $4\|\hat{x} - d\|^2 \le 4\|e\|^2/s_{\min}^2$, and $\|e\|^2 \le mE^2$ because each of the m errors is at most E in size. This is Equation 17.9.
5. **Estimate the singular value.** For a random matrix with m independent rows, $s_{\min}$ concentrates near $\sqrt{m} - \sqrt{n}$ times the scale of the rows (Vershynin, *High-Dimensional Probability*, ch. 4, for the general statement). Section H.2 in the appendices proves a constant-factor version for random subsets. Here the rows are $\frac{1}{2}(\mathbf{1} + s)$ with a random-sign vector s. The all-ones part sends every vector orthogonal to $\mathbf{1}$ to 0, so on those directions A acts as $\frac{1}{2}$

times a random-sign matrix, which gives the approximation $\frac{1}{2}(\sqrt{m}-\sqrt{n})$. The script checks it: at $n = 500$, $m = 2000$, $s_{\min} = 11.43$ against $\frac{1}{2}(\sqrt{2000}-\sqrt{500}) = \frac{1}{2}(44.72-22.36) = 11.18$. Substituting gives $4mE^2/(\frac{1}{4}(\sqrt{m}-\sqrt{n})^2) = 16E^2/(1-\sqrt{n/m})^2$.

Random noise. The plan is to find the variance of each coordinate of $\hat{x}-d$, then ask how often that normal error crosses $\frac{1}{2}$.

1. **The error is Gaussian.** $\hat{x}-d = A^+e$ is a linear map of a Gaussian vector, so given A it is Gaussian. A linear map G turns covariance $\sigma^2 I$ into $\sigma^2 GG^\top$, so its covariance is $\sigma^2 A^+(A^+)^\top = \sigma^2(A^\top A)^{-1}A^\top A(A^\top A)^{-1} = \sigma^2(A^\top A)^{-1}$.
2. **Compute the average Gram matrix.** $A^\top A = \sum_j q_j q_j^\top$ is a sum over the m queries. For a random subset f, $f_i^2 = f_i$ because f_i is 0 or 1, so $\mathbb{E}f_i^2 = \frac{1}{2}$; and for $i \neq k$ the two memberships are independent, so $\mathbb{E}f_i q_k = \frac{1}{4}$. Hence $\mathbb{E}[qq^\top] = \frac{1}{4}(I + \mathbf{1}\mathbf{1}^\top)$ and $\mathbb{E}[A^\top A] = \frac{m}{4}(I + \mathbf{1}\mathbf{1}^\top)$.
3. **Invert it.** $(I + \mathbf{1}\mathbf{1}^\top)^{-1} = I - \frac{1}{n+1}\mathbf{1}\mathbf{1}^\top$. To check, multiply out and use $\mathbf{1}^\top\mathbf{1} = n$: the product is $I + \mathbf{1}\mathbf{1}^\top - \frac{1}{n+1}\mathbf{1}\mathbf{1}^\top - \frac{n}{n+1}\mathbf{1}\mathbf{1}^\top = I$ (Exercise 4 in the exercise book). Its diagonal is $1 - \frac{1}{n+1} = \frac{n}{n+1} \approx 1$, so replacing $A^\top A$ by its mean gives a per-coordinate variance of about $\sigma^2 \cdot \frac{4}{m} = 4\sigma^2/m$.
4. **Correct for finite m.** $A^\top A$ fluctuates around its mean, and the inverse of a fluctuating matrix is on average larger than the inverse of its mean, just as $\mathbb{E}[1/Z] \geq 1/\mathbb{E}Z$ for a positive number Z. For Gaussian rows the exact mean is known. A sum of outer products of m independent Gaussian rows with covariance Σ is called a Wishart matrix, and if $A^\top A$ is Wishart with m rows and scale Σ, then $\mathbb{E}[(A^\top A)^{-1}] = \Sigma^{-1}/(m-n-1)$ (the inverse-Wishart mean; Muirhead 1982, ch. 3; Section H.1 in the appendices derives it step by step and checks that 0/1 rows come within about 3% of it). Using it with $\Sigma = \mathbb{E}[qq^\top]$ replaces m by $m-n-1$: the variance is $4\sigma^2\frac{n}{n+1}\cdot\frac{1}{m-n-1} \approx \frac{4\sigma^2}{m-n}$. The rows here are 0/1, not Gaussian, so this is an approximation; the simulations below check it.
5. **Find when a bit goes wrong.** A 0 rounds to 1 when its error exceeds $+\frac{1}{2}$; a 1 rounds to 0 when its error is below $-\frac{1}{2}$. Either way only one tail counts. The error has standard deviation $\frac{2\sigma}{\sqrt{m-n}}$, so the probability is $\Phi(-\frac{1}{2}\big/\frac{2\sigma}{\sqrt{m-n}}) = \Phi(-\frac{\sqrt{m-n}}{4\sigma})$. The fraction recovered is one minus that, which by the symmetry $1-\Phi(-t) = \Phi(t)$ of the normal curve is Equation 17.10.

17.5.4. Interpretation

At a fixed ratio of queries to people, only $\sigma/\sqrt{n}$ matters. With $m = \kappa n$, $\sqrt{m-n} = \sqrt{\kappa-1}\sqrt{n}$, so Equation 17.10 is $\Phi(\sqrt{\kappa-1}/(4\sigma/\sqrt{n}))$. Plotted against $\sigma/\sqrt{n}$, the curves for $n = 100$, 300 and 900 fall on top of each other (Figure 17.3). The scale of the threat is $\sqrt{n}$, as in the theorem.

Noise of order $\sqrt{n}$ is not automatically safe. At $\sigma = 0.25\sqrt{n}$ and $m = 4n$, the argument of Φ is $\sqrt{3}/(4\times 0.25) = \sqrt{3} \approx 1.73$, and least squares recovers about 96% of the bits. Recovery degrades smoothly as $\sigma/\sqrt{n}$ grows; it does not switch off at a threshold.

More queries average independent noise away. At a fixed σ, Equation 17.10 tends to 1 as m grows, because $m-n$ independent noisy equations average to an error of order $\sigma/\sqrt{m-n}$ per coordinate. To keep the attack at a fixed accuracy, the argument $\sqrt{m-n}/(4\sigma)$ must stay fixed, so the noise must grow like $\sqrt{m}$ (Figure 17.4). This is the second half of the Fundamental Law: a bound on the error of *each* answer is not enough when the number of answers is not bounded.

Worst-case errors hurt more than random ones of the same size. A curator that chooses its errors along the decoder's weakest direction, the right singular vector of $s_{\min}$, which least squares amplifies the most, does much more damage than Gaussian noise with the same scale, whose errors point in all directions equally. The bound Equation 17.9 is loose by more than a factor of 10 in the example below, but it is the only statement that holds for every curator.

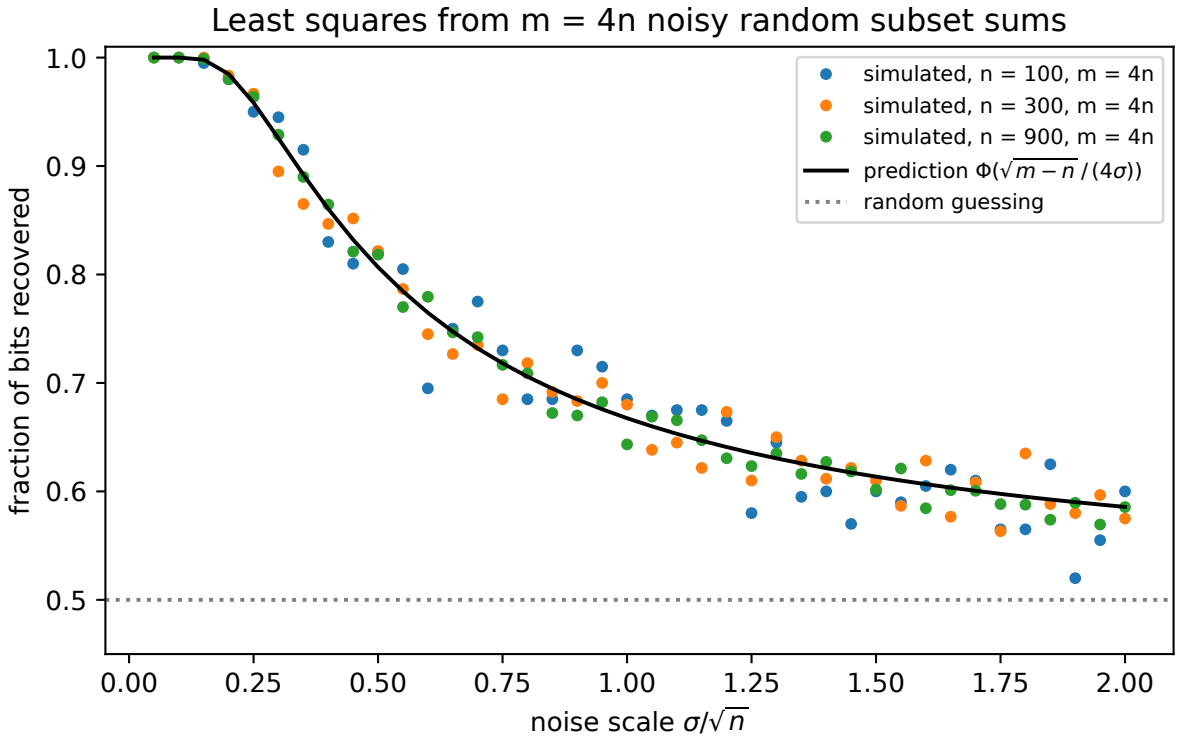

Figure 17.3.: Fraction of bits recovered by least squares from $m = 4n$ noisy random subset sums, against the noise scale in units of $\sqrt{n}$, for three database sizes. The black curve is Equation 17.10. The curves for different n coincide: the attack's success depends on $\sigma/\sqrt{n}$ only.

17.5.5. Example: $n = 500$ people, $m = 2000$ queries

The script averages over four random databases and query matrices (Table 17.4). Here $\sqrt{n} = \sqrt{500} = 22.36$, which gives the second row.

Table 17.4.: Least-squares reconstruction of $n = 500$ bits from $m = 2000$ random subset sums with Gaussian noise.

$\sigma/\sqrt{n}$	0.1	0.25	0.5	1	2
σ	2.24	5.59	11.18	22.36	44.72
Recovered, simulated	1.0000	0.9655	0.8130	0.6550	0.5875

$\sigma/\sqrt{n}$	0.1	0.25	0.5	1	2
Recovered, Equation 17.10	1.0000	0.9585	0.8069	0.6676	0.5858

The prediction is within 0.013 of every simulated value. By hand at $\sigma = 0.5\sqrt{n}$: $\sqrt{m-n}/(4\sigma) = \sqrt{1500}/44.72 = 0.866$, and $\Phi(0.866) = 0.807$.

For worst-case errors, the script measures $s_{\min}(A) = 11.43$ and runs a curator that adds $E \cdot \text{sign}(Av)$, with v the weakest right singular vector. That curator pushes every answer by the full E in the direction that least squares turns into the largest error along v. At $E = 1$, the bound Equation 17.9 allows $4 \times 2000 \times 1/11.43^2 = 61.2$ wrong bits, and this curator causes 0. At $E = 2$, the bound is four times larger, 245.0, and this curator causes 20. At $E = 0.25\sqrt{n} = 5.59$, the bound (1914.0) exceeds n and says nothing, while this curator causes 143 wrong bits, against about 17 for Gaussian noise with $\sigma = 5.59$ ($1 - 0.9655$ of 500).

17.5.6. Check yourself

- At $m = n$ with exact answers, least squares recovers d exactly. Why does the prediction Equation 17.10 fail there with noise? *(At $m = n$ the system is square and $s_{\min}$ is close to 0, so tiny errors are amplified enormously. The factor $1/(m-n-1)$ in the variance blows up; Figure 17.4 shows recovery near $\frac{1}{2}$ there.)*
- A curator adds independent noise with $\sigma = 2\sqrt{n}$ to every answer and lets anyone ask as many questions as they want. How many queries per person does least squares need to recover 90% of the bits? *(Solve $\Phi(\sqrt{m-n}/(4\sigma)) = 0.9$. The standard normal is below 1.2816 with probability 0.9, so $\sqrt{m-n}/(4\sigma) = 1.2816$; dividing through by $\sqrt{n}$ gives $\sqrt{m/n - 1} = 4 \times 2 \times 1.2816$, so $m/n = 106.1$.)*

17.6. The Fundamental Law of Information Recovery

17.6.1. Context

The attacks so far say when answers are too accurate. Two questions remain. Is error of order $\sqrt{n}$ really enough to stop reconstruction, or is it just where the proofs stop? And how many queries does *any* attack need? This section answers both, with one construction and one counting argument, and collects the results in the form Dwork and Roth call the Fundamental Law of Information Recovery: overly accurate answers to too many questions destroy privacy, and they do so spectacularly.

17.6.2. Statement

Table 17.5 collects the regimes. The first three rows are the attacks of the previous sections; the last two are the converses proved in this section.

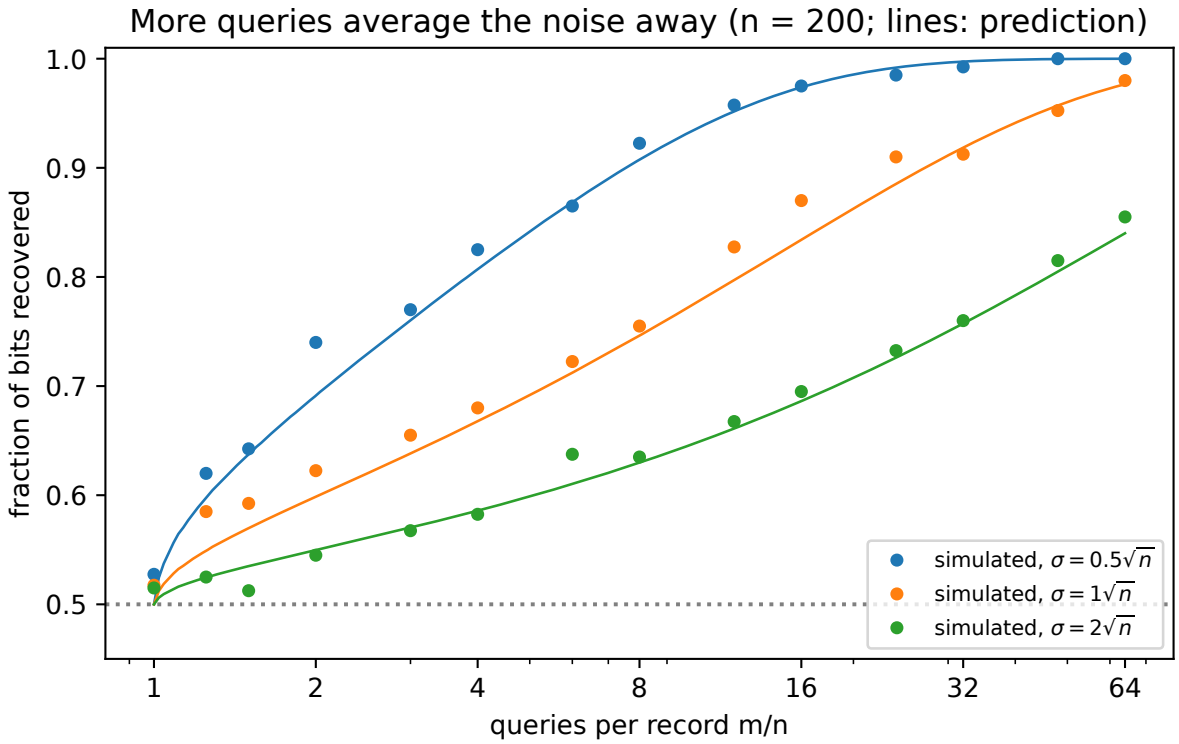

Figure 17.4.: Fraction of bits recovered by least squares at $n = 200$ as the number of queries grows, for three noise levels. Lines are Equation 17.10; dots are simulations. Near $m = n$ the system is barely determined and the noise is amplified; beyond that, more queries average the noise away, and even at $\sigma = 2\sqrt{n}$ the attack recovers most bits with $64n = 12\,800$ queries.

Table 17.5.: The regimes of reconstruction from subset sums. The first three rows are attacks; the last two are limits on attacks.

Queries	Error per answer	Outcome	Source
All 2^n subsets	at most E	at most $4E$ wrong bits; $E = o(n)$ is blatantly non-private	Equation 17.3
$O(n \log n)$ random subsets	at most E, $E = o(\sqrt{n})$	$o(n)$ wrong bits, by a linear program	Equation 17.6
m random subsets	independent $\mathcal{N}(0, \sigma^2)$	fraction recovered $\approx \Phi(\sqrt{m-n}/(4\sigma))$, tending to 1 as m grows	Equation 17.10
m arbitrary	$O(\sqrt{n \log m})$, sampling curator	no attack recovers more than $\frac{3}{4}$ of the bits	Equation 17.11
m, each answer one of V values	any	at least $n(1-h(\gamma))/\log_2 V$ queries are needed for γn wrong bits	Equation 17.12

A sampling curator. To show that error of order $\sqrt{n}$ can stop reconstruction, you need a curator whose errors are that small yet hide many bits completely. The idea is to answer from a random sample of the people and scale up. The curator fixes a sampling rate q and draws a secret set T, keeping each person independently with probability q, and answers every query by $a_j = \frac{1}{q} \sum_{i \in S_j \cap T} d_i$. Dividing by q makes each answer correct on average, and its error is a sum of independent zero-mean terms, one per person, so it is of order $\sqrt{n}$. People outside T never affect any answer, so nothing reveals their bits. Then, for a failure probability β, with probability at least $1 - \beta$ all m answers have error at most

$$\max_j |a_j - \langle f_j, d \rangle| \leq \sqrt{\frac{n \ln(2m/\beta)}{2q^2}}, \tag{17.11}$$

and if d is uniform, no attacker recovers an expected fraction of more than $q + \frac{1-q}{2}$ of the bits; at $q = \frac{1}{2}$, $\frac{1}{2} + \frac{1}{4}$, three quarters.

An information bound. To bound the number of queries any attack needs, count bits of information. The secret is n uniform bits, so it carries n bits of information. An answer that takes at most V values can carry at most $\log_2 V$ bits. A guess that is wrong on a fraction γ of the bits still leaves some uncertainty, measured by the **binary entropy** $h(\gamma) = -\gamma \log_2 \gamma - (1-\gamma) \log_2 (1-\gamma)$, the uncertainty in bits of a coin that comes up heads with probability γ. So the answers must carry at least $n(1 - h(\gamma))$ bits. Precisely, let d be uniform on $\{0,1\}^n$, and let each of the m answers take at most V values (for example, exact counts take $V = n + 1$ values). If an attacker's guess $\hat{d}$ has an expected fraction $\gamma \leq \frac{1}{2}$ of wrong bits, then

$$m \geq \frac{n\,(1 - h(\gamma))}{\log_2 V}, \tag{17.12}$$

where h is the binary entropy function in bits.

17.6.3. Derivation

The sampling curator's error (Hoeffding and the union bound). The plan is to bound one answer's error with Hoeffding's inequality, then all m answers at once with the union bound.

1. **Write the error as a sum.** With $t_i = \mathbf{1}[i \in T]$, the answer is $\sum_{i \in S_j} d_i t_i / q$, so the error of query j is $\sum_{i \in S_j} d_i (\frac{t_i}{q} - 1)$. Only the $k \le n$ people with $d_i = 1$ in S_j contribute. Their terms are independent, have mean $q \cdot \frac{1}{q} - 1 = 0$, and lie in $[-1, \frac{1}{q} - 1]$, an interval of length $\frac{1}{q}$.
2. **Apply Hoeffding's inequality to the sum.** Hoeffding's inequality (Concentration inequalities) says that the mean of independent bounded terms is unlikely to stray far from its expectation, with a tail that falls like a Gaussian's. For a mean $\bar{X}$ of k independent terms with range $\frac{1}{q}$ and expectation μ, it reads $\Pr[\bar{X} - \mu \ge t] \le \exp(-2kt^2q^2)$. A sum deviates by u when the mean deviates by u/k, so substituting $t = u/k$ and counting both tails, $\Pr[|\text{error}| \ge u] \le 2\exp(-2q^2u^2/k) \le 2\exp(-2q^2u^2/n)$, the last step because $k \le n$.
3. **Union bound over the m queries.** The probability that some answer has error at least u is at most the sum over the m queries: $\Pr[\text{some error} \ge u] \le 2m\exp(-2q^2u^2/n)$. Set this equal to β and solve: $2q^2u^2/n = \ln(2m/\beta)$, so $u^2 = n\ln(2m/\beta)/(2q^2)$, which is Equation 17.11.

What the attacker can learn. The idea is that a person outside T is invisible to every answer.

1. **The answers ignore the people outside T.** They are a function of T and of d_i for $i \in T$ only.
2. **So a person outside T is a fair coin to the attacker.** Given $i \notin T$, the answers are independent of d_i, which is a fair bit independent of everything else. Any guess of d_i is right with probability $\frac{1}{2}$.
3. **Average over who is in T.** Each person is in T with probability q, and at best the attacker gets all of those right. Each person is outside with probability $1 - q$, and then the attacker is right half the time. The expected fraction recovered is at most $q \cdot 1 + (1 - q) \cdot \frac{1}{2} = q + \frac{1-q}{2}$.

The information bound (entropy and Fano). Let $Y = (a_1, \ldots, a_m)$ be the answers, with the queries fixed. The **mutual information** $I(d; Y)$ is the number of bits the answers reveal about d: the uncertainty about d before seeing Y minus the uncertainty after, $H(d) - H(d \mid Y)$, where H is entropy. The plan is to bound it from above by what the answers can carry and from below by what a good guess requires.

1. **Bound what the answers can carry.** $I(d; Y) \le H(Y) \le \sum_j H(a_j) \le m \log_2 V$. Mutual information is at most the entropy of the output, because it is $H(Y)$ minus the non-negative $H(Y \mid d)$. The entropy of a tuple is at most the sum of the entropies, with equality only when the entries are independent. And a variable with V values has entropy at most $\log_2 V$ bits, attained when all values are equally likely.

2. **Processing cannot add information.** $\hat{d}$ is computed from Y, so $I(d;\hat{d}) \le I(d;Y)$ by the DPI, which says that no function of Y, random or not, can tell you more about d than Y itself.
3. **Write what a good guess requires.** $I(d;\hat{d}) = H(d) - H(d \mid \hat{d}) = n - H(d \mid \hat{d})$, since n uniform bits have entropy n. To bound the remaining uncertainty bit by bit, use the chain rule, $H(d \mid \hat{d}) = \sum_i H(d_i \mid \hat{d}, d_1, \dots, d_{i-1})$, and the fact that conditioning on less cannot reduce entropy: dropping $d_1, \dots, d_{i-1}$ and then all of $\hat{d}$ except $\hat{d}_i$ gives $H(d \mid \hat{d}) \le \sum_i H(d_i \mid \hat{d}) \le \sum_i H(d_i \mid \hat{d}_i)$.
4. **Apply Fano for one bit.** With two values, Fano's inequality reads $H(d_i \mid \hat{d}_i) \le h(P_i)$, where $P_i = \Pr[\hat{d}_i \ne d_i]$. The reason is short: if you knew both the guess $\hat{d}_i$ and whether it was wrong, you would know d_i. So the uncertainty about d_i given $\hat{d}_i$ is at most the uncertainty about "was the guess wrong?", a coin that comes up "wrong" with probability P_i, whose entropy is at most $h(P_i)$.
5. **Average with concavity.** h is concave (its graph bends downward), so by Jensen's inequality the average of its values is at most its value at the average: $\frac{1}{n}\sum_i h(P_i) \le h(\gamma)$, where $\gamma = \frac{1}{n}\sum_i P_i \le \frac{1}{2}$ is the expected fraction of wrong bits.
6. **Combine.** Steps 3 to 5 give $I(d;\hat{d}) \ge n - nh(\gamma)$, and steps 1 and 2 give $I(d;\hat{d}) \le m \log_2 V$. So $n - nh(\gamma) \le I(d;\hat{d}) \le m \log_2 V$, which is Equation 17.12.

17.6.4. Interpretation

Error of order $\sqrt{n}$ is necessary to stop reconstruction, and it can be enough. The sampling curator's error is $O(\sqrt{n \log m})$, only a logarithm above the $o(\sqrt{n})$ that the attacks need, and it caps every attacker at $\frac{3}{4}$ of the bits.

But it is not privacy. The same curator answers exactly for the people in T: an attacker with enough queries learns their bits perfectly, because least squares recovers d_i/q for every $i \in T$. Half the people are fully exposed so that the other half can be fully hidden. Stopping blatant reconstruction is a much weaker goal than protecting everyone, and Part 3 defines a guarantee that holds for every individual.

Reconstruction is also the most demanding attack on aggregates, not the only one. An attacker who only wants to know whether one person is in the data needs far less. Homer et al. (2008) showed this with the published allele frequencies of a genome-wide association study: comparing one person's DNA with those averages revealed whether the person had taken part. The US National Institutes of Health withdrew such summaries from public access the same year. That attack, a tracing attack, returns in Lower bounds, where it sets the noise any private release of many averages must add.

The attacks use about as few queries as possible. With exact counts, Equation 17.12 asks for at least $n(1 - h(\gamma))/\log_2(n+1)$ queries, of order $n/\ln n$, and least squares with exact answers uses n. Answers with error, published to a coarser precision, take fewer values, carry fewer bits each and need more queries.

The law has two halves, and a defence must control both. "Overly accurate" is the error scale: below $\sqrt{n}$ for random queries, below n for all queries. "Too many" is the count: independent noise per answer is averaged away unless it grows with the number of answers. That is why Part 3 tracks a budget that is spent across queries.

17.6.5. Example: three curators

The sampling curator at $n = 500$, $m = 2000$. With $q = \frac{1}{2}$ the script keeps 250 of the 500 people. The largest error over the 2000 queries is 28.00, or $28.00/\sqrt{500} = 1.25\sqrt{n}$. That is well under the Hoeffding bound at $\beta = 0.05$: with $q = \frac{1}{2}$, $2q^2 = \frac{1}{2}$, so Equation 17.11 is $\sqrt{2 \cdot 500 \ln(4000/0.05)} = 106.25$. (Hoeffding assumes the worst-case spread of each term; the actual terms have a smaller variance.) Least squares on these answers recovers 0.7560 of the bits, right at the ceiling of $\frac{3}{4}$.

The information bound at $n = 1000$. For at most 5% wrong bits, $h(0.05) = 0.2864$, so each person still needs $1 - 0.2864 = 0.7136$ bits. Exact answers ($V = 1001$) carry at most $\log_2 1001 \approx 9.97$ bits each and need $m \geq 1000 \times 0.7136 / \log_2 1001 = 71.6$ queries, so at least 72. If the curator rounds every count to a multiple of 10, an answer takes at most $\lfloor 1000/10 \rfloor + 2 = 102$ values (the 101 multiples of 10 from 0 to 1000, plus one to be safe; the script uses $\lfloor n/w \rfloor + 2$ for every width w), and the bound rises to 106.9. Rounding to multiples of 32 leaves $\lfloor 1000/32 \rfloor + 2 = 33$ values and a bound of 141.5. These are lower bounds for any attack, whatever its running time.

Independent noise with unlimited queries. From Table 17.4, a curator with $\sigma = 2\sqrt{n}$ lets least squares recover 0.5875 of the bits at $m = 4n$. If it answers any number of queries with the same noise level, an attacker who asks $m = 106.1\,n$ queries recovers 90% (the second Check yourself question of Section 17.5).

17.6.6. Check yourself

- Why does the information bound need the answers to take finitely many values? *(Step 1 bounds $H(a_j)$ by $\log_2 V$. A real-valued answer can carry unbounded information in its low-order digits, so the count of values is what limits it. Any published table has finite precision.)*
- A curator answers each query with an independent error of size $\sqrt{n \ln m}$ chosen at random. Is it as safe as the sampling curator? *(No. Its errors are independent across queries, so least squares averages them away as m grows. The sampling curator's errors come from one secret set T shared by all answers, so asking more never reveals the people outside T.)*

17.7. Attacking a deployed query system

17.7.1. Context

The company Aircloak offered a cash bounty in 2017 to anyone who could re-identify data behind Diffix, its commercial query system. Diffix let an analyst ask an unlimited number of counting queries in a restricted form of SQL, the standard language for querying databases. It protected the data in three ways. First, every answer carried Gaussian noise. A query is a count of the records that satisfy some **conditions**, such as "status is C" or "identifier between 2000 and 3000". Each condition added its own independent layer of noise with standard deviation 1. So the noise grew with the length of the query, not with the number of records or of queries. Second, the noise was **sticky**. It was computed from the query itself, so asking the same query twice returned the

same answer, and repetition could not average it away. Third, the query language forbade OR and restricted arithmetic, so that an analyst could not describe an arbitrary set of people.

That last rule targets the attack of this chapter. A random subset of n people is a list of about $n/2$ names, and without OR there is no short way to write it down. Each name written as a separate condition would add a layer of noise. Cohen and Nissim (2020) turned the problem around. Instead of drawing a random set and then describing it, they drew a random short description and took whatever set it selected. This section derives what least squares achieves with such queries, if they behave like random subsets, and checks by simulation that they do.

17.7.2. Statement

The queries. Each record has a public identifier i, a whole number. A query is fixed by four parameters: a prime p, a digit position j, an exponent e and a modulus r. It selects record i when the j-th digit after the decimal point of $(p \cdot i)^e$ is divisible by r. The exponent is fractional, so $(p \cdot i)^e$ has digits after the decimal point. Diffix's language allowed this arithmetic, and it counted the whole test as one condition, so the predicate adds only one layer of noise. Cohen and Nissim used the first 25 primes and the digit positions 1 to 5. They took the 14 exponents $0.5, 0.6, \ldots, 1.9$ other than 1, which would give a whole number, and the moduli 2 and 5. That makes $25 \times 5 \times 14 \times 2 = 3500$ queries. A digit is divisible by 2 for five of its ten values and by 5 for two of them, so the fraction ρ of records that a query includes is about $\frac{1}{2}$ or $\frac{1}{5}$.

The prediction. Write the query as its 0/1 indicator vector f, as before, and stack the m queries as the rows of A. Suppose these selections behave like independent coin flips, and the curator adds independent noise of standard deviation σ to each of the m distinct queries. Write v for the average of $\rho(1-\rho)$ over the queries, the average variance of one record's inclusion. Then each coordinate of the least-squares error has standard deviation about $\sigma/\sqrt{v(m-n-1)}$, and the expected fraction of bits recovered is about

$$\Phi\left(\frac{\sqrt{v\,(m-n-1)}}{2\sigma}\right). \tag{17.13}$$

With $\rho = \frac{1}{2}$ for every query, $v = \frac{1}{4}$, and the formula is Equation 17.10 with $m-n-1$ in place of $m-n$, a difference that vanishes as m grows.

17.7.3. Derivation

The derivation of Equation 17.10 used the inclusion probability $\frac{1}{2}$ only in the average Gram matrix. Redo that step with a general rate.

1. **The average Gram matrix of one query.** A query that includes each record independently with probability ρ has 0/1 entries, so $f_i^2 = f_i$ and $\mathbb{E}f_i^2 = \mathbb{E}f_i = \rho$, and $\mathbb{E}f_i q_k = \rho^2$ for $i \neq k$. So $\mathbb{E}[qq^\top] = \rho(1-\rho)I + \rho^2\mathbf{1}\mathbf{1}^\top$: the variance $\rho(1-\rho)$ on the diagonal, plus the square of the mean everywhere.
2. **Add up the queries.** The Gram matrix is a sum over the rows of A, namely $A^\top A = \sum_j q_j q_j^\top$. Summing step 1 over the m queries therefore gives $\mathbb{E}[A^\top A] = m(vI + w\mathbf{1}\mathbf{1}^\top)$, where v is the average of $\rho(1-\rho)$ and w the average of ρ^2.

3. **Invert it.** For $a, b > 0$, the matrix $aI + b\mathbf{1}\mathbf{1}^\top$ has inverse $\frac{1}{a}(I - \frac{b}{a+nb}\mathbf{1}\mathbf{1}^\top)$, which you can check by multiplying out as in Exercise 4 in the exercise book. Its diagonal is $\frac{1}{a}(1 - \frac{b}{a+nb})$, and the correction $\frac{b}{a+nb}$ is below $\frac{1}{n}$, negligible for all but tiny n. With $a = mv$ and $b = mw$, each diagonal entry of $\mathbb{E}[A^\top A]^{-1}$ is therefore about $1/(mv)$.
4. **Correct for finite m and finish.** As in step 4 of the earlier derivation, the inverse-Wishart mean (Section H.1) replaces m by $m - n - 1$. It is exact only for Gaussian rows, so here, as there, it is an approximation that the simulation checks. The covariance of the error is $\sigma^2(A^\top A)^{-1}$, so each coordinate has variance about $\sigma^2/(v(m - n - 1))$. A bit goes wrong when its error passes $\frac{1}{2}$, which gives Equation 17.13 as in step 5 there.

The derivation assumes that inclusions are independent coin flips. The digit of $(p \cdot i)^e$ is a fixed function of i, not a coin, so this is a modelling assumption, and the example below checks it by simulation.

17.7.4. Interpretation

The noise was not small by the chapter's standard. Each attack query also carried conditions on a range of identifiers and on the status asked about, and Cohen and Nissim report a total standard deviation of 4. For the smallest range, 73 records, that is $0.47\sqrt{n}$, far above the errors the linear-programming theorem tolerates. What defeated the noise was the number of queries. Diffix's noise did not grow with m, so 3,500 distinct queries averaged it away. That is the second half of the Fundamental Law: independent errors that do not grow with the number of answers are averaged away by asking more. Sticky noise does not change this, because it stops only the repetition of one query, and the attacker never repeats one.

Restricting the query language did not help either. A rule that forbids describing an arbitrary set is a rule about syntax, and any short formula that splits the records in a way unrelated to their secret bits serves as a random query. Aircloak then restricted the arithmetic Diffix accepts further, which blocks this formula but not the principle. A defence has to bound what the answers reveal, whatever the queries look like.

To stop the attack, the noise would have to grow with the number of queries. Solving Equation 17.13 for σ, keeping least squares down to 75% of the bits with 3,500 queries takes a standard deviation of about 19.5, which is 4.9 times what Diffix added. Once m is much larger than n, ten times as many queries need about $\sqrt{10}$ times as much noise (Exercise 10 in the exercise book). The privacy definition of Part 3 makes that growth automatic, because it charges every answer against a fixed privacy budget.

17.7.5. Example: replaying the attack

Cohen and Nissim attacked the loans table of a public banking dataset, 827 loans with a status from A to D. The secret was one bit per loan: whether the loan had a given status. They restricted the queries to four ranges of identifiers, holding between 73 and 142 loans. In each range they asked the 3,500 queries and decoded the answers with the linear program of Dwork, McSherry and Talwar (2007). The program reconstructed all four ranges perfectly.

The script repeats the experiment on synthetic data with the least-squares decoder. It draws 73 distinct identifiers, as many as Cohen and Nissim's smallest range held, and gives each a fair secret

bit. It then answers all 3,500 digit-predicate queries with Gaussian noise of standard deviation 4. The inclusion rates are as the statement assumed: on average a query with modulus 2 includes 0.502 of the records, and a query with modulus 5 includes 0.198. Averaging $\rho(1-\rho)$ query by query, which is slightly less than plugging in these two averages, gives $v = 0.2016$. Over 50 runs the attack recovered every bit in 49, an average of 0.02 wrong bits per run, while Equation 17.13 predicts 0.036 wrong bits per run. With 142 records it was perfect in 45 of 50 runs, an average of 0.10 wrong bits against 0.077 predicted. Agreement this close also says that the digit predicates are close enough to independent coin flips for the model.

Figure 17.5 shows the same attack as the number of queries grows. With a few hundred queries least squares already recovers most bits, and the prediction follows the simulation. Even with noise of $2\sqrt{n} = 17.1$, the prediction for all 3,500 queries is 0.779 of the bits.

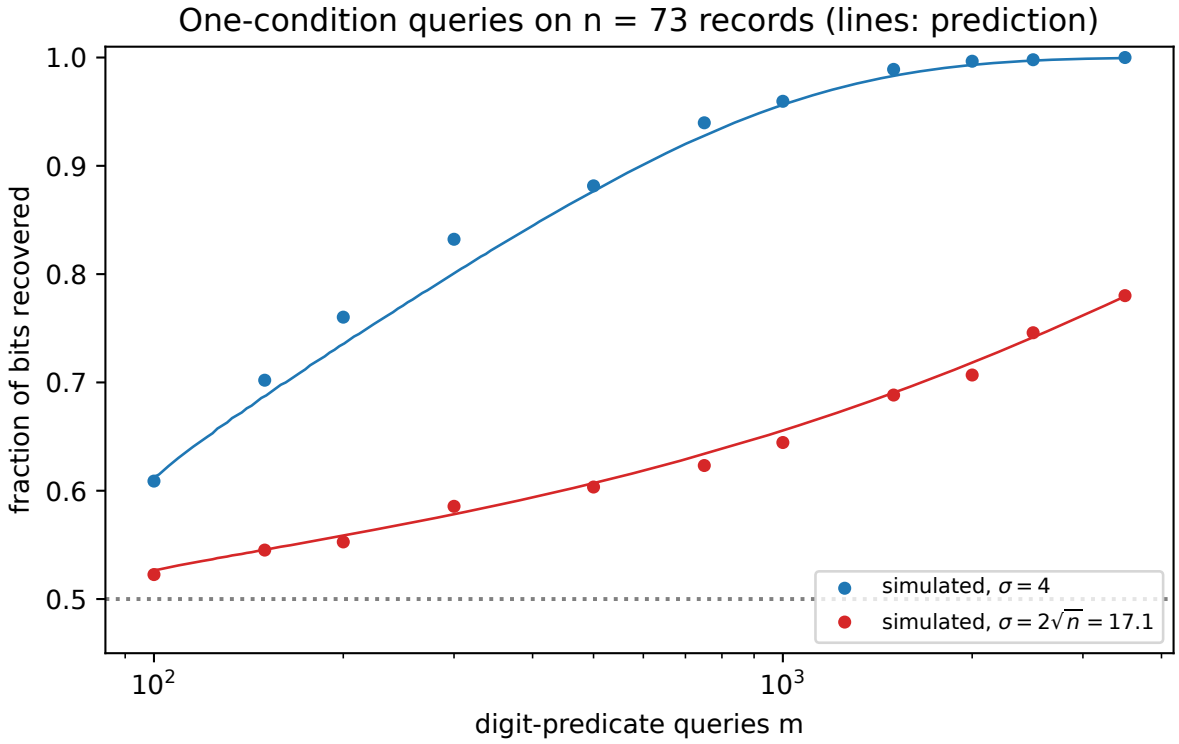

Figure 17.5.: Fraction of 73 secret bits recovered by least squares from the first m of the 3,500 digit-predicate queries, for noise of standard deviation 4 (as reported for Diffix) and $2\sqrt{n}$, averaged over 20 runs. Lines are Equation 17.13.

17.7.6. Check yourself

- Diffix returned the same noisy answer when the same query was asked again. Why did that not protect it? *(The attack never asks a query twice. Each of the 3,500 predicates is a different query, so each got its own noise, and least squares averaged the independent errors away.)*

- A query that includes each record with probability $\frac{1}{5}$ is less informative than one with probability $\frac{1}{2}$. By how much, in this analysis? *(Each query contributes $\rho(1-\rho)$ to v: $\frac{4}{25} = 0.16$ against $\frac{1}{4}$. So a query with modulus 5 is worth 0.64 of a query with modulus 2.)*

17.8. Reconstructing a census block

17.8.1. Context

National statistical offices publish many tables computed from the same confidential records: counts by age, sex and race for every block, the same counts by household type, medians and means, and so on. Each table cell is a query. Garfinkel, Abowd and Martindale (2019) showed with a toy block of seven people that a modest set of published statistics can determine every person's age, sex, race and marital status, and that a constraint solver finds the solution in seconds. Finding whole-number ages that satisfy a list of constraints is an integer program, a problem that is hard in the worst case, but off-the-shelf satisfiability and integer-programming solvers handle blocks of this size easily. By then the US Census Bureau had already run the attack on its own 2010 publications at national scale, an experiment Abowd (2021) later described in detail.

This section repeats the toy experiment with a block of our own. It is a reconstruction game where the queries are not random subsets but the tables an agency actually publishes, and where the decoder is a search over all databases consistent with them.

17.8.2. Statement

A fictional block has seven people, each with an age (a whole number from 0 to 99), a sex, a race (Black or White) and a marital status, and nobody under 18 is married. Table 17.6 is everything the agency publishes about the block. Means are given to two decimals, which is enough to recover the sum of ages in each group exactly: the sum is a whole number, and $34.29 \times 7 = 240.03$, so the total is 240.

Table 17.6.: The published statistics for a fictional census block of seven people. A median over an even count is the average of the two middle ages.

Group	Count	Median age	Mean age
Total	7	33	34.29
Female	4	31	30.25
Male	3	33	39.67
Black	4	33.5	36.25
White	3	33	31.67
Married	4	43.5	47.75

Each statistic is a constraint on the unknown ages and labels, and the claim is that together they leave no freedom at all.

Claim. Exactly one block of seven people is consistent with Table 17.6, and it is the true one (Table 17.7).

Table 17.7.: The block reconstructed from Table 17.6, which is the true block.

Person	1	2	3	4	5	6	7
Age	7	15	27	33	35	52	71
Sex	F	M	F	M	F	F	M
Race	B	B	W	W	W	B	B
Married	no	no	no	yes	yes	yes	yes

17.8.3. Derivation

The decoder enumerates candidate blocks and discards those that contradict a published number. Each step uses the statistics in a way you can check by hand.

1. **Turn means into sums.** Mean × count gives the sum of ages: total 240, female 121, male 119, Black 145, White 95, married 191. The sums for female and male add to 240, so the male mean is implied by the other two; the same holds for Black and White. Single people number $7 - 4 = 3$ and their ages sum to $240 - 191 = 49$.
2. **Enumerate the women's ages.** Sort them $a \le b \le c \le d$. With four women the median is the average of the two middle ages, so $b + c = 2 \times 31 = 62$, and the sum gives $a + d = 121 - 62 = 59$. Choose $b \le 31$ (so that $c = 62 - b \ge b$) and $a \le b$; then $d = 59 - a$ must be at least $c = 62 - b$, that is $a \le b - 3$. For each b from 3 to 31 that leaves $a = 0, \dots, b - 3$, which is $b - 2$ choices, so there are $1 + 2 + \cdots + 29 = \sum_{k=1}^{29} k = 435$ age lists in all.
3. **Enumerate the men's ages.** Three sorted ages with median 33 and sum 119: the middle one is 33, so $x_1 + x_3 = 119 - 33 = 86$ with $x_1 \le 33 \le x_3 \le 99$. Every x_1 from 0 to 33 gives $x_3 = 86 - x_1$ between 53 and 86, which is allowed, so x_1 ranges over $0, \dots, 33$: 34 lists.
4. **Combine and check the total median.** The $435 \times 34 = 14\,790$ combined age vectors are all distinct; 12 906 have overall median 33.
5. **Check the race split.** For each age vector, try every way of choosing 4 of the 7 people as Black ($\binom{7}{4} = 35$ ways), and keep it if the Black ages have median 33.5 and sum 145 and the White ages have median 33 and sum 95. Only 387 age vectors admit such a split.
6. **Check the marital split** in the same way (married median 43.5, sum 191, everyone married at least 18): 33 age vectors admit one.
7. **Require all three at once.** Exactly one age vector admits a valid sex split, race split and marital split, and its splits are unique. Assigning each person the labels of the splits gives Table 17.7.

Each published statistic removes most of the remaining candidates. The block is not determined by any one table, but by their intersection.

17.8.4. Interpretation

Withholding one number rarely helps. Figure 17.6 repeats the search with each of the twelve medians and means withheld in turn. Eight of the twelve leave the block uniquely determined, because the remaining statistics imply the missing one or pin the block down without it (Exercise 8 in the exercise book). The worst case for the attacker, withholding the married mean, still

leaves only 45 consistent blocks, and 51% of them have the true sex, race and marital pattern of all seven people.

Real publications are far more exposed than this toy, because published tables overlap. Real tables cross-classify many variables at many geographic levels, so the same people appear in thousands of cells. That is exactly the "many queries" condition of the Fundamental Law. The main protection of the 2010 Census, swapping a small fraction of households between blocks, changes some answers but leaves most constraints exact. Coarsening (age bands instead of single years) and suppressing small cells, common in other tables, have the same weakness: they remove some constraints and leave the rest exact. A suppressed cell does not even vanish from the system. Publishing that a count was suppressed tells the attacker that it is below the threshold, and the solver adds that inequality like any other constraint.

The attack also works at scale. The Census Bureau's own reconstruction of the 2010 Census, described by Abowd (2021), rebuilt a record for each of the 308,745,538 people counted, with block, sex, age, race and ethnicity. About 46% of the reconstructed records matched a real person exactly on all five fields, and about 71% matched when the age was allowed to be off by one year. Linking them to commercial data confirmed the identity of about 17% of the population. The Bureau's response was to change its disclosure-avoidance method for the 2020 Census to one based on the privacy definition of Part 3.

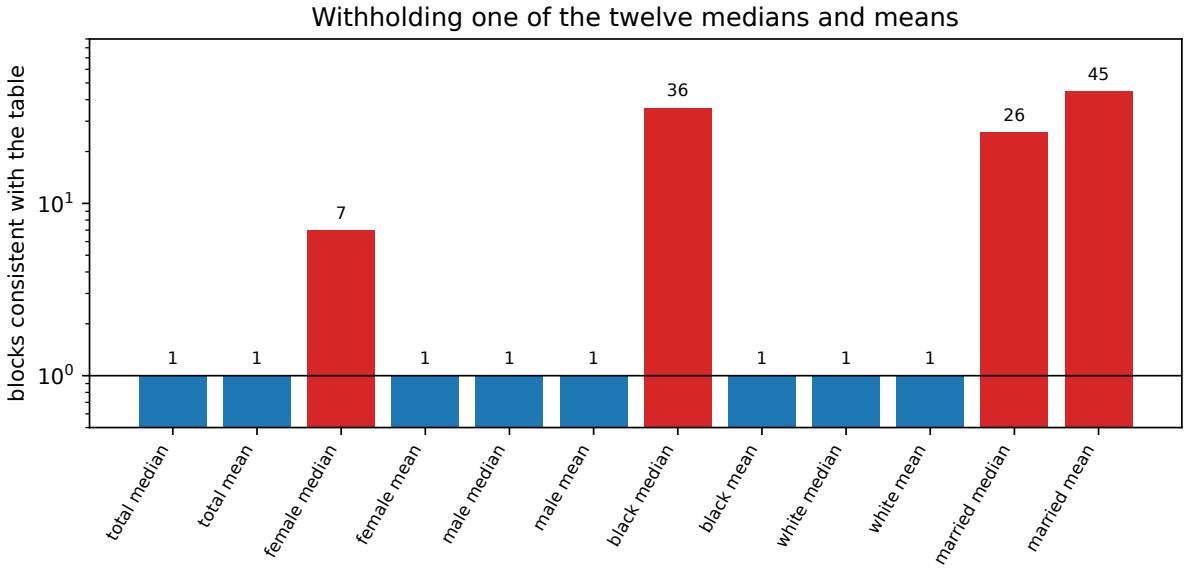

Figure 17.6.: Number of seven-person blocks consistent with Table 17.6 when one median or mean is withheld (log scale). Blue bars: the block is still unique. Red bars: a few candidates remain, still far fewer than the possible blocks.

17.8.5. Example: what each withheld statistic leaves

Table 17.8 lists, for each statistic whose removal leaves more than one block, how many blocks remain, how many different sex/race/marital patterns they show, and what share of them has the true pattern.

Table 17.8.: Blocks consistent with the published table when one statistic is withheld.

Withheld	Consistent blocks	Distinct sex/race/marital patterns	Share with the true pattern
Female median	7	6	0.14
Black median	36	3	0.64
Married median	26	4	0.46
Married mean	45	7	0.51
Any of the other eight	1	1	1.00

Withholding the married mean hurts the attacker most, because it is the only statistic about the single people's ages: without it, the married and single sums are no longer known. Withholding the female mean changes nothing, because the total and male sums imply it: it equals $(240 - 119)/4$.

17.8.6. Check yourself

- Why can the attacker turn a mean published to two decimals into an exact sum? *(The sum is a whole number and the mean is the sum over a count of at most 7. Two decimals locate the sum to within* $7 \times 0.005 = 0.035$*, which leaves one whole number.)*
- If the agency published only counts and no ages, could the attacker still reconstruct something? *(Yes: counts of every cross-classification by sex, race and marital status fix how many people fall in each combination, which is the attribute pattern. Ages need age statistics, which real tables publish in single years for small groups.)*

17.9. Code: check every attack by computation and simulation

The script code/reconstruction.py computes every number in this chapter and draws every figure. Each attack, bound and curator is a small typed function, and the figures loop over them. It uses NumPy only and runs in well under a minute. From the repository root:

```
uv run python code/part02-attacks/reconstruction.py
```

Output (seed 0), summarized in Table 17.9:

Table 17.9.: The script's output with the default seed.

Experiment	Result
Fact 1, $d = (1, 0, 1, 1)$	The 16 subset sums, in binary order: 0, 1, 0, 1, 1, 2, 1, 2, 1, 2, 1, 2, 2, 3, 2, 3
Exponential attack, $n = 10$	Survivors 1, 35, 242, 630, 912 and largest distance 0, 2, 4, 6, 8 for $E = 0, 0.5, 1, 1.5, 2$; rounding to multiples of 2 or 4: one survivor

Experiment	Result
Fact 2	$\mathbb{E}(s_1 + s_2 + s_3)^4 = 21$ by enumeration and by formula
Lemma, $n = 1000$, $\gamma = 0.1$	Threshold 0.8333; escape probability 0.6161 (balanced), 1.0000 (aligned), bound 0.1875
Theorem, $n = 1000$, $\gamma = 0.1$, $\beta = 0.01$	$E \le 0.1667$; $m \ge 33\,296$ ($33.3n$)
Least squares, Gaussian noise, $n = 500$, $m = 2000$	Table 17.4; m/n for 90% recovery: 106.1 at $\sigma = 2\sqrt{n}$, 657.9 at $5\sqrt{n}$
Least squares, worst case, $n = 500$, $m = 2000$	$s_{\min} = 11.43$ (approximation 11.18); wrong bits 0, 20, 143 for $E = 1, 2, 5.59$, bounds 61.2, 245.0, 1914.0
Sampling curator, $q = \frac{1}{2}$	Kept 250 of 500; max error 28.00 ($1.25\sqrt{n}$); Hoeffding bound 106.25; recovered 0.7560
Information bound, $n = 1000$	$\gamma = 0.05$: 71.6 (exact), 106.9 (rounded to 10), 141.5 (rounded to 32); $\gamma = 0.01$: 92.2 (exact)
Digit-predicate queries, $\sigma = 4$	3500 queries; inclusion 0.502 (modulus 2), 0.198 (modulus 5), $v = 0.2016$. $n = 73$: perfect in 49 of 50 runs, 0.02 wrong bits per run, predicted fraction 0.99950; $n = 142$: perfect in 45 of 50, predicted 0.99946. σ for 75% recovery 19.5 (4.9 times 4); at $\sigma = 2\sqrt{n} = 17.1$, predicted 0.779
Census block	435 female and 34 male age lists; 14 790 age vectors; 12 906 after the total median; 387 with a race split; 33 with a marital split; 1 block; Table 17.8

tests/test_reconstruction.py checks that the output still matches.

What to take from it. Six things stand out. First, the exponential attack's bound is exact: every surviving candidate is within $4E$ of d, and some candidate is at exactly $4E$, so no better guarantee is possible for that attack. Second, the proved constants are pessimistic, but the scaling is not. The theorem tolerates only $E \le 0.17$ at $n = 1000$, yet least squares with $m = 4n$ recovers 96.55% of 500 bits at $\sigma = 5.59$, because both are governed by the same $\sqrt{n}$ scale and only the proof's constants differ. Third, the least-squares prediction is accurate: Equation 17.10 is within 0.013 of the simulation at every noise level, once the $m - n$ correction is included. Fourth, the sampling curator meets its ceiling: its answers have error $1.25\sqrt{n}$, and the best decoder gets exactly the people in its sample, plus half of the rest by chance. Fifth, a real query system falls to the same analysis: one-condition "random" queries behave like random subsets, and noise that does not grow with the number of queries is averaged away. Sixth, published tables are systems of equations: eighteen numbers determine seven people's ages, sexes, races and marital statuses.

17.11. Cheat sheet

$d \in \{0,1\}^n$ is the secret, A the $m \times n$ 0/1 query matrix, $a = Ad + e$ the answers, E a bound on every $|e_j|$, σ the scale of random noise, γ a fraction of wrong bits, β a failure probability. Table 17.10 collects the results.

Table 17.10.: Every result in this chapter.

Result	Statement	Proof idea
Exponential attack	All 2^n subsets, error E: any consistent c has $\mathrm{dist}(c,d) \le 4E$; tight	Triangle inequality on S_0 and S_1
Paley–Zygmund	$\Pr[W > \lambda\,\mathbb{E}W] \ge (1-\lambda)^2(\mathbb{E}W)^2/\mathbb{E}W^2$	Split $\mathbb{E}W$; Cauchy–Schwarz

Result	Statement	Proof idea
Anti-concentration lemma	γn entries of z at least $\frac{1}{3}$: $\Pr[\lvert\langle f, z\rangle\rvert > \sqrt{\gamma n}/12] \geq \frac{3}{16}$	Fourth moment $\leq 3\times$ squared second moment
Linear-programming decoder	$2E + \frac{1}{2} \leq \sqrt{\gamma n}/12$ and $m \geq \frac{n\ln(n+1)+\ln(1/\beta)}{\ln(16/13)}$: at most γn wrong bits	Grid of step $1/n$, lemma, union bound
Least squares, worst case	Wrong bits $\leq 4mE^2/s_{\min}^2 \approx 16E^2/(1-\sqrt{n/m})^2$	$\lVert A^+ e\rVert \leq \lVert e\rVert/s_{\min}$
Least squares, Gaussian noise	Fraction recovered $\approx \Phi(\sqrt{m-n}/(4\sigma))$	Covariance $\sigma^2(A^\top A)^{-1}$; inverse-Wishart mean
Sampling curator	Error $\leq \sqrt{n\ln(2m/\beta)/(2q^2)}$; recovery $\leq q + \frac{1-q}{2}$	Hoeffding, union bound; unsampled bits are independent of the answers
Information bound	$m \geq n(1-h(\gamma))/\log_2 V$	DPI, chain rule, Fano for one bit, concavity of h
Least squares, inclusion rate ρ	Fraction recovered $\approx \Phi(\sqrt{v(m-n-1)}/(2\sigma))$, v the mean of $\rho(1-\rho)$	Gram matrix $m(vI + w\mathbf{1}\mathbf{1}^\top)$

Rules of thumb

- The threat scale of a random subset-sum query is $\sqrt{n}$; of the worst query, n. Errors well below that scale reveal the database.
- Independent noise per answer is averaged away by more answers: to keep reconstruction at bay, the noise must grow like $\sqrt{m}$.
- A curator that stops blatant reconstruction can still expose many individuals completely; stopping reconstruction is not the same as privacy.
- Exact counts carry at most $\log_2(n+1)$ bits each, so about $n/\ln n$ of them can already determine n bits.
- Restricting what queries may say is not a defence: any short formula that splits the records independently of their secrets is a random query.
- Every published table cell is a constraint. Many overlapping tables of exact or nearly exact statistics are a solvable system.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

Part III.

Differential privacy foundations

The previous part showed that models and statistics leak: membership, attributes, training text, whole datasets. This part introduces the defence that the rest of the book is built on, **differential privacy (DP)**, and develops it far enough that you can prove a new mechanism private, calibrate its noise, compose it with others, and say what any such mechanism must cost. The finer tools for tracking privacy over many steps (Rényi DP, numerical accountants, amplification by subsampling) come in the next part, which builds directly on this one.

Who this part is for

You are expected to have read the Prerequisites and Threat models and attacks. This part uses the max-divergence and the hockey-stick divergence, the data processing inequality, the trade-off function of a hypothesis test, and tail bounds for the Laplace and normal distributions, all derived in the prerequisites. It uses the games and the advantage of the attacks part, since the definition of DP is a bound on exactly those games.

The common thread

A randomized algorithm is differentially private when changing one person's record changes the distribution of its output by at most a factor e^{ε}, up to a small slack δ. Everything in this part follows from reading that one sentence in three ways.

- **As a bound on a divergence.** Pure ε-DP bounds the max-divergence between the outputs on neighbouring datasets, and (ε, δ)-DP bounds their hockey-stick divergence. The data processing inequality then gives post-processing for free, and the **privacy loss** $L_{D,D'}$, the log of the likelihood ratio, is the quantity whose sum governs composition.
- **As a bound on every attack.** By the hypothesis-testing view, $\mathrm{FPR} + e^{\varepsilon}\,\mathrm{FNR} \geq 1 - \delta$ for any test of "was this record used". Every game of the attacks part, from membership inference to reconstruction, is therefore capped by a number you can compute before the data is touched.
- **As a budget to spend.** Privacy is lost a little at each release. Noise is calibrated to how much one record can move the answer (its **sensitivity**), losses add up under composition, and lower bounds say how much accuracy no mechanism can avoid paying.

Table 17.11 lists the chapters.

Table 17.11.: The chapters of this part, the question each one answers, and the earlier chapters it uses, by number (chapters 1–8 are the prerequisites, 9–17 the attacks part).

Chapter	The question it answers	Builds on
The definition of differential privacy	What exactly does DP promise, to whom, and what does it not protect? How do you tell a privacy violation from learning about the population?	3, 4, 9, 10

Chapter	The question it answers	Builds on
Post-processing, group privacy and composition	Which operations keep a guarantee, and how do guarantees add up?	3, 18
The Laplace and Gaussian mechanisms	How much noise does a numerical query need, and what is the exact privacy of Gaussian noise?	1, 2, 3, 18, 19
Advanced and optimal composition	How does privacy degrade over many releases, exactly?	2, 3, 4, 18, 19
Selection: exponential mechanism, report-noisy-max, sparse vector	How do you privately choose the best of many options, or find the few queries above a threshold?	1, 2, 18–20
Query release and private multiplicative weights	How do you answer millions of linear queries, or publish a synthetic dataset, when noise on every answer would drown them?	2, 18, 20–22
Beyond global sensitivity	What if the worst case is far from the data you actually have?	1, 2, 3, 9, 18–20, 22
Discrete and floating-point-safe mechanisms	Why do textbook mechanisms break on real computers, and how is that fixed?	1, 3, 18, 20
Local, shuffle and distributed trust models	What changes when no one is trusted with the raw data?	2, 8, 9, 18, 20
Lower bounds: what privacy costs	How much accuracy must every private mechanism give up?	2, 4, 5, 10, 17, 18–20
Private mean estimation	How many records does a private estimate of a population mean need, and what does not knowing the range, the dimension or the tails cost?	1, 2, 20–22, 24, 27

How to read this part

Order. Chapters 18 to 21 are the core and should be read in order: the definition, the properties that make it usable, the two mechanisms everything else is built from, and advanced and optimal composition, which finishes the story of composition that chapter 19 starts and introduces the privacy loss random variable that the next part uses throughout. Chapter 22 adds mechanisms for selection, and chapter 23 builds on them to answer many queries at once, by releasing synthetic

data with private multiplicative weights. Chapter 24 handles data whose worst case is far from typical. Chapter 25 is short and practical: read it before you implement any mechanism yourself. Chapter 26 changes who is trusted with the raw data. Chapter 27 is the most theoretical; it ties back to reconstruction and membership attacks and says what privacy must cost. Chapter 28 closes the part by putting these tools together on the most common statistical task, estimating a mean, and matches each of its error rates with a lower bound from chapter 27.

Structure of a chapter. Every chapter has the same shape as in the earlier parts: why it matters, a toolkit, one section per result with a statement, derivation, interpretation, worked example and two *check yourself* questions, then code, references and a cheat sheet. Exercises with worked solutions are collected in the exercise book, a companion website, with a link at the end of each chapter.

Proofs you can check by computer. Most privacy claims in this part are checked numerically as well as proved: the exact privacy profile of a mechanism is computed and compared with its bound, a composition formula is compared with brute-force enumeration, and a buggy mechanism is shown to leak by computing its privacy loss. Running the scripts is the fastest way to see how loose each bound is. From the repository root, for example,

```
uv run python code/part03-dp-foundations/laplace_gaussian.py
```

Notation

The chapters share the conventions in Table 17.12, set in the definition of differential privacy and fixed for the whole book. The next part uses the same notation. There the noise multiplier, the noise standard deviation per unit of sensitivity, is usually written σ; it equals the standard deviation when the sensitivity is 1.

Table 17.12.: Notation shared by the chapters of this part and the next.

Symbol	Meaning
$D = (x_1, \dots, x_n)$, $\mathcal{X}$	A dataset of n records, each from the data universe $\mathcal{X}$, so $D \in \mathcal{X}^n$
M; $M_1, \dots, M_k$	A mechanism, a randomized algorithm whose privacy is analysed; k mechanisms in a composition
$y \in \mathcal{Y}$, $S \subseteq \mathcal{Y}$	An output, the output space and an event; $Y = M(D)$ is the random output
$D \sim D'$	Neighbouring datasets: by default one is the other with one record added or removed; "replace one record" is named explicitly when used

Symbol	Meaning
$D' = D \cup \{x\}$	Under add/remove, D' is the dataset that contains the record x and D the one without it. A membership test says "D'" when it guesses that the record is in; its false positive rate is the chance of saying "D'" when the data were D, and its true positive rate the chance of saying "D'" when they were D'
ε, δ	The privacy parameters: ε-DP is pure DP, (ε, δ)-DP approximate DP
f; $\Delta_1 f$, $\Delta_2 f$	A query $f\colon \mathcal{X}^n \to \mathbb{R}^d$ with output dimension d; its ℓ_1 and ℓ_2 sensitivities, written Δf when the norm is clear
$L_{D,D'}(y) = \ln \frac{p_{M(D)}(y)}{p_{M(D')}(y)}$	The privacy loss of output y; $L = L_{D,D'}(Y)$ with $Y \sim M(D)$ is the privacy loss random variable
$E_\gamma(P \,\|\, Q)$, $\delta(\varepsilon)$	The hockey-stick divergence at level $\gamma \geq 1$; (ε, δ)-DP means $E_{e^\varepsilon}(M(D) \,\|\, M(D')) \leq \delta$ for all $D \sim D'$, and the privacy profile $\delta(\varepsilon)$ is the smallest such δ
$\mathrm{Lap}(b)$, $\mathcal{N}(0, \sigma^2)$	Laplace noise with scale $b = \Delta_1 f/\varepsilon$; normal noise with standard deviation σ
$r \in \mathcal{R}$, $u(D, r)$, Δu	The exponential mechanism's candidates, its score function and the score's sensitivity
$\mathcal{Q}$, τ, $\perp$, $\top$	A workload of counting queries; the sparse vector technique's threshold and its answers "below" and "above"
(α, β)	An (α, β)-accurate mechanism errs by at most α with probability at least $1 - \beta$; β is a failure probability
FPR, FNR	A test's false positive and false negative rates, its type I and type II errors, written α and β on a page without an accuracy guarantee
$R\colon \mathcal{X} \to \mathcal{Y}$, ε_0	A local randomizer and its privacy parameter

What you will be able to do

By the end of this part you should be able to:

- state pure and approximate DP for a stated neighbouring relation and unit of privacy, and translate a guarantee into a bound on membership advantage and on posterior odds;
- prove post-processing, group privacy and basic composition, and say what does not compose;
- calibrate the Laplace and Gaussian mechanisms, including the exact (analytic) Gaussian calibration;
- derive advanced composition and compute optimal composition exactly;
- prove the exponential mechanism, report-noisy-max and the sparse vector technique private, and recognize the common broken variants of the last;
- handle data-dependent sensitivity with smooth sensitivity, propose-test-release, subsample-and-aggregate and clipping;
- implement discrete Laplace and discrete Gaussian samplers exactly, and explain why naive floating-point noise is not private;
- design frequency estimation in the local model and explain what shuffling and secure aggregation buy;
- prove packing and fingerprinting lower bounds, and run the tracing attack they come from.

Each of these is a result derived in one of the chapters that follow.

18. The definition of differential privacy

Each attack of Part 2 was a game in which the challenger ran an algorithm on one of two datasets that differ in one person, and the adversary guessed which (Threat models and privacy games). Each worked because a test could tell the two datasets apart from the output. **Differential privacy (DP)** forbids exactly that: for every pair of datasets that differ in one person, the distribution of the output barely changes. Then every attack of Part 2 fails at once, whatever the adversary knows and computes.

The one idea is the **privacy loss**. For one output of a randomized algorithm, it is the logarithm of how much more likely that output was under one dataset than under its neighbour, the log-likelihood ratio of Divergences. Differential privacy bounds it. Pure DP bounds it at every output, and approximate DP lets it exceed the bound on outputs of small total probability δ. Every later result is that bound read through a tool of Part 1.

The running example is a survey. Alice, Bob and Carol are asked whether they smoke, and each answers with two coins. On heads they tell the truth, and on tails they toss again and say "yes" on heads and "no" on tails. So each person tells the truth with probability $\frac{3}{4}$, and every "yes" has an excuse. This survey is $\ln 3$-DP, as Section 18.3 shows. A count released with Gaussian noise of standard deviation 2 is the contrast case, because its privacy loss is unbounded and it needs a δ.

18.1. Neighbouring datasets

"Differ in one person" needs a precise meaning before anything can be proved. A dataset D is a multiset of **records** drawn from a universe $\mathcal{X}$ of possible records. The **neighbouring relation** says which pairs of datasets the guarantee must protect, and so it fixes the **unit of privacy**, the thing whose presence or value the output must not reveal.

Definition 18.1 (Neighbouring datasets)**.** Datasets D and D' are **neighbours**, written $D \sim D'$, in one of two senses, which every guarantee must name.

- **Add/remove** (also called unbounded DP): D' is D with one record added or removed. The size n of the dataset is itself private.
- **Replace** (also called bounded DP, or substitution): $|D| = |D'|$, and they differ in the value of one record. The size n is public.

Both relations are symmetric: if $D \sim D'$ then $D' \sim D$.

Add/remove protects participation, which is the question membership inference asks. Replace protects the value of your record and treats the dataset size as known. Separately, you choose what one record is. At **example-level** a record is one row, and at **user-level** it is all the data of one person, so example-level DP on 200 messages from one user protects each message, not

the user. Neighbours also range over absurd records, such as a person aged 900, which is why mechanisms bound their inputs before adding noise.

Example 18.1. Take $D = (\text{Alice: smoker}, \text{Bob: non-smoker}, \text{Carol: smoker})$. Table 18.1 checks five candidate datasets against both relations.

Table 18.1.: Five candidate datasets, checked against the add/remove and the replace relation.

Candidate D'	Add/remove neighbour?	Replace neighbour?
(Alice: smoker, Bob: non-smoker)	yes: Carol removed	no: size differs
(Alice: smoker, Bob: non-smoker, Carol: smoker, Dan: non-smoker)	yes: Dan added	no: size differs
(Alice: non-smoker, Bob: non-smoker, Carol: smoker)	no: two steps	yes: Alice's answer changed
(Alice: smoker, Bob: non-smoker, Dan: smoker)	no: two steps	yes: Carol replaced by Dan
(Alice: non-smoker, Bob: smoker, Carol: smoker)	no	no: two records changed

18.2. Pure and approximate differential privacy

"The output distribution barely changes" needs a measure. An average such as the Kullback–Leibler divergence can hide one rare output with an enormous loss. A difference such as the total variation (TV) distance adds up along a chain of n replacements, so no single tolerance is both useful and private (Exercise 8 in the exercise book). Differential privacy therefore bounds a ratio, in the worst case over every pair and every event, and allows a small difference only on top. Section A.1 in the appendices derives the definition's forms from scratch.

Write M for a **mechanism**, a randomized algorithm that maps a dataset to a random output in a set $\mathcal{Y}$. The probability that the output lands in an event $S \subseteq \mathcal{Y}$ is taken over the mechanism's own coins.

Definition 18.2 (Differential privacy)**.** A mechanism M is (ε, δ)**-differentially private**, for $\varepsilon \geq 0$ and $\delta \in [0, 1]$, if for every pair of neighbours $D \sim D'$ and every event $S \subseteq \mathcal{Y}$,

$$\Pr[M(D) \in S] \leq e^{\varepsilon} \Pr[M(D') \in S] + \delta. \tag{18.1}$$

Because the neighbouring relation is symmetric, the inequality also holds with D and D' swapped. The case $\delta = 0$ is **pure DP**, written ε**-DP**. The case $\delta > 0$ is **approximate DP** (Dwork, Kenthapadi, McSherry, Mironov & Naor, 2006).

The definition bounds events because an adversary's decision rule, "say D' when the output is in S", is an event. The dataset is fixed and the randomness is the mechanism's own, so privacy comes only from added noise. A deterministic algorithm that is not constant fails the definition

for every $\delta < 1$ (Exercise 9 in the exercise book), so rounding or suppressing small cells gives no guarantee by itself.

The privacy loss of the opening checks the definition output by output.

Definition 18.3 (Privacy loss)**.** Write $p_{M(D)}$ for the probability mass function or density of $M(D)$. The **privacy loss** of an output y for the ordered pair (D, D') is

$$L_{D,D'}(y) = \ln \frac{p_{M(D)}(y)}{p_{M(D')}(y)}. \tag{18.2}$$

It is 0 when y is equally likely in both worlds, large when y is strong evidence for D, and infinite when y is impossible under D'.

Pure DP can be checked one output at a time, because grouping outcomes into an event can only dilute the worst ratio. Approximate DP cannot, because the slack δ is paid once per event, not once per outcome.

Proposition 18.1 (Pure DP is pointwise, approximate DP is not)**.** *Let M have a discrete output set. Then M is ε-DP if and only if $|L_{D,D'}(y)| \le \varepsilon$ for every neighbouring pair and every output y, and for densities the same holds at almost every y. For $\delta > 0$, (ε, δ)-DP implies the pointwise bound*

$$p_{M(D)}(y) \le e^{\varepsilon} p_{M(D')}(y) + \delta \quad \text{for every } y, \tag{18.3}$$

but the pointwise bound does not imply (ε, δ)-DP.

Proof. The plan is to show that events and outcomes say the same thing when $\delta = 0$, then to see the slack add up over the outcomes of an event when $\delta > 0$.

1. *Events imply outcomes.* A single outcome is an event, so taking $S = \{y\}$ in Equation 18.1 gives the pointwise bound. With $\delta = 0$, together with the same bound for the swapped pair, this is $|L_{D,D'}(y)| \le \varepsilon$.
2. *Outcomes imply events when $\delta = 0$.* An event's probability is the sum of the probabilities of its outcomes, so summing the pointwise bound over $y \in S$ gives

$$\Pr[M(D) \in S] = \sum_{y \in S} p_{M(D)}(y) \le e^{\varepsilon} \sum_{y \in S} p_{M(D')}(y) = e^{\varepsilon} \Pr[M(D') \in S]. \tag{18.4}$$

   For densities, changing the density on a set of probability zero changes no event's probability, which is why almost every y is enough.
3. *Outcomes do not imply events when $\delta > 0$.* Each of the $|S|$ outcomes of an event brings its own δ, so summing the pointwise bound over S gives only

$$\Pr[M(D) \in S] \le e^{\varepsilon} \Pr[M(D') \in S] + |S|\,\delta. \tag{18.5}$$

4. *A counterexample.* Let $M(D)$ be uniform on $\{1, \dots, m\}$ and $M(D')$ uniform on $\{m+1, \dots, 2m\}$. Every outcome has probability at most $1/m$, so the pointwise bound holds with $\delta = 1/m$. But the event $\{1, \dots, m\}$ has probability 1 under $M(D)$ and 0 under $M(D')$, so Equation 18.1 needs $\delta = 1$. With $m = 1000$ the chapter's script (Section 18.11) finds a pointwise δ of 0.0010 and an event δ of 1.0000.

□

For small ε the factor e^{ε} is about $1+\varepsilon$, so every event changes probability by at most about a fraction ε of itself. Along a chain of datasets or releases the factors multiply and the exponents add, which is how group privacy and composition work in Post-processing, group privacy and composition. At $\varepsilon = 0.1$, an event of probability 0.5 under $M(D')$ has probability at most $0.5e^{0.1} = 0.553$ under $M(D)$, while at $\varepsilon = 1$ the bound is 1.36 and says nothing.

In Figure 18.1, Laplace noise keeps the density on D inside the band that pure DP allows, while Gaussian noise leaves it in the tail, where δ must pay.

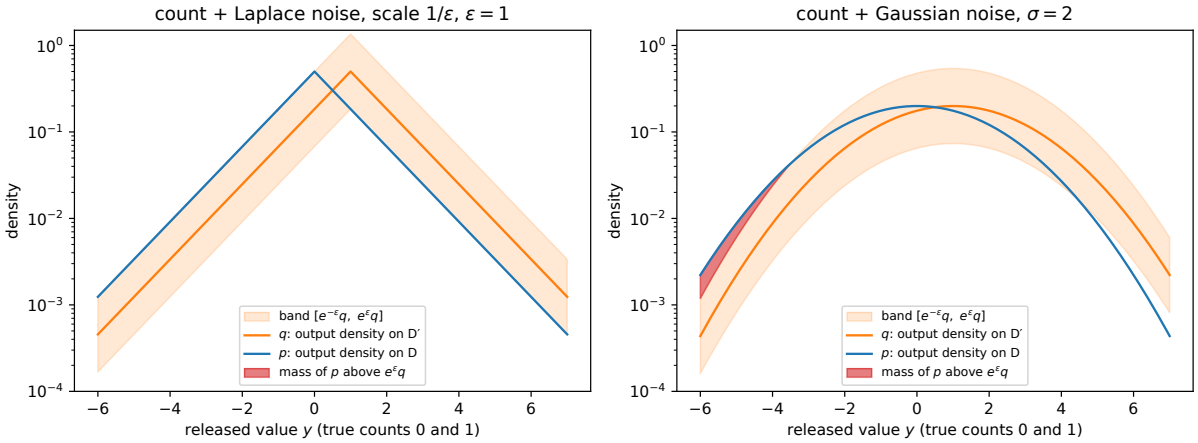

Figure 18.1.: The band from $e^{-\varepsilon}$ to e^{ε} times the density on D' (orange), at $\varepsilon = 1$. Left: Laplace noise keeps the density on D (blue) inside. Right: Gaussian noise ($\sigma = 2$) leaves it in the tail, and the red mass is what δ covers.

The chain of factors also converts between the neighbouring relations, because a replace neighbour is two add/remove steps away.

Proposition 18.2 (From add/remove to replace)**.** *If M is ε-DP under add/remove, then it is 2ε-DP under replace:*

$$\varepsilon\text{-DP under add/remove} \implies 2\varepsilon\text{-DP under replace.} \tag{18.6}$$

The converse fails: a mechanism can be 0*-DP under replace and not ε-DP under add/remove for any ε.*

Proof.

1. *Build the two-step path.* Let $D \sim D'$ under replace, with D holding the record x where D' holds x', and let $D_0 = D \setminus \{x\}$. Then D and D_0 differ by one removal, and D_0 and D' by one addition.
2. *Chain the ratio bound along the path.* Pure DP bounds each step by a factor e^{ε}, so applying it to (D, D_0) and then to (D_0, D') gives, for every event S,

$$\Pr[M(D) \in S] \le e^{\varepsilon} \Pr[M(D_0) \in S] \le e^{2\varepsilon} \Pr[M(D') \in S]. \tag{18.7}$$

   Walking the path from D' back to D gives the other order.

3. *The counterexample for the converse.* Let M output the number of records. It is 0-DP under replace, because datasets of the same size give the same output. Under add/remove, the event $\{n+1\}$ has probability 1 on a dataset of $n+1$ records and 0 on its neighbour, and no finite e^ε times 0 reaches 1.

□

The factor 2 is reached when one replacement changes two counts, as changing Alice's answer does in the survey's histogram (smokers, non-smokers). With Laplace noise of scale $1/\varepsilon$ in each bin, the script finds largest losses of 1.0000 under add/remove and 2.0000 under replace at $\varepsilon = 1$. For approximate DP the same path gives $(2\varepsilon, (1+e^\varepsilon)\delta)$ (Exercise 2 in the exercise book).

Example 18.2. In the survey, take the true bits $(1, 0, 1)$ for Alice, Bob and Carol and the replace neighbour $(0, 0, 1)$. The script checks all 256 events of the 8 report vectors. The largest ratio over events is 3.0000, the same as over single outcomes, as Proposition 18.1 says. Every replace pair gives the same, so the survey is $\ln 3$-DP under replace and no better, and Theorem 18.1 shows why only Alice's coins matter.

18.3. Randomized response

You want the fraction of people who have done something embarrassing, but asked directly, people lie. Warner (1965) found the answer four decades before the definition. Each respondent tells the truth only with a known probability, so every "yes" has an excuse, yet the randomization averages out over the population. The two coins of the running example are the **forced-response** variant credited to Boruch (1971). Section A.4 in the appendices derives the mechanism from scratch.

The idea is to tell the truth with a probability t a little above $\frac{1}{2}$, so that the ratio $t/(1-t)$ of the chances of a report under the two true bits is e^ε.

Definition 18.4 (Randomized response)**. Randomized response at level** ε reports a person's bit $x \in \{0, 1\}$ truthfully with probability $t = e^\varepsilon/(1+e^\varepsilon)$ and flipped with probability $1-t$. On a dataset of n bits it is applied to each person independently, and the output is the vector of n reports.

With two coins, a respondent tells the truth on heads, or on tails when the second coin gives the true answer, so $t = \frac{3}{4}$, $t/(1-t) = 3$, and the survey is randomized response at $\varepsilon = \ln 3 = 1.0986$ (Table 18.2).

Table 18.2.: Randomized response as a table of output probabilities. The ratios between the two rows are the privacy loss.

True bit	Pr[report 1]	Pr[report 0]	At $\varepsilon = \ln 3$
1	$t = \frac{e^\varepsilon}{1+e^\varepsilon}$	$1-t = \frac{1}{1+e^\varepsilon}$	0.75, 0.25
0	$1-t$	t	0.25, 0.75
Ratio, row 1 / row 0	e^ε	$e^{-\varepsilon}$	3, 1/3

Write $\bar{x}$ for the true fraction of ones and $\bar{y}$ for the mean of the reports. The coins push $\bar{y}$ toward $\frac{1}{2}$ in a known way, and undoing the push scales up the noise by $1/(2t-1)$.

Theorem 18.1 (Privacy and accuracy of randomized response)**.** *Randomized response at level ε on n people is ε-DP under replace. The estimate*

$$\hat{\bar{x}} = \frac{\bar{y} - (1-t)}{2t-1} \tag{18.8}$$

of the true fraction is unbiased, and its standard deviation is

$$\mathrm{sd}(\hat{\bar{x}}) = \frac{\sqrt{t(1-t)}}{(2t-1)\sqrt{n}} = \frac{e^{\varepsilon/2}}{(e^{\varepsilon}-1)\sqrt{n}} \approx \frac{1}{\varepsilon\sqrt{n}} \quad \textit{for small } \varepsilon. \tag{18.9}$$

Proof. The plan is to read one person's privacy off Table 18.2, to show that the other people cancel out of the likelihood ratio, and then to compute the mean and the variance of the estimate.

1. *One person.* Every ratio between the two rows of Table 18.2 is e^{ε} or its inverse, so the privacy loss of each report is $\pm\varepsilon$, and one report is ε-DP by Proposition 18.1.
2. *The output distribution factors.* People toss their own coins independently, so the probability of a report vector is a product of one factor per person, $\prod_i p_i(y_i \mid x_i)$, where $p_i(y_i \mid x_i)$ is the chance that person i reports y_i when their true bit is x_i.
3. *Neighbours differ in one factor.* Under replace, D and D' differ only in person j's bit, so every other factor cancels in the ratio. The loss is person j's alone, so it is $\pm\varepsilon$, and the vector is ε-DP by Proposition 18.1.
4. *The mean of the reports.* A report is 1 with probability t if the true bit is 1 and $1-t$ if it is 0. Averaging over a population in which a fraction $\bar{x}$ have bit 1 gives

$$\mathbb{E}[\bar{y}] = \bar{x}\,t + (1-\bar{x})(1-t) = (1-t) + \bar{x}(2t-1). \tag{18.10}$$

   Solving for $\bar{x}$ gives Equation 18.8, which is unbiased because it is a linear function of $\bar{y}$.
5. *The spread.* Each report is a Bernoulli variable with variance $t(1-t)$, whatever its true bit, and the reports are independent, so

$$\mathrm{Var}(\bar{y}) = \frac{t(1-t)}{n}. \tag{18.11}$$

   Dividing $\bar{y}$ by $2t-1$ divides the variance by $(2t-1)^2$, which gives the first form. Substituting $t = e^{\varepsilon}/(1+e^{\varepsilon})$ gives the closed form, because

$$t(1-t) = \frac{e^{\varepsilon}}{(1+e^{\varepsilon})^2}, \qquad 2t-1 = \frac{e^{\varepsilon}-1}{e^{\varepsilon}+1}. \tag{18.12}$$

□

Deniability is the privacy, and the noise is added before the data leave each person, the **local** model of Local, shuffle and distributed trust models. Under add/remove the number of reports would reveal whether you took part, so the guarantee holds under replace only.

Privacy costs samples: halving ε doubles the error, so recovering the accuracy takes four times as many people, and much of that is the price of trusting nobody. A trusted curator can instead add Laplace noise of scale $1/\varepsilon$ to the true count once, which is ε-DP by the Laplace and Gaussian mechanisms. Its error on the fraction, $\sqrt{2}/(\varepsilon n)$, falls like $1/n$ rather than $1/\sqrt{n}$.

Example 18.3. Of $n = 1000$ respondents, a fraction $\bar{x} = 0.3$ smoke, so the expected fraction of "yes" reports is $0.3 \times 0.75 + 0.7 \times 0.25 = 0.4$, which Equation 18.8 turns back into 0.3. The formula gives $\mathrm{sd}(\hat{\bar{x}}) = \sqrt{0.1875}/(0.5\sqrt{1000}) = 0.0274$, and ten thousand simulated surveys give a mean of 0.2996 and a standard deviation of 0.0278. At $\varepsilon = 0.5$ the formula gives 0.0626 (Figure 18.2). A trusted curator at $\varepsilon = \ln 3$ would reach $\sqrt{2}/(1000 \ln 3) = 0.00129$, which is 21.3 times smaller.

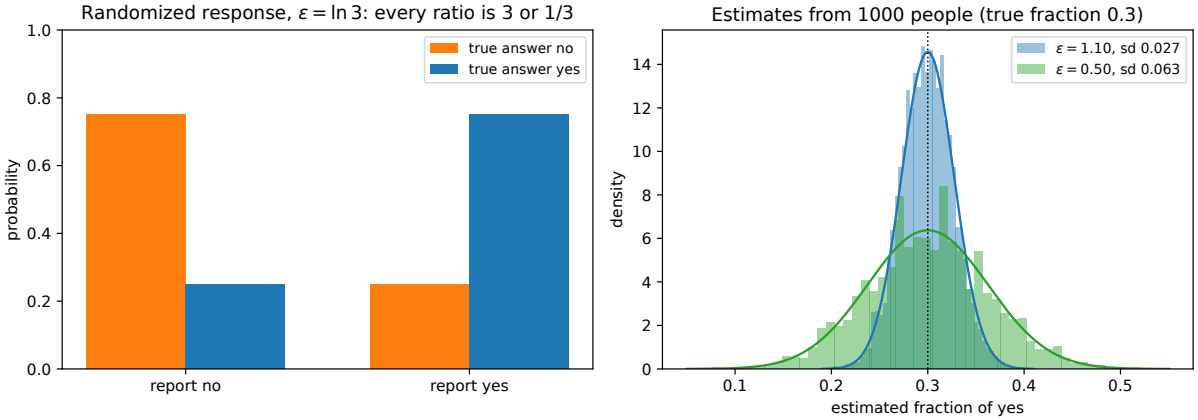

Figure 18.2.: Left: randomized response at $\varepsilon = \ln 3$ as output probabilities. Right: estimates from 4000 simulated surveys of 1000 people with true fraction 0.3, at $\varepsilon = \ln 3$ and 0.5, with the normal curves the formula predicts.

18.4. Divergence forms and the privacy loss

Equation 18.1 quantifies over all events, which is unusable for continuous outputs. A divergence turns "for all events" into one formula and shows what δ measures. The two divergences are those of Divergences. The **max-divergence** $D_\infty(P\|Q) = \ln \max_y p(y)/q(y)$ is the largest privacy loss (Section 3.4). The **hockey-stick divergence** $E_\gamma(P\|Q) = \sum_y (p(y) - \gamma q(y))_+$ is the mass of P that sticks out above γ times Q (Section 3.8), where $(x)_+ = \max\{x, 0\}$.

Theorem 18.2 (Differential privacy as a divergence bound)**.** *For every pair of neighbours $D \sim D'$ write $P = M(D)$ and $Q = M(D')$, with probabilities $p(y)$ and $q(y)$ (densities when the output is continuous, with sums read as integrals), and $L = L_{D,D'}$.*

1. *M is ε-DP if and only if $D_\infty(P\|Q) \le \varepsilon$ for every ordered pair of neighbours.*
2. *M is (ε, δ)-DP if and only if, for every ordered pair of neighbours,*

$$E_{e^\varepsilon}(P\|Q) = \sum_y \left(p(y) - e^\varepsilon q(y)\right)_+ = \mathbb{E}_{y\sim P}\left[\left(1 - e^{\varepsilon - L(y)}\right)_+\right] \le \delta. \tag{18.13}$$

3. *If $\Pr_{y\sim P}[L(y) > \varepsilon] \le \delta$ for every ordered pair, then M is (ε, δ)-DP.*

Proof. The plan is to find the worst event for the definition's difference, to rewrite the resulting sum as an average under P, and to bound that average by a tail probability.

1. *Pure DP.* By Proposition 18.1, ε-DP is $|L(y)| \le \varepsilon$ at every output and in both orders of the pair, and the largest value of L is $D_\infty(P\|Q)$ by definition.
2. *The worst event for a difference.* The definition asks $\Pr_P[S] - e^\varepsilon \Pr_Q[S] \le \delta$ for every event. Each outcome in S adds $p(y) - e^\varepsilon q(y)$ to the left side, which is positive exactly when $L(y) > \varepsilon$. So the worst event takes every outcome with a positive contribution and no other, and the definition holds for every S exactly when it holds for this one:
$$\max_S \big[\Pr_P[S] - e^\varepsilon \Pr_Q[S]\big] = \sum_y \big(p(y) - e^\varepsilon q(y)\big)_+ = E_{e^\varepsilon}(P\|Q). \tag{18.14}$$
3. *As an average under P.* Factor $p(y)$ out of each term and use $q/p = e^{-L}$ from Equation 18.2, so that each term becomes $p\,(1 - e^{\varepsilon - L})_+$. A sum of $p(y)$ times a function of y is the average of that function under P, and outcomes with $p(y) = 0$ contribute nothing.
4. *The sufficient condition.* The weight $(1 - e^{\varepsilon - L})_+$ is 0 when $L \le \varepsilon$ and less than 1 otherwise, so it is at most the indicator $\mathbf{1}[L > \varepsilon]$. Averaging both sides under P gives
$$E_{e^\varepsilon}(P\|Q) \le \Pr_P[L > \varepsilon] \le \delta. \tag{18.15}$$

□

So the smallest valid δ is not the probability that the loss exceeds ε, but an average that counts an output with loss just above ε for almost nothing and an infinite loss in full. What δ bounds exactly is the chance of a total failure. The outputs that are impossible on D' have infinite loss, and Equation 18.1 applied to them says that their total probability on D is at most δ.

A mechanism has a curve, not a pair: it is $(\varepsilon, \delta(\varepsilon))$-DP for every ε (Figure 18.3). The curve reaches 0 only if the loss is bounded. The distribution of L with y drawn from $M(D)$ is the **privacy loss distribution**, which the accountants of Numerical accounting work with directly.

Example 18.4. For each mechanism, add up the excess mass where the likelihood ratio exceeds e^ε. For the survey only the report with ratio 3 counts, which gives $\delta(\varepsilon) = (3 - e^\varepsilon)_+/4$ (Exercise 3 in the exercise book), so $\delta(0.5) = 0.3378$ and $\delta(1) = 0.0704$. For the Laplace count, the closed form of Section 3.8 gives $\delta(0.5) = 0.2212$ and $\delta(1) = 0$.

For the Gaussian count, whose true value moves by 1 between neighbours, write $\mu = 1/\sigma = 0.5$ for that shift in units of the noise. The privacy loss is normal with variance μ^2 and mean $\mu^2/2$ under $M(D)$, $-\mu^2/2$ under $M(D')$ (Section 3.5). By step 2 of the proof, $\delta(\varepsilon)$ is the P-probability of $\{L > \varepsilon\}$ minus e^ε times its Q-probability, and standardizing the loss with the standard normal distribution function Φ gives
$$\delta(\varepsilon) = \Phi\Big(\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) - e^\varepsilon\, \Phi\Big(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big). \tag{18.16}$$

Table 18.3 compares it with the tail, the first term alone.

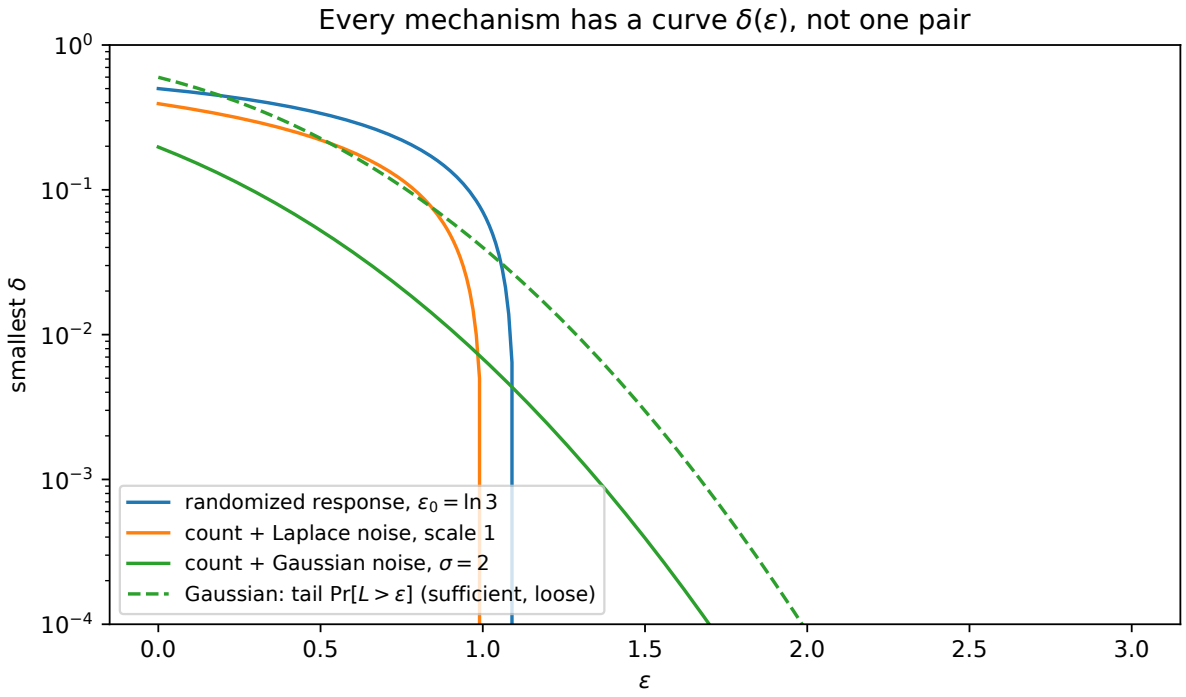

Figure 18.3.: The smallest δ against ε for randomized response at $\ln 3$, the Laplace count of scale 1 and the Gaussian count with $\sigma = 2$. Only the Gaussian curve never reaches 0. Dashed: its loose tail $\Pr[L > \varepsilon]$.

Table 18.3.: The exact $\delta(\varepsilon)$ of a count with Gaussian noise of standard deviation 2, against the sufficient condition $\Pr[L > \varepsilon]$.

ε	0.5	1	2	3
Exact $\delta(\varepsilon)$, Equation 18.13	5.244×10^{-2}	6.830×10^{-3}	9.439×10^{-6}	3.401×10^{-10}
Tail $\Pr[L > \varepsilon]$	2.266×10^{-1}	4.006×10^{-2}	8.842×10^{-5}	4.462×10^{-9}
Tail / exact	4.32	5.87	9.37	13.12

A Monte Carlo average over a million draws of L gives 6.859×10^{-3} at $\varepsilon = 1$. The tail is loose by a factor of 4 to 13, because most outputs in it have a loss only a little above ε.

18.5. The hypothesis-testing interpretation

A membership attacker is a test that sees the output and decides between "the data were D" and "the data were D'". Hypothesis testing described the best achievable pairs of error rates by the **trade-off function**. Differential privacy is exactly a lower bound on that function, uniform over all neighbours (Wasserman & Zhou, 2010; Kairouz, Oh & Viswanath, 2015), and Section D.1 in the appendices derives it from scratch.

Let a test say "D'" on the event S. Its **false positive rate (FPR)** is $\alpha = \Pr[M(D) \in S]$, and its **false negative rate (FNR)** is $\beta = \Pr[M(D') \notin S]$. A randomized test says "D'" with probability $\phi(y) \in [0, 1]$ after seeing y (Section 4.3).

Theorem 18.3 (Differential privacy as a bound on every test)**.** *M is (ε, δ)-DP if and only if every test, randomized or not, for every pair of neighbours, satisfies*

$$\alpha + e^{\varepsilon}\beta \geq 1 - \delta \qquad \text{and} \qquad e^{\varepsilon}\alpha + \beta \geq 1 - \delta. \tag{18.17}$$

Equivalently, the trade-off function of every pair of neighbours lies above

$$f_{\varepsilon,\delta}(\alpha) = \max\left\{0,\ 1 - \delta - e^{\varepsilon}\alpha,\ e^{-\varepsilon}(1 - \delta - \alpha)\right\}. \tag{18.18}$$

*In terms of the **true positive rate (TPR)** $1 - \beta$, the second inequality reads* $\mathrm{TPR} \leq e^{\varepsilon}\alpha + \delta$.

Proof. The plan is to apply the definition to the complement of S and to the swapped pair, to extend both bounds to randomized tests, and to read them backwards for the converse.

1. *The first inequality.* Apply Equation 18.1 to the pair (D, D') and the complement S^c, on which the test says "D". The left side is $1 - \alpha$ and the probability on the right is β, so
$$1 - \alpha \leq e^{\varepsilon}\beta + \delta. \tag{18.19}$$
2. *The second inequality.* Apply Equation 18.1 to the swapped pair (D', D) and the event S. The left side is then $1 - \beta$ and the probability on the right is α.
3. *Randomized tests.* A test ϕ is not an event, but the gap $\mathbb{E}_{M(D)}[\phi] - e^{\varepsilon}\mathbb{E}_{M(D')}[\phi]$ is linear in each $\phi(y)$, with coefficient $p(y) - e^{\varepsilon}q(y)$. So it is largest at the worst event of Theorem 18.2, and at most δ, and steps 1 and 2 go through with ϕ and $1 - \phi$ in place of the events.

4. *The converse.* Every event is a test, so if Equation 18.17 holds for all tests, steps 1 and 2 read backwards give Equation 18.1.
5. *The trade-off form.* Solved for β, the two inequalities give two lower bounds on β, and $\beta \geq 0$ is a third, so the smallest β at level α is at least the largest of the three.

□

The result draws a forbidden region: every attack lies on or above the two lines of Equation 18.17 (Figure 18.4). Low FPR is where DP bites. Part 2 judged membership attacks by their TPR at a low FPR, which DP caps at $e^{\varepsilon}\alpha + \delta$, and as $\alpha \to 0$ the δ term dominates.

Auditing runs this in reverse. Solving the cap for ε at an attack's measured FPR and TPR gives the smallest ε consistent with the measurement. The neighbouring pair is a training set with and without a **canary**, a record planted to be easy to detect (Memorization and extraction). The bound is tight for randomized response and loose for most mechanisms, and keeping a mechanism's whole trade-off curve is the idea of f-DP in Gaussian differential privacy.

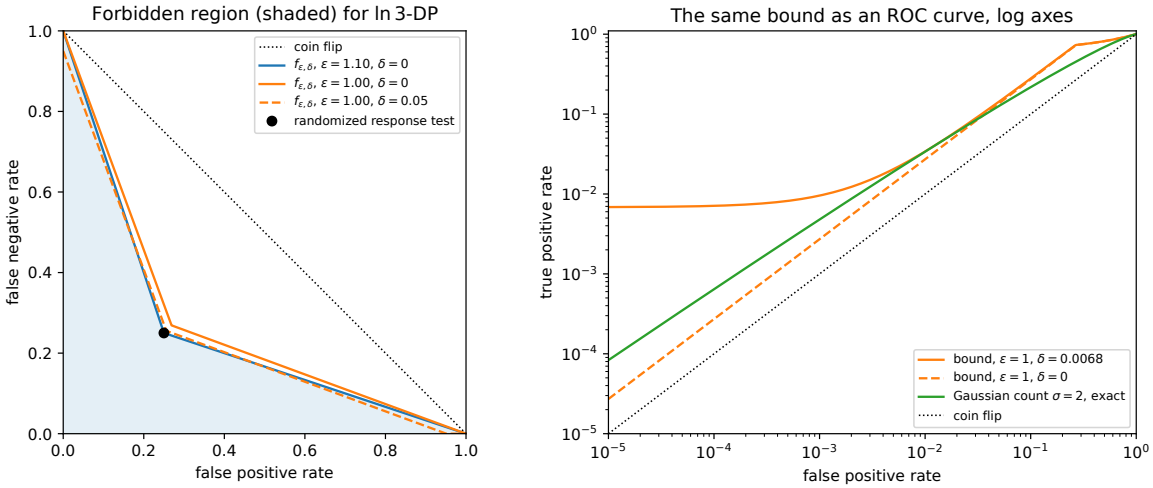

Figure 18.4.: Left: the region below $f_{\varepsilon,\delta}$ that no test can enter, for $\varepsilon = \ln 3$ and for $\varepsilon = 1$ with $\delta = 0$ and 0.05. Right: the largest TPR against FPR at $\varepsilon = 1$, with the best TPR against the Gaussian count.

Example 18.5. In the survey, the best test says "D'" when Alice reports 0. Its FPR and FNR are both 0.25, so $\alpha + 3\beta = 1$, the corner of the region.

The Gaussian count is $(1, 0.00683)$-DP, so at FPR 10^{-3} the bound allows TPR up to $e \times 10^{-3} + 0.00683 = 0.0095$, against 0.002728 under $(1, 10^{-5})$-DP. The best test thresholds y (Neyman–Pearson), and the Gaussian trade-off curve of Section 4.6 gives its TPR as $1 - \Phi(\Phi^{-1}(0.999) - 0.5) = 0.0048$.

18.6. Bound on the membership advantage

Part 2 measured a membership attacker by its **advantage**. In the membership game the challenger flips a fair coin to pick D or D' and runs M on it, and the adversary guesses which. The advantage

is $2\Pr[\text{correct}] - 1$, which with a fair coin equals $\text{TPR} - \text{FPR} = 1 - \alpha - \beta$ (Section 4.8). So the adversary wants the smallest sum of errors, and the lines of Equation 18.17 keep it away from the origin.

Corollary 18.1 (Membership advantage)**.** *If M is (ε, δ)-DP, every adversary in the membership game between any two neighbours has*

$$\text{Adv} = \text{TPR} - \text{FPR} \le \frac{e^\varepsilon - 1 + 2\delta}{e^\varepsilon + 1}, \qquad \Pr[\textit{correct}] \le \frac{e^\varepsilon + \delta}{e^\varepsilon + 1}. \tag{18.20}$$

For $\delta = 0$ the bound is $\tanh(\varepsilon/2)$, about $\varepsilon/2$ for small ε, and randomized response attains it. The bound also holds when the game draws the dataset at random before the coin flip.

Proof. The plan is to turn the advantage into a sum of error rates, to find the smallest sum over the region that Theorem 18.3 allows, and to check that randomized response sits at the corner.

1. *Turn the advantage into a sum of errors.* The advantage is $1 - (\alpha + \beta)$, so the largest advantage comes from the smallest $\alpha + \beta$ allowed by Equation 18.17 with $\alpha, \beta \ge 0$.
2. *Draw the feasible region.* Its lower boundary has corners where the two lines meet the axes, at $(0, 1 - \delta)$ and $(1 - \delta, 0)$, and where they cross, at $\alpha = \beta = (1 - \delta)/(1 + e^\varepsilon)$.
3. *Check the corners.* A linear function such as $\alpha + \beta$ changes at a constant rate along a straight edge, so its smallest value is at a corner. At the first two corners $\alpha + \beta = 1 - \delta$, and the crossing point is smaller because $e^\varepsilon \ge 1$:

$$\alpha + \beta = \frac{2(1 - \delta)}{1 + e^\varepsilon} \le 1 - \delta. \tag{18.21}$$

4. *Compute the advantage.* One minus the smallest sum is

$$1 - \frac{2(1 - \delta)}{1 + e^\varepsilon} = \frac{e^\varepsilon - 1 + 2\delta}{e^\varepsilon + 1}, \tag{18.22}$$

   and $\Pr[\text{correct}] = \frac{1}{2} + \frac{1}{2}\text{Adv}$ gives the second bound. Multiplying the top and bottom of the $\delta = 0$ bound by $e^{-\varepsilon/2}$ turns it into $\tanh(\varepsilon/2)$.
5. *Tightness and random datasets.* Against randomized response, the test "say D' on report 0" has $\alpha = \beta = 1/(1 + e^\varepsilon)$, the crossing point, so it attains the bound. A bound that holds for each fixed pair also holds for an average over random pairs.

□

Small ε is strong and large ε promises little. At $\varepsilon = 0.1$ the best attacker is right with probability at most 0.525, while at $\varepsilon = 5$ it may be right 99.3% of the time. The older bound $e^\varepsilon - 1$ (Yeom et al., 2018) is about twice as large and says nothing once $e^\varepsilon \ge 2$. A count with Laplace noise of scale $1/\varepsilon$ has best advantage $1 - e^{-\varepsilon/2}$, from Section 3.8, which stays below $\tanh(\varepsilon/2)$ (Figure 18.5; Exercise 7 in the exercise book measures the gap).

Example 18.6. Table 18.4 compares the bound with the best advantage against two mechanisms. In 200,000 games with the likelihood-ratio adversary, which guesses D when the privacy loss is positive, the script measures 0.4624 against randomized response (exact 0.4621) and 0.3953 against the Laplace count (exact 0.3935) at $\varepsilon = 1$.

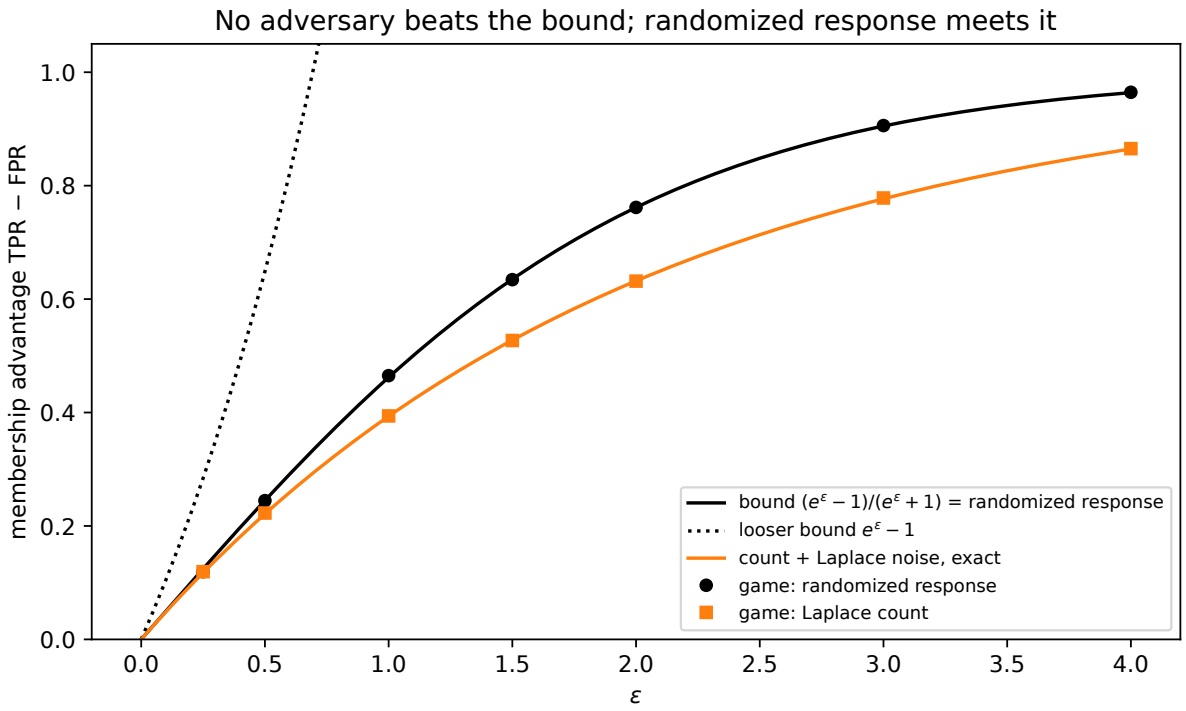

Figure 18.5.: The largest membership advantage under ε-DP (black), the looser bound $e^\varepsilon - 1$ (dotted) and the exact best advantage against the Laplace count (orange). Markers: 100,000 simulated games with the likelihood-ratio adversary.

Table 18.4.: The membership advantage bound for ε-DP and the exact best advantage against two ε-DP mechanisms.

ε	0.1	0.5	1	$\ln 3$	2	5
Bound $\tanh(\varepsilon/2)$	0.0500	0.2449	0.4621	0.5000	0.7616	0.9866
Looser bound $e^{\varepsilon}-1$	0.1052	0.6487	1.7183	2.0000	6.3891	147.4
Randomized response	0.0500	0.2449	0.4621	0.5000	0.7616	0.9866
Laplace count	0.0488	0.2212	0.3935	0.4226	0.6321	0.9179

18.7. The Bayesian interpretation

People often ask a different question: after seeing the output, how sure can someone be about me? Bayes' rule in odds form (Section 4.10) says that the posterior odds are the prior odds times the likelihood ratio, which for an output y is $e^{L_{D,D'}(y)}$. So a bound on the privacy loss is a bound on how far any belief can move, whatever the prior (Kasiviswanathan & Smith, 2014). Section D.2 in the appendices derives it with a two-hypothesis table.

Take an adversary who knows that the data are D or D' and gives D the prior probability π. Under approximate DP, outputs whose loss exceeds a level $\varepsilon' > \varepsilon$ are rare, because each adds a fixed fraction of its probability to the excess that δ bounds.

Theorem 18.4 (What one output does to a belief)**.** *If M is ε-DP, then after any output y,*

$$e^{-\varepsilon}\frac{\pi}{1-\pi} \le \frac{\Pr[D \mid y]}{\Pr[D' \mid y]} \le e^{\varepsilon}\frac{\pi}{1-\pi}, \qquad \Pr[D \mid y] \le \frac{e^{\varepsilon}\pi}{e^{\varepsilon}\pi + 1 - \pi}. \tag{18.23}$$

If M is (ε,δ)-DP, then for every $\varepsilon' > \varepsilon$ the upper bounds hold with ε' in place of ε for every output except those in the set $B = \{y : L_{D,D'}(y) > \varepsilon'\}$, which has

$$\Pr_{y\sim M(D)}[y \in B] \le \frac{\delta}{1 - e^{\varepsilon-\varepsilon'}}. \tag{18.24}$$

Proof. The plan is to write the posterior odds as prior odds times e^{L}, to bound e^{L} under pure DP, and then to show that the outputs where L is large are rare under approximate DP.

1. *Odds.* By Bayes' rule, $\Pr[D \mid y]$ is $\pi\, p_{M(D)}(y)$ divided by the overall probability of y, and the same holds for D' with the same denominator. The ratio cancels it and leaves the prior odds times $e^{L_{D,D'}(y)}$.
2. *Pure DP.* By Proposition 18.1, e^{L} lies between $e^{-\varepsilon}$ and e^{ε}, and multiplying the prior odds by these extremes gives the odds bound.

3. *From odds to a probability.* Odds o convert to the probability $o/(1+o)$, which increases with o. Taking $o = e^{\varepsilon}\pi/(1-\pi)$ and multiplying top and bottom by $1-\pi$ gives the bound on $\Pr[D \mid y]$.
4. *The bad set is rare.* Write $P = M(D)$ and $Q = M(D')$, and apply Equation 18.1 to B:

$$\Pr_P[B] - e^{\varepsilon} \Pr_Q[B] \le \delta. \tag{18.25}$$

   On B the loss exceeds ε', so $q < e^{-\varepsilon'} p$ and $\Pr_Q[B] < e^{-\varepsilon'} \Pr_P[B]$. Putting this larger quantity in place of $\Pr_Q[B]$ makes the left side smaller, which leaves

$$\Pr_P[B](1 - e^{\varepsilon - \varepsilon'}) < \delta, \tag{18.26}$$

   and the factor is positive because $\varepsilon' > \varepsilon$.
5. *Outside the bad set.* There the loss is at most ε', and steps 1 to 3 with ε' in place of ε give the upper bounds.

□

DP bounds the *change* in belief, not the belief, so an adversary who is already 99% sure stays about that sure. Against adversaries who do not know every other record, the same bound holds relative to the posterior computed without the person's record (Kasiviswanathan & Smith, 2014).

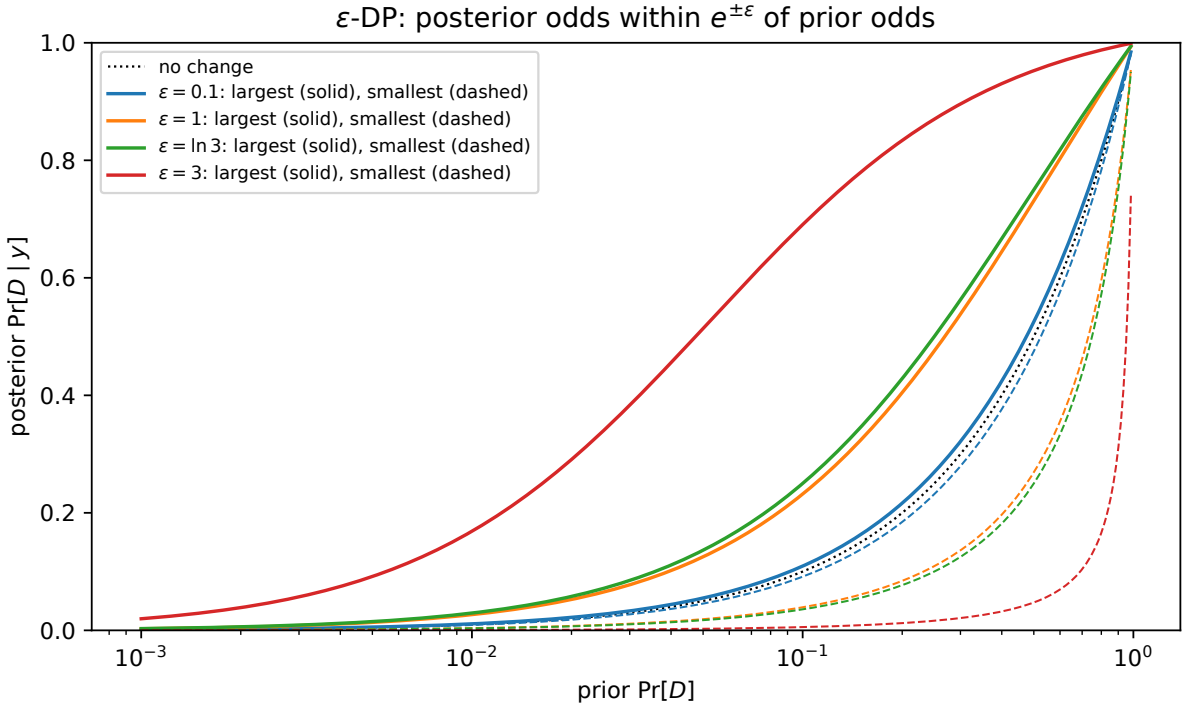

Figure 18.6.: The largest (solid) and smallest (dashed) posterior after one output of an ε-DP mechanism, against the prior, for four values of ε. Even at $\varepsilon = 3$ a prior of 0.01 rises only to 0.169.

Example 18.7. In the survey, the interviewer knows every answer but Alice's and gives a 50% chance that she smokes. Her "yes" is 3 times as likely from a true "yes", so the posterior odds are at most 3 and the interviewer is at most 75% sure. From a prior of 1%, the posterior is at most 0.0294 (Table 18.5).

Table 18.5.: The largest posterior probability after one output of an ε-DP mechanism, from Equation 18.23.

ε	Prior 0.01	Prior 0.1	Prior 0.5
0.1	0.0110	0.1094	0.5250
1	0.0267	0.2320	0.7311
$\ln 3$	0.0294	0.2500	0.7500
3	0.1687	0.6906	0.9526

For the $(1, 0.0068)$-DP Gaussian count, Equation 18.24 with $\varepsilon' = 2$ bounds the probability of a loss above 2 by $0.0068/(1 - e^{-1}) = 0.0108$, while the exact value is 8.842×10^{-5}. The bound uses only the pair (ε, δ), not the shape of the tail.

18.8. Why δ must be much smaller than 1/n

How small must δ be? The advantage bound barely notices a small δ, but a deliberately terrible mechanism shows the danger. It is DP with $\varepsilon = 0$ and yet publishes records verbatim, because over a whole dataset its small chances add up.

Proposition 18.3 (Release each record with probability δ)**.** *The mechanism that publishes each record of the dataset, in full, independently with probability δ is $(0, \delta)$-DP under add/remove. On a dataset of n records it publishes $n\delta$ records on average, and at least one record with probability*

$$1 - (1 - \delta)^n \approx 1 - e^{-n\delta}, \tag{18.27}$$

so $\delta = 1/n$ exposes someone with probability about $1 - e^{-1} = 0.632$.

Proof. The plan is to run the mechanism on D and on $D' = D \cup \{x\}$ with the same coins, so that the outputs differ only through one extra coin, and then to count the exposures.

1. *Couple the two runs.* Run the mechanism on D' by first running it on D and then tossing one more coin for x. The two outputs are equal unless that coin publishes x, which happens with probability δ.
2. *Bound one direction.* The output on D' lands in an event S either because the output on D did or because the extra coin changed it, so
$$\Pr[M(D') \in S] \le \Pr[M(D) \in S] + \delta. \tag{18.28}$$
3. *Bound the other direction.* With probability $1 - \delta$ the extra coin does nothing, and a probability is at most 1, so
$$\Pr[M(D') \in S] \ge (1 - \delta) \Pr[M(D) \in S] \ge \Pr[M(D) \in S] - \delta. \tag{18.29}$$
Both directions match Equation 18.1 with factor $e^0 = 1$ and slack δ.

4. *Count the exposures.* The number of records published is $\mathrm{Bin}(n, \delta)$, with mean $n\delta$, and none is published with probability $(1-\delta)^n$. For small δ, $\ln(1-\delta) \approx -\delta$, which gives

$$(1-\delta)^n = e^{n\ln(1-\delta)} \approx e^{-n\delta}. \tag{18.30}$$

□

So δ is a per-person budget for catastrophe. Pick it well below $1/n$, with n the number of people rather than records. A common choice is $\delta = 1/n^{1.5}$, and fixed values need checking: Abadi et al. (2016) used $\delta = 10^{-5}$ for 60,000 training examples, so $n\delta = 0.6$.

One pair (ε, δ) can describe mechanisms that fail in very different ways (Figure 18.7). The Gaussian count with $\sigma = 2$ is $(1, 6.830 \times 10^{-3})$-DP, and its loss exceeds 3 with probability 4.462×10^{-9}. Publishing a person's bit with probability 6.830×10^{-3}, and otherwise running randomized response at $\varepsilon = 1$, gives the same pair, with the whole δ on outputs of infinite loss (Exercise 10 in the exercise book). From the pair alone, Equation 18.24 at level 3 allows

$$\Pr[L > 3] \le \frac{6.830 \times 10^{-3}}{1 - e^{1-3}} = 7.899 \times 10^{-3}, \tag{18.31}$$

and the catastrophic mechanism comes close to it. So read a quoted pair pessimistically unless you know the whole curve $\delta(\varepsilon)$.

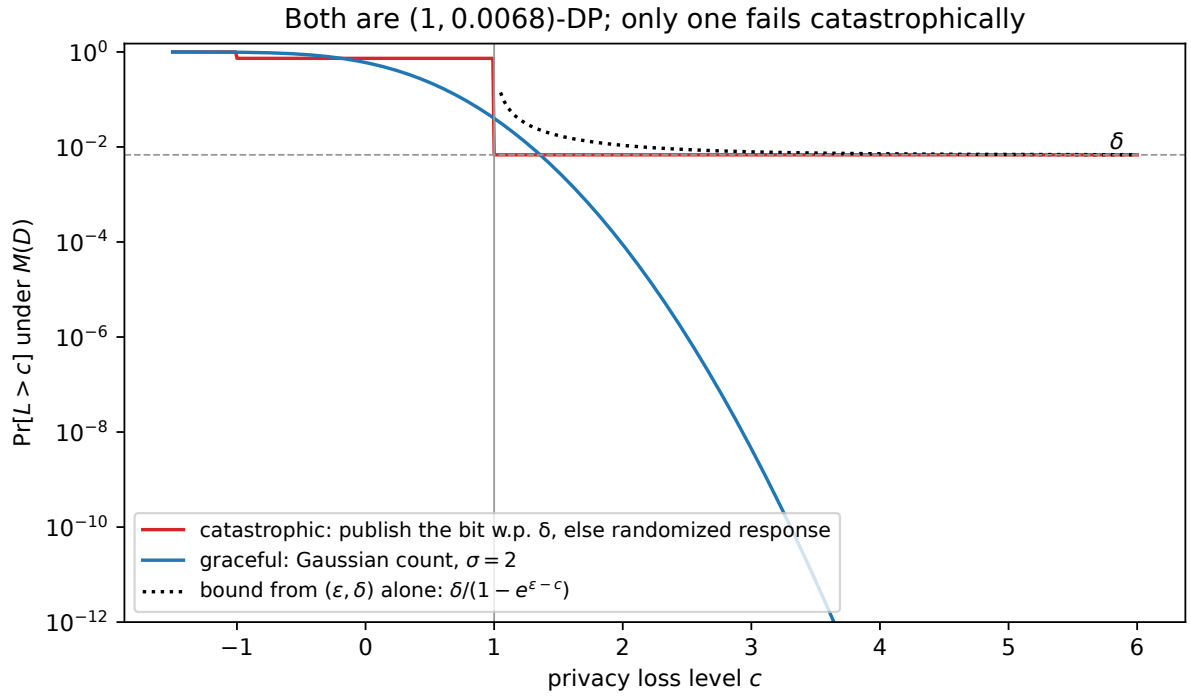

Figure 18.7.: The tail $\Pr[L > c]$ of two $(1, 0.0068)$-DP mechanisms on a log scale. Blue: the Gaussian count, whose tail falls fast. Red: publish the bit with probability δ, else randomized response; its tail stays at δ. Dotted: the largest tail the pair allows, from Equation 18.24.

Example 18.8. With $n = 3$ and $\delta = 0.1$ the script enumerates every output on D and on $D \cup \{x\}$ and finds a largest gap over events of 0.1000, so the mechanism is $(0, 0.1)$-DP and no better. Table 18.6 takes $n = 10{,}000$ records. In 100,000 runs at $\delta = 1/n$ it published 1.0077 records on average and at least one in a fraction 0.6351 of the runs, against 1 and 0.6321 from the formulas (Figure 18.8).

Table 18.6.: Exposure under the $(0, \delta)$-DP mechanism that releases each of 10,000 records with probability δ.

δ	Expected records published, $n\delta$	Pr[at least one]
$10^{-4} = 1/n$	1	0.6321
10^{-6}	0.01	9.950×10^{-3}
10^{-8}	0.0001	9.999×10^{-5}

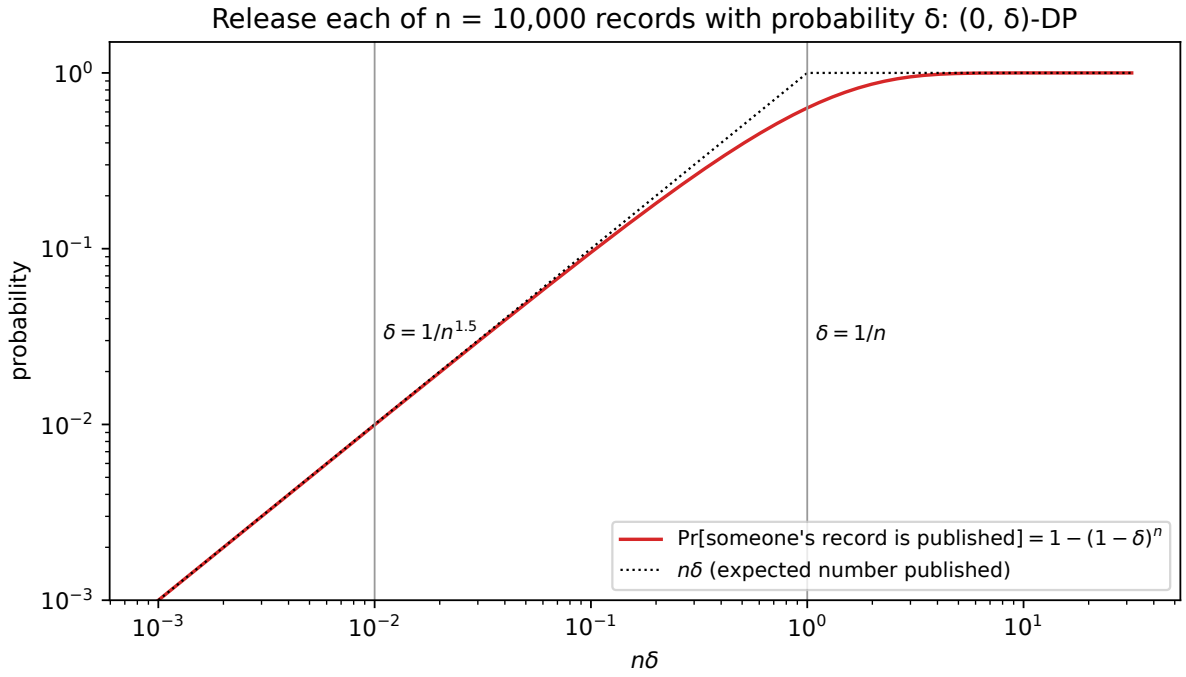

Figure 18.8.: The probability of publishing at least one of 10,000 records against $n\delta$, on log axes. Below $n\delta \approx 0.1$ it is essentially $n\delta$, and at $\delta = 1/n$ it is already 0.63.

18.9. What differential privacy does not protect

The definition compares two worlds that differ in one record, not the world before and after the release. Kifer & Machanavajjhala (2011) showed that no definition can block every inference without assumptions on how the data were generated. Four limits matter in practice.

Population inference. Suppose the cancer rate among smokers is 0.1 or 0.3, equally likely, so your belief that Alice, a smoker, will get cancer is 0.2. A study that excludes her reveals the rate 0.3, and your belief rises to 0.3. Yet the study never saw her record, so nothing happened to her *because she took part*.

Correlated records. If k records move together, as in a household, their joint privacy loss can reach $k\varepsilon$, so the unit of privacy must match the unit of correlation.

Everything outside the mathematical mechanism. Floating-point leaks (Discrete and floating-point-safe mechanisms), timing side channels and other releases need separate care.

Tasks about one person. Contact tracing must find whom one infected person met, so its output must depend on that person, which DP forbids. DP protects your contribution, not secrets that other people's data reveal.

Example 18.9. A count with Laplace noise of scale $1/\varepsilon$ meets a household of $k = 5$ people who always answer alike. At $\varepsilon = 1$ the script finds a largest privacy loss of 5.0000 for the household, which is protected only as if by a 5-DP mechanism. The exact best advantage against it is $1 - e^{-5/2} = 0.9179$, under the bound 0.9866. An attacker who asks whether the household took part is right with probability up to 0.959, although each record is "protected at $\varepsilon = 1$".

18.10. Is it a privacy violation?

Some reported privacy failures show that a release reveals something about the people whose data it used, and others that it reveals something true about the world, which then applies to particular people. DP is designed to stop only the first kind. Three questions, taught in Kamath's course on private data analysis, sort a claim into one kind or the other.

1. **Does it depend on this person's record?** DP bounds an inference's probability by e^{ε} times its probability without the record, plus δ, so it has nothing against an inference that is as likely without the record.
2. **Does the inference succeed exactly when the model is accurate?** Then it comes from patterns shared by many records, and blocking it is a decision not to learn.
3. **When, and by whom, was the information given up?** An inference from what the person disclosed elsewhere, such as her purchases, is the same whether or not her record was used.

The first question decides, and the other two explain a no. To measure a claimed attack, compare its success on members with its success on non-members, because only the excess can be a privacy loss (Attribute inference). An inference that is no violation can still be unacceptable, since norms of information flow (Nissenbaum, 2004) cover far more than DP.

Example 18.10. Train a regression model on points that all lie on the line $y = x + 1$, among them $(2.7, 3.7)$. Asked about $x = 2.7$ it answers the training label 3.7, which looks like a leak. But without that point the line and the answer stay the same, so the first question says no. Table 18.7 applies the test to four well-known cases.

Table 18.7.: Four claimed privacy failures and the three-question test.

Case	A violation in the DP sense?	The question that decides it
Facebook likes predict politics (Kosinski, Stillwell & Graepel, 2013)	No	First: the patterns hold without any one user
A retailer infers a shopper's pregnancy from her purchases (Duhigg, 2012; anecdotal)	No	First: a model not trained on her infers the same
Netflix Prize data linked to public reviews (Narayanan & Shmatikov, 2008)	Yes	First: without her record there is nothing to find
A language model completes one user's identification number (Carlini et al., 2019)	Yes	First: only her messages make it likely

The last two rows are the contrast that matters for machine learning: generalizing passes the first question, and memorizing a rare string fails it (Memorization and extraction).

18.11. Code

The script code/definition.py computes every number in this chapter and draws every figure. It checks the definition by brute force over small outcome sets, and the closed forms by simulation. From the repository root:

```
uv run python code/part03-dp-foundations/definition.py
```

Table 18.8.: The script's output with the default seed.

Experiment	Result
Histogram, Laplace noise $1/\varepsilon$ per bin, $\varepsilon = 1$	Largest loss 1.0000 (add/remove), 2.0000 (replace)
Disjoint uniform distributions, $m = 1000$	Pointwise δ 0.0010; event δ 1.0000
Additive-only definition, $n = 1000$ (Exercise 8)	TV 0.1000, accuracy 0.5500; exposure 0.6323
Randomized response, 3 people, 256 events	Event ratio 3.0000 = outcome ratio; hockey-stick at $\gamma = 2$ 0.2500
Survey, $n = 1000$, $\varepsilon = \ln 3 = 1.0986$	sd 0.0274, simulated 0.0278 (mean 0.2996); central 0.00129
$\delta(0.5)$, $\delta(1)$	Randomized response 0.3378, 0.0704; Laplace 0.2212, 0; Gaussian Table 18.3
TPR at FPR 10^{-3}	Cap 0.002728 at $(1, 10^{-5})$; Gaussian 0.0048, cap 0.0095

Experiment	Result
Membership advantage	Table 18.4; games at $\varepsilon = 1$: 0.4624, 0.3953
Bayesian	Table 18.5; Gaussian $\Pr[L > 2] = 8.842 \times 10^{-5}$, bound 0.0108
Release each record	$(0, 0.1)$-DP at $n = 3$; 1.0077 records, $\Pr[\geq 1] = 0.6351$ at $n = 10^4$
$\Pr[L > 3]$ at $(1, 6.830 \times 10^{-3})$	Gaussian 4.462×10^{-9}, catastrophic 6.830×10^{-3}, bound 7.899×10^{-3}
Household of 5, $\varepsilon = 1$	Largest loss 5.0000; bound 0.9866; Laplace 0.9179

tests/test_definition.py checks that the output still matches.

18.12. Summary

Table 18.9.: The results of this chapter, and where each is used.

Result	Statement	Use
Definition 18.1	Add/remove (n private) or replace (n public)	Name it with every ε; subsampling
Definition 18.2	$\Pr[M(D) \in S] \leq e^{\varepsilon} \Pr[M(D') \in S] + \delta$	Every mechanism of this part
Definition 18.3	$L_{D,D'}(y) = \ln\left(p_{M(D)}(y)/p_{M(D')}(y)\right)$	What every reading of the definition bounds
Proposition 18.1	ε-DP iff $\lvert L\rvert \leq \varepsilon$ everywhere	Prove pure DP output by output, never approximate DP
Proposition 18.2	Add/remove ε gives replace 2ε	With δ: $(2\varepsilon, (1 + e^{\varepsilon})\delta)$
Theorem 18.1	Truth with probability $e^{\varepsilon}/(1 + e^{\varepsilon})$; error about $1/(\varepsilon\sqrt{n})$	The local model; worst case for composition
Theorem 18.2	(ε, δ)-DP iff $E_{e^{\varepsilon}}(P\|Q) \leq \delta$	Quote the curve $\delta(\varepsilon)$; numerical accounting
Theorem 18.3	$\text{TPR} \leq e^{\varepsilon}\,\text{FPR} + \delta$	Auditing; f-DP
Corollary 18.1	$\text{Adv} \leq (e^{\varepsilon} - 1 + 2\delta)/(e^{\varepsilon} + 1)$	ε below 1 is strong; around 10 it says little
Theorem 18.4	Posterior odds within $e^{\pm\varepsilon}$ of prior odds	Explaining ε
Proposition 18.3	$(0, \delta)$-DP, yet exposes someone with probability $1 - (1 - \delta)^n$	Pick $\delta \ll 1/n$
Example 18.9	k correlated records cost $k\varepsilon$	Match the unit of privacy to the unit of correlation

Result	Statement	Use
Example 18.10	Record? Accuracy? Disclosure?	Only the excess over non-members is a privacy loss

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

19. Post-processing, group privacy and composition

You have proved that one mechanism satisfies differential privacy (DP), and now you use it: you round its output, you protect users who each contributed fifty records, and you answer a hundred queries rather than one. So three questions come up. Is a processed output still private? What does a guarantee about one record give for a group of k records? And what is the guarantee of many mechanisms run on the same data?

The answers are the three properties that make DP usable as an engineering tool. Two datasets D and D' are neighbours, written $D \sim D'$, when they differ by adding or removing one record, unless a section says otherwise. One idea organizes all three properties, the **privacy loss** of an output y from the definition of differential privacy, the log of how much more likely y is on D than on D':

$$L_{D,D'}(y) = \ln \frac{p_{M(D)}(y)}{p_{M(D')}(y)}. \tag{19.1}$$

Here $p_{M(D)}$ is the probability, or density, that the mechanism M gives to y on D. Pure ε-DP, the case $\delta = 0$ of (ε, δ)-DP, keeps this loss within $[-\varepsilon, \varepsilon]$ for every output and every neighbouring pair. When you walk through several datasets, or run mechanisms whose coins (their internal randomness) are independent, likelihood ratios multiply, so privacy losses add, and that is what costs. Processing instead merges outputs and averages their likelihood ratios, which is free.

The running example is **randomized response** at level $\varepsilon_0 = \ln 3$: a person whose record is one private bit reports it truthfully with probability $\frac{3}{4}$ and flips it with probability $\frac{1}{4}$. If the bit is 1 the report 1 has probability $\frac{3}{4}$, and if it is 0 it has probability $\frac{1}{4}$, a ratio of 3, while the report 0 has the ratio $\frac{1}{3}$. So the privacy loss is $\pm \ln 3$ on every output. The output distributions $M(D)$ and $M(D')$ are written P and Q, with mass functions or densities p and q, and a sum over continuous outputs means an integral.

19.1. Post-processing

A private output is rarely published as is. You round a noisy count, fit a model to noisy marginals, or let an analyst decide what to do next, each time without looking at the data again. This section asks whether such processing can undo the protection. It cannot, because a processed output merges outputs, and its likelihood ratio is an average of theirs, which stays in the band $[e^{-\varepsilon}, e^{\varepsilon}]$. For approximate DP the privacy loss is not bounded, so the proof works with events and needs one small lemma first.

In its event form, from the definition chapter, (ε, δ)-DP says that $\Pr_P[S] \le e^{\varepsilon} \Pr_Q[S] + \delta$ for every set S of outputs and every ordered neighbouring pair. Step 1 of the proof of post-processing turns an event about the processed output into a soft rule on the original output, one that accepts each output with some probability, and the lemma says that soft rules obey the same bound.

Lemma 19.1 (Soft tests obey the definition)**.** *Let M be (ε, δ)-DP, fix a neighbouring pair with output distributions $P = M(D)$ and $Q = M(D')$, and let g be any function of the output with values in $[0, 1]$. Then*

$$\mathbb{E}_P[g(Y)] \le e^{\varepsilon}\, \mathbb{E}_Q[g(Y)] + \delta. \tag{19.2}$$

Proof.

1. *Write the gap as a sum.* The difference $\mathbb{E}_P[g] - e^{\varepsilon}\mathbb{E}_Q[g]$ equals $\sum_y g(y)(p(y) - e^{\varepsilon}q(y))$, a sum in which each value $g(y)$ multiplies a fixed bracket.
2. *Push it to the extreme.* The sum is largest when $g(y) = 1$ wherever the bracket is positive and $g(y) = 0$ wherever it is negative, because any value in between gives up part of a positive term or adds part of a negative one. That choice of g is the indicator of the event $B = \{y : p(y) > e^{\varepsilon}q(y)\}$, so the sum is at most $\Pr_P[B] - e^{\varepsilon}\Pr_Q[B]$.
3. *Apply the definition* to the event B, which bounds $\Pr_P[B] - e^{\varepsilon}\Pr_Q[B]$ by δ.

□

This is the randomized version of the worst-event argument of Divergences. The largest value of $\Pr_P[S] - e^{\varepsilon}\Pr_Q[S]$ over events S is the **hockey-stick divergence**,

$$E_{e^{\varepsilon}}(P\|Q) = \sum_y \big(p(y) - e^{\varepsilon}q(y)\big)_+, \tag{19.3}$$

where $(x)_+ = \max(x, 0)$ keeps the positive parts. So M is (ε, δ)-DP exactly when that divergence is at most δ for every ordered neighbouring pair. The smallest such δ at each ε is the **privacy profile** $\delta(\varepsilon)$ of M, and the script computes it exactly for every mechanism in this chapter.

To cover randomized processing, describe it as a **channel** K: $K(z \mid y)$ is the probability that the processing outputs z when its input is y. A deterministic function f is the case $K(z \mid y) = \mathbf{1}[z = f(y)]$, which is 1 when $z = f(y)$ and 0 otherwise. The processed output on D has the distribution $PK(z) = \sum_y p(y)K(z \mid y)$, which weights each y by how likely it is to become z, and $L^f_{D,D'}(z)$ is its privacy loss. The theorem says that processing never makes D and D' easier to tell apart.

Theorem 19.1 (Post-processing)**.** *Let M be (ε, δ)-DP and let f be any randomized function of its output whose coins are independent of the data and of M's coins. Then $f \circ M$, the mechanism $D \mapsto f(M(D))$, is (ε, δ)-DP. In terms of the channel K of f, for every neighbouring pair the hockey-stick divergence can only go down, and so can the largest privacy loss:*

$$E_{e^{\varepsilon}}(PK \,\|\, QK) \le E_{e^{\varepsilon}}(P\|Q), \qquad \max_z \big|L^f_{D,D'}(z)\big| \le \max_y \big|L_{D,D'}(y)\big|. \tag{19.4}$$

Proof. The plan is to turn any event about the processed output into a soft test on the original output and apply Lemma 19.1, then to show the privacy-loss form by the averaging argument of the data processing inequality (DPI).

1. *Fix an event S of processed outputs.* Let $g(y) = \sum_{z \in S} K(z \mid y)$, the probability that processing y lands in S. It is a probability, so it takes values in $[0, 1]$, and it does not depend on the data, because f does not look at the data: the same g serves for D and for D'.

2. *Average over the output.* To land in S, the mechanism first produces some y, and then processing sends it into S with probability $g(y)$, so $\Pr[f(M(D)) \in S] = \sum_y p(y)g(y) = \mathbb{E}_P[g(Y)]$, and the same with q for D'.
3. *Apply the lemma to g.* Lemma 19.1 gives $\mathbb{E}_P[g] \le e^{\varepsilon}\mathbb{E}_Q[g] + \delta$, that is $\Pr[f(M(D)) \in S] \le e^{\varepsilon}\Pr[f(M(D')) \in S] + \delta$. This holds for every S and every ordered neighbouring pair, which is the event form of (ε, δ)-DP for $f \circ M$. The hockey-stick inequality of Equation 19.4 is the same statement for the worst event S.
4. *The privacy-loss form.* The likelihood ratio of z is $PK(z)/QK(z)$. In the numerator, for outputs with $q(y) > 0$, write each $p(y)$ as $q(y)$ times its likelihood ratio $e^{L(y)} = p(y)/q(y)$. That turns the ratio into a weighted average of the likelihood ratios of the y that can produce z:

$$e^{L^f(z)} = \frac{PK(z)}{QK(z)} = \sum_y \frac{q(y)K(z \mid y)}{QK(z)}\, e^{L(y)}. \tag{19.5}$$

   The weight of each y is the share of the D'-probability of z that comes through y. The weights are non-negative and sum to 1, because $\sum_y q(y)K(z \mid y) = QK(z)$. So $e^{L^f(z)}$ lies between the smallest and the largest $e^{L(y)}$, and $|L^f(z)|$ is at most the largest $|L(y)|$, which is the second inequality of Equation 19.4. This is step 1 of the DPI derivation in Divergences.

□

So nothing downstream needs a new proof. A model trained on DP statistics, or a plot of them, never reads the data again and inherits the guarantee. Attackers are covered too: a membership-inference attacker of Part 2 applies a channel to y, so the bounds of the definition chapter on its error rates hold for every attack. An analyst who picks the next question from earlier private answers is post-processing them, though answering that question is a new mechanism (Section 19.3; Adaptive data analysis).

Invertible processing, such as a change of units, keeps the privacy loss exactly, since nothing is averaged. Processing that merges outputs with different losses lowers it, though usually only a little. The one condition is that f must not read the data, because step 1 needed the same g under D and D'. Looking up the exact count of the noisy winning category is therefore a second, non-private mechanism (Section 19.5).

Example 19.1. Collect answers with randomized response at $\varepsilon_0 = \ln 3$ and then, before publishing, flip each answer with probability $r = \frac{1}{4}$ using a fresh coin. The published answer $z = 1$ can be reached in two ways: the first answer was 1 and was kept, or it was 0 and was flipped. Each path's probability is the product of its two steps, and Table 19.1 follows both paths.

Table 19.1.: Randomized response with $\varepsilon_0 = \ln 3$, then a fresh coin that flips the answer with probability $\frac{1}{4}$. The published $z = 1$ is reached by two paths.

Path to $z = 1$	Probability under bit 1 (D)	Probability under bit 0 (D')	$e^{L(y)}$ of the first answer
$y = 1$, kept	$\frac{3}{4} \cdot \frac{3}{4} = \frac{9}{16}$	$\frac{1}{4} \cdot \frac{3}{4} = \frac{3}{16}$	3
$y = 0$, flipped	$\frac{1}{4} \cdot \frac{1}{4} = \frac{1}{16}$	$\frac{3}{4} \cdot \frac{1}{4} = \frac{3}{16}$	$\frac{1}{3}$
total	$\frac{10}{16} = 0.625$	$\frac{6}{16} = 0.375$	—

The likelihood ratio of $z = 1$ is $0.625/0.375 = \frac{5}{3}$. Step 4 of the proof predicts it as the average of 3 and $\frac{1}{3}$, each weighted by its share $\frac{1}{2}$ of the D' column. The published $z = 0$ has the ratio $\frac{3}{5}$, so the published answers are $\ln \frac{5}{3} = 0.5108$-DP, less than $\ln 3 = 1.0986$. The right panel of Figure 19.1 shows ε for every flip probability: it falls to 0 at $r = \frac{1}{2}$, where the published bit is a fair coin.

A count with noise shows that processing can also lower δ while keeping ε. Add Laplace noise of scale 1 to a count whose neighbouring values are 0 and 1, so that the outputs are $\mathrm{Lap}(0, 1)$ and $\mathrm{Lap}(1, 1)$, with densities $\frac{1}{2}e^{-|y|}$ and $\frac{1}{2}e^{-|y-1|}$. Their privacy loss $|y - 1| - |y|$ lies within $[-1, 1]$ by the triangle inequality, so the noisy count is 1-DP (The Laplace and Gaussian mechanisms). Table 19.2 and the left panel of Figure 19.1 give the exact privacy profiles of the noisy count, of the count rounded to an integer, and of the bit "is the noisy count above $\frac{1}{2}$?".

Table 19.2.: Exact privacy profiles of a count with $\mathrm{Lap}(0, 1)$ noise, before and after two post-processings. Each row is on or below the one above it, as Equation 19.4 requires.

Published	Smallest pure ε	$\delta(0.25)$	$\delta(0.5)$
Noisy count $c + Z$	1.0000	0.3127	0.2212
Rounded to an integer	1.0000	0.3073	0.1967
Only "is $c + Z > \frac{1}{2}$?"	0.8318	0.3073	0.1967

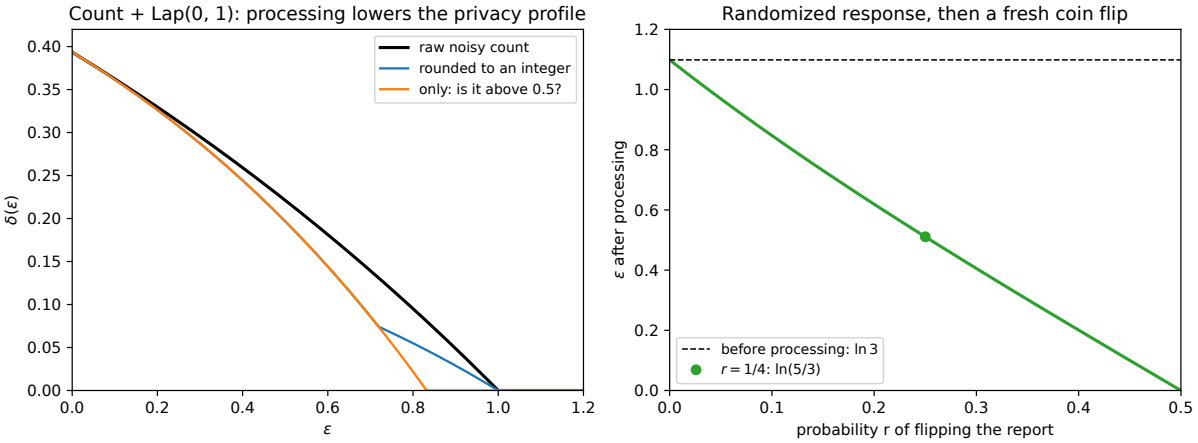

Figure 19.1.: Left: the privacy profile $\delta(\varepsilon)$ of a count with $\mathrm{Lap}(0, 1)$ noise (black), after rounding to an integer (blue), and after keeping only whether it exceeds $\frac{1}{2}$ (orange). Post-processing can only lower the curve. Right: randomized response with $\varepsilon_0 = \ln 3$ followed by a fresh coin that flips the answer with probability r; the dot is $r = \frac{1}{4}$, where $\varepsilon = \ln \frac{5}{3}$.

Rounding keeps the pure ε. Each rounded value at or below -1 gathers outputs that all lie left of 0, where the densities have the constant ratio e, and an average of equal ratios is that ratio. It still lowers $\delta(\varepsilon)$, because the cell $[-\frac{1}{2}, \frac{1}{2}]$ mixes losses from -1 to 1. The one-bit summary is the most private. Its "yes" has probability $\frac{1}{2}e^{-1/2} = 0.3033$ when the count is 0 and 0.6967 when it is 1, a privacy loss of $\ln(0.6967/0.3033) = 0.8318$.

19.2. Group privacy

The definition protects one record, but people are not rows. A user of a messaging app contributes hundreds of messages, and a household shares an address. To bound what an adversary learns about all k records of one user, you need a guarantee for datasets that differ in k records. Group privacy derives it from the one-record guarantee, at a price that is linear in k for ε and exponential in k for δ.

Say that D and D'' are at **distance** k if a path $D = D_0 \sim D_1 \sim \cdots \sim D_k = D''$ joins them, changing one record per step. The idea is to apply the one-record guarantee once per step. Each step multiplies the bound by e^{ε} and adds a slack δ, which later steps multiply again, so the slacks pile up in a geometric sum.

Theorem 19.2 (Group privacy)**.** *Let M be (ε, δ)-DP. Then for every pair of datasets D and D'' at distance k and every event S,*

$$\Pr[M(D) \in S] \le e^{k\varepsilon} \Pr[M(D'') \in S] + \delta_k, \qquad \delta_k = \delta \sum_{j=0}^{k-1} e^{j\varepsilon} = \delta \, \frac{e^{k\varepsilon} - 1}{e^{\varepsilon} - 1} \le k \, e^{(k-1)\varepsilon} \delta. \tag{19.6}$$

In particular, pure ε-DP gives pure $k\varepsilon$-DP for groups of size k.

Proof. The plan is to prove the pure case through the privacy loss, which adds along the path, and the approximate case through events, chaining the one-step bound k times.

1. *Pure DP: telescope the likelihood ratio along the path.* Multiply and divide by the densities at the intermediate datasets $D_1, \dots, D_{k-1}$. Each appears once in a numerator and once in a denominator, so they cancel and only the two ends remain:

$$\frac{p_{M(D_0)}(y)}{p_{M(D_k)}(y)} = \prod_{i=1}^{k} \frac{p_{M(D_{i-1})}(y)}{p_{M(D_i)}(y)}, \qquad \text{so} \qquad L_{D_0, D_k}(y) = \sum_{i=1}^{k} L_{D_{i-1}, D_i}(y). \tag{19.7}$$

2. *Bound each term.* Each pair $D_{i-1} \sim D_i$ is neighbouring, so $|L_{D_{i-1}, D_i}(y)| \le \varepsilon$ by pure DP.
3. *Add.* A sum of k terms, each between $-\varepsilon$ and ε, lies between $-k\varepsilon$ and $k\varepsilon$, so $|L_{D_0, D_k}(y)| \le k\varepsilon$ for every y, which is pure $k\varepsilon$-DP.
4. *Approximate DP: one step.* With $\delta > 0$ the privacy loss is no longer bounded, so there is nothing to add up, and the proof chains the event form instead. Fix an event S and write s_i for the probability $\Pr[M(D_i) \in S]$. The definition applied to the neighbouring pair $D_{i-1} \sim D_i$ gives $s_{i-1} \le e^{\varepsilon} s_i + \delta$.
5. *Substitute the next step* into the right side. The bound on s_1 goes in place of s_1:

$$s_0 \le e^{\varepsilon} s_1 + \delta \le e^{\varepsilon}\big(e^{\varepsilon} s_2 + \delta\big) + \delta = e^{2\varepsilon} s_2 + \delta(1 + e^{\varepsilon}). \tag{19.8}$$

6. *Repeat k times.* By induction, $s_0 \le e^{k\varepsilon} s_k + \delta(1 + e^{\varepsilon} + \cdots + e^{(k-1)\varepsilon})$. Each new δ enters before $k-1, k-2, \dots, 0$ more multiplications by e^{ε}, which is where the geometric sum comes from.
7. *Simplify.* The geometric sum is $\frac{e^{k\varepsilon}-1}{e^{\varepsilon}-1}$, because multiplying it by $e^{\varepsilon} - 1$ cancels all terms but the first and last. Each of its k terms is at most the largest one, $e^{(k-1)\varepsilon}$, which gives the simpler but looser $k \, e^{(k-1)\varepsilon} \delta$.

□

No better bound holds for all (ε, δ)-DP mechanisms. The mechanism below shows it, because it has an event on which every one-step bound of steps 4 to 6 is an equality.

Proposition 19.1 (The alarm mechanism attains the bound)**.** *Fix $\varepsilon > 0$, $\delta \in (0, 1)$ and a cap K on the count of some kind of record. On a count $c \le K$ the* ***alarm mechanism*** *outputs "alarm" with probability*

$$a_c = \delta \sum_{j=0}^{K-c-1} e^{j\varepsilon} \tag{19.9}$$

and "quiet" otherwise, and on a count above K it always outputs "quiet". If $a_0 \le (e^\varepsilon + \delta)/(e^\varepsilon + 1)$, the mechanism is (ε, δ)-DP for neighbouring counts, which differ by 1, and for the counts 0 and $k \le K$ it meets Equation 19.6 with equality on the event "alarm".

Proof.

1. *One step is tight.* Pulling the first term δ out of the sum and a factor e^ε out of the rest shows that $a_c = e^\varepsilon a_{c+1} + \delta$ for $c < K$. So each neighbouring pair meets the event form with equality on "alarm".
2. *The mechanism is private.* The other three checks, "alarm" in the reverse order and "quiet" in both orders, hold exactly when $a_0 \le (e^\varepsilon + \delta)/(e^\varepsilon + 1)$. Section J.7 in the appendices proves it, and Exercise 2 in the exercise book proves the simpler sufficient condition $a_0 \le 1 - e^{-\varepsilon}$. For $\varepsilon = 0.5$ and $\delta = 10^{-5}$ the condition allows $K \le 21$.
3. *The chain is tight.* Along the path of counts $0, 1, \dots, k$, step 5 of the proof of Theorem 19.2 substitutes equalities into equalities, so $a_0 - e^{k\varepsilon} a_k = \delta \sum_{j=0}^{k-1} e^{j\varepsilon} = \delta_k$.

□

Pure DP degrades linearly. A 0.1-DP guarantee per record is 10-DP for a user with 100 records, which is almost nothing, since a likelihood ratio of up to $e^{10} \approx 22{,}000$ lets an adversary be nearly certain. This is the formal version of the "correlated records" caveat of the definition chapter. For approximate DP the δ term grows exponentially: with $\varepsilon = 1$ and $k = 10$ it is $\delta_k = \frac{e^{10}-1}{e-1}\,\delta = 12818.3\,\delta$. Since δ must already be much smaller than $1/n$ for n records (the definition chapter), group privacy for large groups is often vacuous.

A specific mechanism can do much better than the generic bound. With Gaussian noise on a count, a group of k records shifts the count by k, so its exact group profile is that of a Gaussian pair with a larger shift (Part 4). The better fix is often to define neighbours as datasets that differ in one user's records, bound each user's contribution, and prove DP at that level.

Example 19.2. For randomized response a group of k records is k people, and the reports in which all k favour the same side have privacy loss exactly $k \ln 3$, so the pure bound is exact. A noisy count shows the telescoping of step 1 at work. Take $\mathrm{Lap}(0, 1)$ noise and the path of counts $0, 1, 2, 3$, so $k = 3$. With density $\frac{1}{2}e^{-|y-c|}$ at true count c, the privacy loss between counts c and $c + 1$ is $L_{c,c+1}(y) = |y - c - 1| - |y - c|$, how much farther y is from $c + 1$ than from c. Table 19.3 adds the steps at three outputs.

Table 19.3.: Privacy losses along a path of three neighbouring counts, with $\mathrm{Lap}(0, 1)$ noise. The step losses add up to the loss between the ends.

Output y	$L_{0,1}(y)$	$L_{1,2}(y)$	$L_{2,3}(y)$	Sum	Direct: $\lvert y-3\rvert - \lvert y\rvert$
-2	$3-2=1$	$4-3=1$	$5-4=1$	3	$5-2=3$
0.5	$0.5-0.5=0$	$1.5-0.5=1$	$2.5-1.5=1$	2	$2.5-0.5=2$
1.5	$0.5-1.5=-1$	$0.5-0.5=0$	$1.5-0.5=1$	0	$1.5-1.5=0$

At $y=-2$ the output lies left of every count on the path, so every step points the same way and the sum reaches 3. At $y=1.5$ the steps point in different directions and cancel. The script confirms that the rounded noisy count has pure ε exactly k for counts that differ by $k=1,2,3,5$, so for a count group privacy is tight.

For approximate DP, protect each record at $(\varepsilon, \delta) = (0.5, 10^{-5})$. Table 19.4 compares the bound with the exact δ_k of the alarm mechanism with $K=10$ and of a count with Gaussian noise of standard deviation σ. Two normal distributions with standard deviation σ and means s apart have an exact δ in closed form, a difference of two normal tail probabilities (Divergences). The script solves that closed form for the σ that gives $\delta(0.5)=10^{-5}$ at shift 1, which is $\sigma=7.0318$, and evaluates it at the shift $s=k$. Figure 19.2 plots the same numbers up to $k=12$.

Table 19.4.: Group privacy from a $(0.5, 10^{-5})$ guarantee per record: the bound, its simple form, and the exact δ_k of two mechanisms at $\varepsilon_k = k\varepsilon$.

Group size k	$\varepsilon_k = k\varepsilon$	δ_k from Equation 19.6	Simple form $ke^{(k-1)\varepsilon}\delta$	Alarm mechanism, exact	Gaussian count, exact
1	0.5	1.000×10^{-5}	1.000×10^{-5}	1.000×10^{-5}	1.000×10^{-5}
2	1	2.649×10^{-5}	3.297×10^{-5}	2.649×10^{-5}	2.551×10^{-5}
3	1.5	5.367×10^{-5}	8.155×10^{-5}	5.367×10^{-5}	4.858×10^{-5}
5	2.5	1.724×10^{-4}	3.695×10^{-4}	1.724×10^{-4}	1.288×10^{-4}
10	5	2.272×10^{-3}	9.002×10^{-3}	2.272×10^{-3}	7.592×10^{-4}

The alarm mechanism attains the geometric sum at every k. The simple form is looser by a factor $3.297/2.649 = 1.24$ at $k=2$ and $9.002/2.272 = 3.96$ at $k=10$, so use the sum. The Gaussian count is a factor $2.272/0.7592 = 2.99$ below the bound at $k=10$. Even so, for a user with 10 records the record-level $(0.5, 10^{-5})$ becomes $(5, 7.6\times10^{-4})$, a weak guarantee.

19.3. Basic sequential composition

An analyst asks k queries of the same dataset, each with fresh noise. Each output alone is private, but an adversary sees all of them. This section asks what guarantee holds for the whole transcript $(y_1, \dots, y_k)$, even when each mechanism is chosen after seeing the previous outputs. For pure DP the answer rests on one fact about independent coins, which step 2 of the proof needs and parallel composition reuses: probabilities multiply, so privacy losses add.

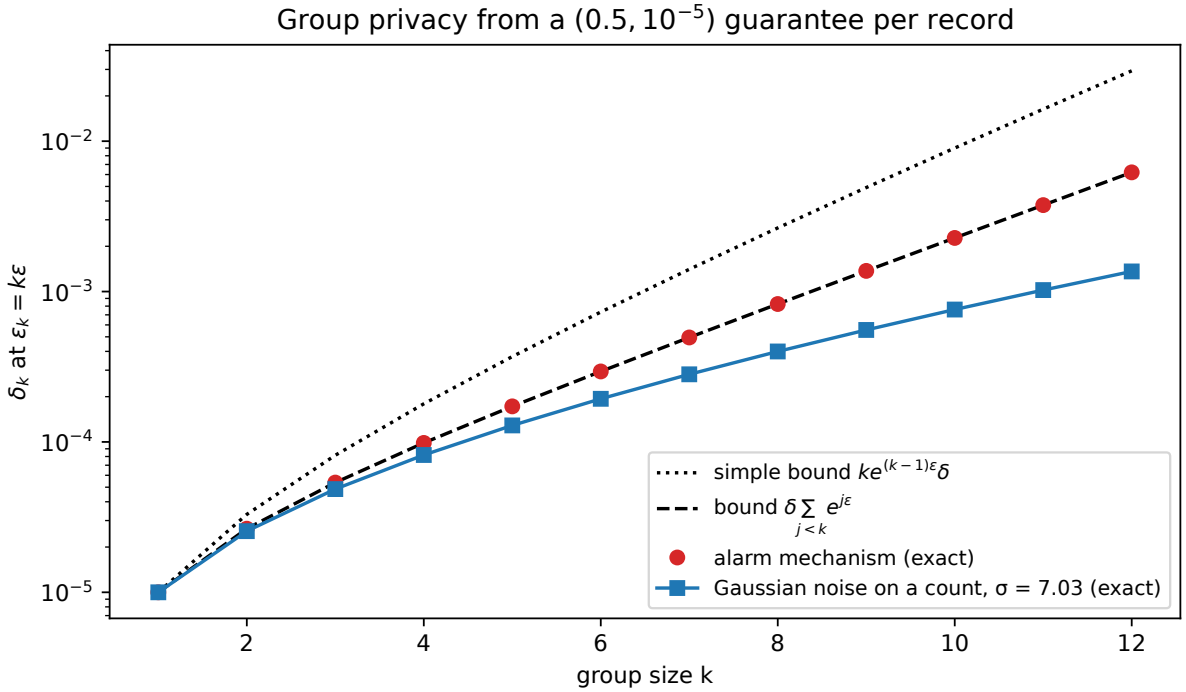

Figure 19.2.: The δ of group privacy at $\varepsilon_k = k\varepsilon$, for a per-record guarantee of $(0.5, 10^{-5})$, on a log scale. The geometric-sum bound (dashed) is attained by the alarm mechanism (red dots); the simple form (dotted) is looser by a factor that grows with k; Gaussian noise on a count (blue squares) does better than the bound but still grows quickly with k.

Lemma 19.2 (Privacy losses of independent outputs add)**.** *Let $Y = (Y_1, Y_2)$, where Y_1 and Y_2 are produced with independent coins, so that $p(y_1, y_2) = p_1(y_1)p_2(y_2)$ on D and likewise $q(y_1, y_2) = q_1(y_1)q_2(y_2)$ on D'. Then the privacy loss of the pair is the sum of the privacy losses of its parts,*

$$L(y_1, y_2) = \ln \frac{p_1(y_1)p_2(y_2)}{q_1(y_1)q_2(y_2)} = L_1(y_1) + L_2(y_2). \tag{19.10}$$

The same holds when the second output depends on the first, with the conditional probabilities $p_2(y_2 \mid y_1)$ and $q_2(y_2 \mid y_1)$ in place of $p_2(y_2)$ and $q_2(y_2)$.

Proof.

1. *Independent outputs.* The probability of seeing both outputs is the product of their probabilities, and the logarithm of a product of two ratios is the sum of the two logarithms.
2. *Dependent outputs.* The chain rule of probability writes any joint probability as "first, times second given first", $p(y_1, y_2) = p_1(y_1)\, p_2(y_2 \mid y_1)$, and the same on D'. The same logarithm then gives the same sum, with the conditional loss $\ln \frac{p_2(y_2|y_1)}{q_2(y_2|y_1)}$ as its second term.

□

In the theorem below, each mechanism M_i may also read the previous outputs, the way an analyst picks the next query after reading the last answer. This is **adaptive** composition, and **non-adaptive** composition is the case where M_i ignores them. The condition is that each step is private however the earlier outputs turned out. Section B.1 in the appendices derives the theorem from scratch, with worked numbers.

Theorem 19.3 (Basic composition)**.** *Let $M_1, \dots, M_k$ run on the same dataset with independent coins, where M_i may read the previous outputs $y_1, \dots, y_{i-1}$. If, for every fixed value of the previous outputs, $D \mapsto M_i(D; y_1, \dots, y_{i-1})$ is $(\varepsilon_i, \delta_i)$-DP, then the mechanism that releases $(y_1, \dots, y_k)$ is*

$$\Big(\sum_{i=1}^{k} \varepsilon_i,\ \sum_{i=1}^{k} \delta_i\Big)\text{-DP.} \tag{19.11}$$

For pure DP the bound $\sum_i \varepsilon_i$ is the exact worst-case privacy loss whenever each M_i attains its own worst case at outputs that can occur together.

Proof. The plan is to prove the pure case by adding privacy losses with Lemma 19.2. The approximate case takes two mechanisms, since induction on k does the rest. That case splits an event over the first output, applies the second mechanism's guarantee for each value of it, and applies the first mechanism's guarantee to what is left, a soft test of the first output.

1. *Pure DP: factor the probability of a transcript.* By the chain rule, the probability of $(y_1, \dots, y_k)$ is the probability of y_1, times that of y_2 given y_1, and so on. On D,

$$p_D(y_1, \dots, y_k) = \prod_{i=1}^{k} p_{M_i(D;\, y_{<i})}(y_i), \tag{19.12}$$

where $y_{<i} = (y_1, \dots, y_{i-1})$ and each factor uses fresh coins. The same holds on D', with the same previous outputs plugged in.

2. *Take the log-ratio.* By Lemma 19.2, applied $k-1$ times in its dependent form, $L_{D,D'}(y_1,\dots,y_k)=\sum_{i=1}^{k} L^{(i)}(y_i;\, y_{<i})$, where $L^{(i)}$ is the privacy loss of M_i with its previous outputs fixed.
3. *Bound each term and add.* For the fixed $y_{<i}$, M_i is ε_i-DP by assumption, so $|L^{(i)}|\le\varepsilon_i$, and the sum is at most $\sum_i \varepsilon_i$ at every transcript, which is pure $\sum_i \varepsilon_i$-DP. When every M_i attains ε_i at outputs that can occur together, the sum is attained, which is the exactness claim.
4. *Approximate DP: split an event over the first output.* Take $k=2$, and write P and Q for the distribution of the transcript (Y_1,Y_2) on D and on D'. For a set S of transcripts, let $S_{y_1}=\{y_2 : (y_1,y_2)\in S\}$, the second outputs that complete y_1 into S. The transcript lands in S when the first output is some y_1 and the second lands in S_{y_1}, so

$$P(S)=\sum_{y_1} p_1(y_1)\, P_2^{y_1}(S_{y_1}), \tag{19.13}$$

   where p_1 is the mass function of $M_1(D)$ and $P_2^{y_1}$ the distribution of $M_2(D;y_1)$. Write q_1 and $Q_2^{y_1}$ for the same objects on D'.
5. *Apply the second mechanism's guarantee inside the sum.* For each y_1, $P_2^{y_1}(S_{y_1})\le e^{\varepsilon_2}Q_2^{y_1}(S_{y_1})+\delta_2$, and also $P_2^{y_1}(S_{y_1})\le 1$ because it is a probability. So $P_2^{y_1}(S_{y_1})\le g(y_1)+\delta_2$ with

$$g(y_1)=\min\left(1,\ e^{\varepsilon_2}Q_2^{y_1}(S_{y_1})\right)\in[0,1]. \tag{19.14}$$

6. *Sum over y_1.* The weights $p_1(y_1)$ add up to 1, so δ_2 comes out once: $P(S)\le \mathbb{E}_{p_1}[g]+\delta_2$.
7. *Apply the first mechanism's guarantee to g.* The function g takes values in $[0,1]$, which is why it was capped at 1, so Lemma 19.1 gives $\mathbb{E}_{p_1}[g]\le e^{\varepsilon_1}\mathbb{E}_{q_1}[g]+\delta_1$.
8. *Undo the cap.* Since $g(y_1)\le e^{\varepsilon_2}Q_2^{y_1}(S_{y_1})$, the average $\mathbb{E}_{q_1}[g]$ is at most $e^{\varepsilon_2}\sum_{y_1} q_1(y_1)Q_2^{y_1}(S_{y_1})$, which by step 4 on D' is $e^{\varepsilon_2}Q(S)$.
9. *Combine.* Steps 6 to 8 give $P(S)\le e^{\varepsilon_1+\varepsilon_2}Q(S)+\delta_1+\delta_2$. Nothing used that M_2 ignores y_1, so this covers adaptive composition.

□

Basic composition is exact for the worst case, and the worst case is rare. For k randomized-response answers about the same bit, "every answer is true" has loss $k\ln 3$ but probability $(\frac{3}{4})^k$. Typical transcripts mix truths with lies, whose losses cancel. Under D, each answer contributes $+\varepsilon_0$ when it tells the truth, with probability $t=e^{\varepsilon_0}/(1+e^{\varepsilon_0})$, and $-\varepsilon_0$ otherwise. Its mean is therefore $\varepsilon_0(2t-1)=\varepsilon_0\tanh(\varepsilon_0/2)$, which is $\varepsilon_0/2$ for $\varepsilon_0=\ln 3$. A sum of k such independent terms stays within a spread of order $\varepsilon_0\sqrt{k}$ of its mean (Concentration). An (ε,δ) guarantee may ignore losses above ε that occur with probability at most δ, so a small δ writes off the unlikely tail, and the ε you need grows like $\sqrt{k}$ rather than k, which is the advanced composition of Advanced and optimal composition, previewed by Exercise 6 in the exercise book.

The δs add without the inflation of group privacy, because each mechanism compares the *same* pair D, D', and step 6 of the proof just averages the second slack. Adaptivity is free, but only with budgets fixed in advance. Choosing the budgets from the outputs ("stop when the answer is good enough") needs the privacy filters of Advanced and optimal composition.

Example 19.3. Start with an adaptive survey. Ask a person for a randomized-response answer with $\varepsilon_1=\ln 3$, then ask again with $\ln 3$ if the answer was 1 and with 0.5 if it was 0. Level 0.5

tells the truth with probability $e^{0.5}/(1+e^{0.5}) = 0.6225$. So the second step depends on y_1, but it is at most $\ln 3$-DP for each value of y_1. In Table 19.5 each probability is the product of the two steps. For example, $(0,1)$ under bit 1 is a lie and then the truth, $\frac{1}{4} \times 0.6225 = 0.1556$.

Table 19.5.: An adaptive composition of two randomized-response answers: the second one uses $\varepsilon = \ln 3$ after a 1 and $\varepsilon = 0.5$ after a 0. Each transcript's privacy loss is the sum of the two step losses.

(y_1, y_2)	Under bit 1 (D)	Under bit 0 (D')	$L = L^{(1)} + L^{(2)}$
$(1,1)$	0.5625	0.0625	$\ln 3 + \ln 3 = 2.1972$
$(1,0)$	0.1875	0.1875	$\ln 3 - \ln 3 = 0$
$(0,1)$	0.1556	0.2832	$-\ln 3 + 0.5 = -0.5986$
$(0,0)$	0.0944	0.4668	$-\ln 3 - 0.5 = -1.5986$

The answers $(1,1)$ are two pieces of evidence pointing the same way, and $(1,0)$ are two that cancel. The worst loss is $2.1972 = \ln 3 + \ln 3$, exactly the bound with $\varepsilon_2 = \max(\ln 3, 0.5)$, the largest budget the second step can have.

Now ask the same question k times with fresh randomized response at $\varepsilon_0 = \ln 3$. If j answers equal 1, the privacy loss is $(2j-k)\ln 3$, and j is binomial with k trials and success probability $\frac{3}{4}$ when the bit is 1, or $\frac{1}{4}$ when it is 0. Figure 19.3 shows the loss for $k = 10$. Table 19.6 gives the script's exact numbers, with "exact ε at $\delta = 10^{-6}$" the smallest ε whose $\delta(\varepsilon)$ is at most 10^{-6}.

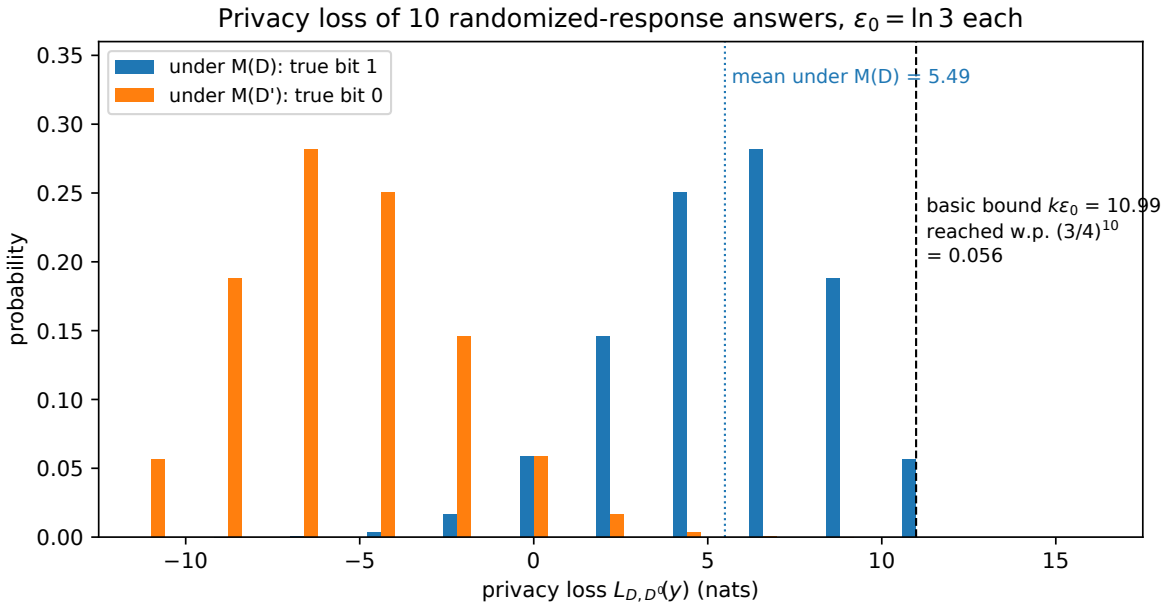

Figure 19.3.: Distribution of the privacy loss $L_{D,D'}$ of 10 randomized-response answers with $\varepsilon_0 = \ln 3$ each, when the true bit is 1 (blue) or 0 (orange). The loss takes the values $(2j-10)\ln 3$, where j is the number of answers equal to 1. The basic bound $10\ln 3$ is reached, but only with probability $(3/4)^{10} = 0.056$; the mean under D is half of it.

Table 19.6.: k randomized-response answers about the same bit, $\varepsilon_0 = \ln 3$ each: the basic bound, the exact worst case, how likely the worst case is, the mean privacy loss, and the exact ε when $\delta = 10^{-6}$ is allowed.

k	Basic bound $k\varepsilon_0$	Exact worst-case loss	$\Pr_D[L = k\varepsilon_0] = (\frac{3}{4})^k$	Mean loss under D	Exact ε at $\delta = 10^{-6}$
1	1.099	1.099	0.75	0.549	1.099
10	10.986	10.986	5.631×10^{-2}	5.493	10.986
20	21.972	21.972	3.171×10^{-3}	10.986	21.972
50	54.931	54.931	5.663×10^{-7}	27.465	52.680
100	109.861	109.861	3.207×10^{-13}	54.931	94.290

A slack δ helps only if transcripts with large loss have total probability below δ. Lowering ε by a small ξ makes the worst transcript alone contribute about $(\frac{3}{4})^k\xi$ to the hockey-stick divergence. So at $k = 20$ the allowed ξ is only about $10^{-6}/(3.171 \times 10^{-3}) \approx 3 \times 10^{-4}$, and the exact ε equals the basic bound to three decimals. At $k = 50$ the worst case drops below 10^{-6}, and at $k = 100$ the slack buys $109.861 - 94.290 = 15.6$. With a smaller per-answer budget the gain is much larger: at $\varepsilon_0 = 0.1$ and $k = 1000$ the basic bound is 100, and the exact ε at $\delta = 10^{-6}$ is 19.345 (Figure 19.4).

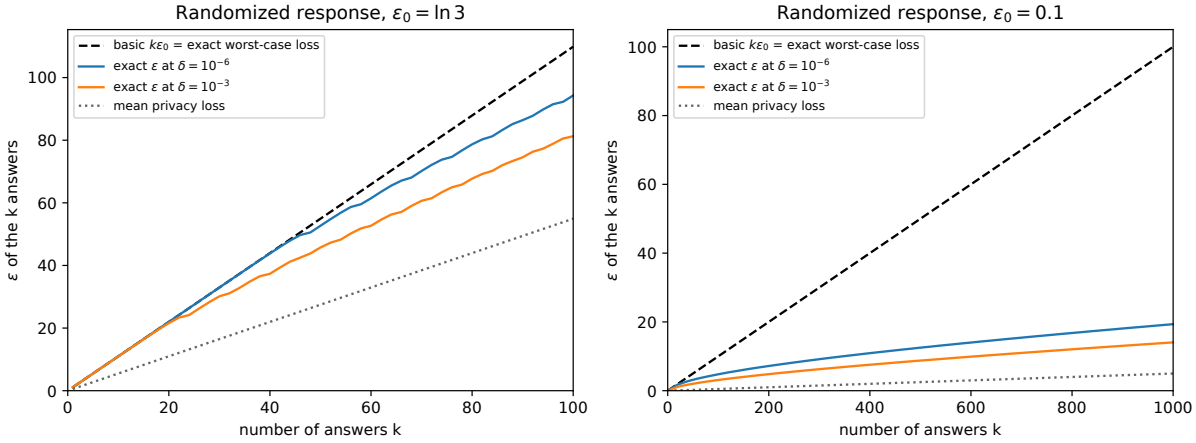

Figure 19.4.: The ε of k randomized-response answers: the basic bound $k\varepsilon_0$, which is also the exact worst-case loss (dashed), the exact ε at $\delta = 10^{-6}$ and 10^{-3}, and the mean privacy loss (dotted). Left: $\varepsilon_0 = \ln 3$; the exact curves leave the basic line only once $(3/4)^k$ drops below δ. Right: $\varepsilon_0 = 0.1$; the exact curves grow like $\sqrt{k}$.

The same gap appears for approximate-DP mechanisms. Take k counts with Gaussian noise, each calibrated to $(0.5, 10^{-5})$ with $\sigma = 7.0318$. One record shifts each noisy count by 1, and k independent Gaussians shifted by 1 carry the same evidence as one shifted by $\sqrt{k}$ (Section B.3 in the appendices derives this). By Table 19.7, basic composition overstates ε for ten queries by a factor of $5/1.504 = 3.3$.

Table 19.7.: k counts with Gaussian noise, each $(0.5, 10^{-5})$-DP: basic composition against the exact ε at the same total δ.

k	Basic: $(k\varepsilon, k\delta)$	Exact ε at the same $\delta = k \times 10^{-5}$
1	$(0.5, 10^{-5})$	0.500
2	$(1, 2 \times 10^{-5})$	0.694
4	$(2, 4 \times 10^{-5})$	0.966
10	$(5, 10^{-4})$	1.504

19.4. Parallel composition

A histogram counts people in disjoint bins. Sequential composition would charge $d\varepsilon$ for d bins, which is far too pessimistic, because one person's record lands in one bin only. Parallel composition makes that precise, with care about the two common neighbouring relations. Under **add/remove**, neighbours differ by adding or removing one record. Under **replace**, neighbours have the same size and differ in the content of one record, which is a removal followed by an addition.

Split the data universe into disjoint parts $U_1, \dots, U_d$ by a rule that may depend on a record's content but not on the rest of the dataset, and run M_i on $D \cap U_i$, the records in part i. A changed record touches only its own part, so you pay only that part's budget.

Theorem 19.4 (Parallel composition)**.** *Let $U_1, \dots, U_d$ be a partition of the data universe fixed in advance, and let M_i run on $D \cap U_i$ with independent coins, each $(\varepsilon_i, \delta_i)$-DP under add/remove. Then the release $(M_1(D \cap U_1), \dots, M_d(D \cap U_d))$ is*

$$(\max_i \varepsilon_i,\ \max_i \delta_i)\text{-DP under add/remove.} \tag{19.15}$$

Under replace, a record that moves from part a to part $b \neq a$ costs $(\varepsilon_a + \varepsilon_b, \delta_a + \delta_b)$, and one replaced within part a costs that part's guarantee for two add/remove steps, at most group privacy with $k = 2$; for pure DP with equal budgets both cases give 2ε. If the parts are fixed slots, so that record i always goes to part i, a replacement changes one part only and the cost is $(\max_i \varepsilon_i, \max_i \delta_i)$ again.

Proof.

1. *Add/remove changes one part.* If $D' = D \cup \{x\}$, then x lies in exactly one part U_j, because the parts are disjoint and cover the universe. For $i \neq j$, $D \cap U_i = D' \cap U_i$, so M_i gets the same input and has the same output distribution on both.
2. *Pure DP: the other losses are zero.* By Lemma 19.2 the privacy loss of the whole release is $\sum_i L^{(i)}$, and $L^{(i)} \equiv 0$ for $i \neq j$ because the two distributions are equal and their ratio is 1. So $|L| = |L^{(j)}| \leq \varepsilon_j \leq \max_i \varepsilon_i$.
3. *Approximate DP: condition on the unchanged parts.* Let W be the outputs of the parts $i \neq j$, which have the same distribution on D and D' and are independent of Y_j. Given W, the release lands in an event S when Y_j falls in S_W, the set of y_j completing W into S. So the probability of S is the average over W of $\Pr[Y_j \in S_W]$. Inside that average, M_j's

guarantee bounds the probability on D by e^{ε_j} times that on D', plus δ_j, and averaging over the same W carries the bound to S.

4. *Replace changes up to two parts.* If D' replaces a record $x \in U_a$ by $x' \in U_b$, then $D \cap U_a$ loses a record and $D \cap U_b$ gains one: two add/remove steps on two independent mechanisms, which is a composition of two mechanisms (Theorem 19.3, with the other parts handled as in step 3), giving $(\varepsilon_a + \varepsilon_b, \delta_a + \delta_b)$. If $a = b$, part a sees a removal and an addition, two neighbouring steps, which is Theorem 19.2 with $k = 2$ inside one part. In fixed slots a replacement changes only slot i, and steps 1 to 3 apply again.

□

So a histogram costs one ε, not d. Laplace noise of scale $1/\varepsilon$ on each of d bins is ε-DP under add/remove, because adding a record changes one bin by 1. Under replace it is 2ε-DP, since moving a record changes two bins, which is why a histogram's sensitivity is quoted as 2 under replace (The Laplace and Gaussian mechanisms).

The partition must not depend on the data. "Split the data at its median" changes when one record changes, which can move many records between parts, and then step 1 of the proof fails. Use fixed bins, or account for the data-dependent split as a mechanism of its own.

Example 19.4. Local randomized response composes in parallel. Each of n people reports their own bit at $\varepsilon_0 = \ln 3$, and each person is one slot, so the whole vector of n reports is $\ln 3$-DP for any n, not $n \ln 3$, under either neighbouring relation.

A two-bin histogram shows the factor of 2. Give each bin rounded $\mathrm{Lap}(0, 1)$ noise, and let the script compute the exact pure ε of the pair under each relation. Adding or removing a record changes one bin by 1, so only that bin contributes privacy loss, and $\varepsilon = 1.0000$. Replacing a record in bin 1 by one in bin 2 moves bin 1 up by 1 and bin 2 down by 1. The worst output then has both noisy counts far out on the side that favours D, where both step losses equal 1 at once, so $\varepsilon = 2.0000$. Exercise 4 in the exercise book works out the losses by hand.

19.5. What composes and what doesn't

The three properties hold under weak assumptions, which makes it tempting to apply them where even those fail. Each assumption appeared in a proof. Post-processing needs f not to read the data, composition needs independent coins and one neighbouring relation, and group privacy and composition need budgets fixed in advance. Table 19.8 collects the ways these break in practice, and the section then proves that the commonest break, two releases sharing one noise draw, is a total failure.

Table 19.8.: What composes and what doesn't.

Situation	Composes?	Why
Function of the output, own coins	Yes, at no cost	Post-processing (Theorem 19.1)

Situation	Composes?	Why
Another query on the same data, fresh noise, even chosen from the first answer	Yes, budgets add	Basic composition (Theorem 19.3)
Two queries sharing one noise draw	**No**	The noise cancels in a difference (Proposition 19.2)
"Post-processing" that reads the data again	**No**	It is a new mechanism, often a non-private one
Budgets chosen from earlier outputs	Not by Equation 19.11	Needs privacy filters (Advanced and optimal composition)
Proved under add/remove, released under replace	Yes, at $(2\varepsilon, (1+e^{\varepsilon})\delta)$	Group privacy with $k=2$, as in Equation 18.6 of the definition chapter
A DP release plus an exact statistic of the same data	**No**	The exact statistic is not DP

When two releases share one noise draw, the noise can be subtracted away, and privacy fails completely.

Proposition 19.2 (Shared noise is not private)**.** *Release two counts with the same Laplace draw Z of scale b: $c_1(D)+Z$ and $c_2(D)+Z$, where removing some record lowers c_1 by 1 and leaves c_2 unchanged. Each count alone is $1/b$-DP, but the pair is not (ε,δ)-DP for any ε and any $\delta<1$.*

Proof.

1. *The difference is noise-free.* $(c_1+Z)-(c_2+Z)=c_1(D)-c_2(D)$, a deterministic function of the data.
2. *It changes between neighbours.* If the difference is c on D, it is $c-1$ on the neighbour D' without that record, since removing the record lowers c_1 by 1 and leaves c_2.
3. *One event separates the two.* The event "the difference equals c" has probability 1 on D and 0 on D', so the event form $1 \le e^{\varepsilon}\cdot 0+\delta$ fails for every ε unless $\delta \ge 1$.

□

What broke is step 1 of the proof of Theorem 19.3: the transcript's probability is no longer a product of the two mechanisms' probabilities. So fresh randomness is part of the mechanism. Seeding two mechanisms with the same seed, re-adding a cached noise draw to a related query, or reusing noise across shards are all the shared-noise bug. An exact total published elsewhere can be differenced against a DP release in the same way.

The neighbouring relation is part of the budget too. A guarantee proved under add/remove and reported under replace can be off by a factor of 2, and mixing the two inside one accountant, the code that totals the budget, is a bug that comes back in Subsampling.

Example 19.5. Randomized response does not have this failure: if two answers reuse one coin, the second repeats the first, which is post-processing, but additive noise does have it. The script simulates the **differencing attack** of Proposition 19.2 on two Laplace counts, the number of smokers and the number of smokers aged 40 or over. Alice is a smoker aged 30, so she counts only in the first. She is in the data with probability $\frac{1}{2}$, and the attacker guesses "in" when the difference of the two counts exceeds the midpoint of its two possible true values. Over 200,000 runs with $\mathrm{Lap}(0, 1)$ noise, the attack with shared noise has accuracy 1.0000, because the difference is exact.

With fresh noise the same attack has accuracy 0.6206. The second count no longer depends on Alice, so the best any attack can reach is that of the first count alone, $\frac{1}{2}$ plus half the total variation distance between what it sees in the two cases (Divergences). For $\mathrm{Lap}(0, 1)$ against $\mathrm{Lap}(1, 1)$ the best event is "the output is above $\frac{1}{2}$", whose probabilities differ by $1 - e^{-1/2}$, so the best accuracy is $\frac{1}{2} + \frac{1}{2}(1 - e^{-1/2}) = 0.6967$. The difference attack falls short of it because it adds the noise of the second count.

19.6. Code

The script code/properties.py computes every number in this chapter and draws every figure, from each mechanism's exact output distributions on two neighbouring datasets. From the repository root:

```
uv run python code/part03-dp-foundations/properties.py
```

Table 19.9.: The script's output with the default seed.

Experiment	Result
Randomized response $\ln 3$, then flip with probability r	$r = 0.1$: $\varepsilon = 0.8473$; $r = 0.25$: $0.5108 = \ln \frac{5}{3}$; $r = 0.5$: 0
Count + $\mathrm{Lap}(0, 1)$, post-processed	Raw: $\varepsilon = 1$, $\delta(0.5) = 0.2212$; rounded: 1.0000, 0.1967; threshold: 0.8318, 0.1967
Group privacy, pure	Rounded Laplace count, counts k apart: $\varepsilon = k$ for $k = 1, 2, 3, 5$
Group privacy, $(0.5, 10^{-5})$ per record	Table 19.4; the alarm mechanism attains the bound at every k
k randomized-response answers	Table 19.6; $\varepsilon_0 = 0.1$, $k = 1000$: basic 100, exact 19.345 at $\delta = 10^{-6}$
Simulation, 10 answers, 200,000 runs	Mean loss 5.500 (exact 5.493); worst case in 0.0559 of runs (exact 0.0563)
Adaptive two-step survey	Table 19.5; worst loss $2.1972 = 2 \ln 3$
k Gaussian counts, $(0.5, 10^{-5})$ each	Table 19.7
Two-bin histogram, rounded $\mathrm{Lap}(0, 1)$	Add/remove: $\varepsilon = 1.0000$; replace across bins: 2.0000
Shared against fresh noise, 200,000 runs	Attack accuracy 1.0000 against 0.6206; best possible with fresh noise 0.6967

tests/test_properties.py checks that the output still matches.

19.7. Summary

Table 19.10.: The results of this chapter, and where each is used.

Result	Statement	Use
Lemma 19.1	$\mathbb{E}_P[g] \le e^{\varepsilon}\mathbb{E}_Q[g] + \delta$ for every g with values in $[0,1]$	Approximate-DP proofs where a later stage depends on an earlier output
Theorem 19.1	$f \circ M$ is (ε,δ)-DP for any f that does not read the data	Privatize once, early; everything after is free, every attack of Part 2 included
Theorem 19.2	$k\varepsilon$ for datasets k records apart, with $\delta_k = \delta\frac{e^{k\varepsilon}-1}{e^{\varepsilon}-1} \le ke^{(k-1)\varepsilon}\delta$	Per-user guarantees; cheap only for small groups, so prefer user-level neighbours
Proposition 19.1	The alarm mechanism meets Equation 19.6 with equality	No better generic bound exists, though Gaussian noise does better
Lemma 19.2	$L(y_1,y_2) = L_1(y_1) + L_2(y_2)$ for independent coins, also given y_1	The fact behind both compositions; it needs fresh noise
Theorem 19.3	$(\sum \varepsilon_i, \sum \delta_i)$, also adaptive with budgets fixed in advance	Budgeting many queries; the worst case is exponentially rare, so for large k use the accountants of Advanced and optimal composition
Theorem 19.4	$(\max \varepsilon_i, \max \delta_i)$ under add/remove for a fixed partition; twice that under replace	Histograms, per-group statistics, local randomized response
Proposition 19.2	Two counts with one noise draw are not DP for any $\delta < 1$	Every composed mechanism needs its own fresh noise

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

20. The Laplace and Gaussian mechanisms

You run a hospital database and want to publish how many patients have diabetes, with a differential privacy (DP) guarantee. The definition of differential privacy says what the release must satisfy: changing one person's record must barely change the distribution of what you publish. It does not say how to build such a release. The two mechanisms of this chapter are the answer used almost everywhere. Both compute the exact answer, call it $f(D)$ for the dataset D, and blur it with random noise Z drawn fresh each time, so that what you publish is

$$M(D) = f(D) + Z. \tag{20.1}$$

If the noise is wide compared with how far one person can move the answer, an observer cannot tell from the output whether that person was there.

Three questions decide everything. The first is how much one record can move the answer. That is the **sensitivity** of f, and it sets the scale of the noise. The second is which noise distribution to use. Laplace noise gives pure ε-DP, while Gaussian noise gives only (ε, δ)-DP but scales better when many numbers are released at once. The third is how much noise exactly. For Laplace noise the answer is a one-line formula. For Gaussian noise the textbook formula is loose, and the exact answer comes from solving one equation numerically.

The running example is the hospital's count: 1,234 of its $n = 10{,}000$ patients have diabetes, and the count must be released under add/remove neighbours. Every later mechanism that adds noise, from the private mean to the noisy gradients of private model training in a later part, is calibrated with the tools of this chapter.

20.1. Sensitivity

To hide one record, the noise has to cover the largest change one record can make to the answer. That change is the sensitivity, and it is the first thing to compute for any release. It depends on the query, on the norm you measure the change in, and on the neighbouring relation of the definition of differential privacy: under **add/remove** a neighbour has one record more or less, so the dataset size changes, and under **replace** one record is swapped for another, so the size n is fixed and public.

For a vector answer you need a way to measure a change, and two are used. The ℓ_1 norm $\|v\|_1 = \sum_i |v_i|$ is the total change summed over coordinates, and Laplace noise is calibrated to it. The ℓ_2 norm $\|v\|_2 = \sqrt{\sum_i v_i^2}$ is the straight-line length, and Gaussian noise is calibrated to it.

Definition 20.1 (Sensitivity)**.** Let $f\colon \mathcal{X}^n \to \mathbb{R}^d$ be a query with values in $\mathbb{R}^d$. For $p \in \{1, 2\}$, the ℓ_p **sensitivity** of f is the largest distance between its answers on two neighbouring datasets,

$$\Delta_p f = \max_{D \sim D'} \big\| f(D) - f(D') \big\|_p. \tag{20.2}$$

The two sensitivities are never far apart, and how far depends on how one record's change spreads over the coordinates. The next result says exactly how far, and Section 20.5 turns it into the rule for choosing between the two mechanisms.

Proposition 20.1 (The two sensitivities)**.** *For every query f with values in $\mathbb{R}^d$,*

$$\Delta_2 f \le \Delta_1 f \le \sqrt{d}\,\Delta_2 f. \tag{20.3}$$

The left bound is reached when one record moves a single coordinate, the right one when it moves all d coordinates equally.

Proof.

1. Fix a vector $v \in \mathbb{R}^d$. Squaring the sum $\sum_i |v_i|$ gives every v_i^2 plus cross terms that are never negative, so $\|v\|_2^2 \le \|v\|_1^2$, that is $\|v\|_2 \le \|v\|_1$.
2. The Cauchy–Schwarz inequality applied to the sum $\sum_i 1 \cdot |v_i|$ gives $\|v\|_1 \le \sqrt{d}\,\|v\|_2$.
3. Both inequalities hold for the change $v = f(D) - f(D')$ of every neighbouring pair, so they hold for the maximum over pairs. If only one coordinate of v is non-zero, both norms equal its absolute value; if all d coordinates equal c, then $\|v\|_1 = dc$ and $\|v\|_2 = \sqrt{d}\,c$.

□

The sensitivities of the standard queries follow by asking what the single worst record can do. Table 20.1 collects them; records take values in a domain $\mathcal{X}$, and B bounds a numerical record.

Table 20.1.: Sensitivities of the standard queries under the two neighbouring relations.

Query	Add/remove Δ_1	Add/remove Δ_2	Replace Δ_1	Replace Δ_2
Count $\lvert D\rvert$	1	1	0	0
Sum, records in $[0, B]$	B	B	B	B
Mean, records in $[0, B]$, n public	—	—	B/n	B/n
Histogram with d bins	1	1	2	$\sqrt{2}$
d threshold counts $\#\{x \ge j\}$, $j = 1..d$	d	$\sqrt{d}$	d	$\sqrt{d}$

Proposition 20.2 (Sensitivities of the standard queries)**.** *The sensitivities in Table 20.1 hold, and each is reached by some neighbouring pair.*

Proof.

1. *Count.* Adding or removing a record changes $|D|$ by exactly 1. Replacing a record leaves it unchanged, which is why under replace the size is not private and a count of all records needs no noise.

2. *Sum.* Adding a record $x \in [0, B]$ changes the sum by $x \leq B$, and replacing x by x' changes it by $|x - x'| \leq B$. Both bounds are reached with $x = B$ and $x' = 0$.
3. *Mean with public n.* Under replace the mean is the sum divided by the fixed n, so its sensitivity is the sum's divided by n, which is B/n. Under add/remove the denominator moves too, so there is no such simple bound; Exercise 1 in the exercise book releases a noisy sum and a noisy count instead.
4. *Histogram.* Under add/remove the record lands in one bin, so that bin changes by 1 and the others not at all. The change vector is $\pm e_j$, where e_j has a 1 in bin j and 0 elsewhere, and both of its norms are 1. Under replace one bin loses 1 and another gains 1, so the change is $e_{j'} - e_j$, with ℓ_1 norm $1 + 1 = 2$ and ℓ_2 norm $\sqrt{1^2 + 1^2} = \sqrt{2}$.
5. *Threshold counts.* The count for threshold j is the number of records with $x \geq j$, so a record x adds 1 to every count with $j \leq x$. A record with $x \geq d$ moves all d counts by 1, so the change vector is $(1, \ldots, 1)$, with ℓ_1 norm d and ℓ_2 norm $\sqrt{d}$. Under replace, changing x to x' moves only the counts with j between the two values, at most d of them, by 1 each, so the same bounds hold.

□

Sensitivity is a worst case over datasets. It does not depend on the data you hold, only on what the domain allows, which is why it can be computed before looking at the data. It is also why the sum of arbitrary real numbers has infinite sensitivity, since one record can be as large as it likes; clipping, in Beyond global sensitivity, forces a finite B. The neighbouring relation changes the answer by up to a factor of 2, because replacing is removing one record and adding another, so a guarantee stated without its neighbouring relation is ambiguous by that factor in ε.

Example 20.1. The hospital also releases the mean age of its $n = 10{,}000$ patients, with ages clipped to $[0, 100]$, under replace neighbours. By row 3 of Table 20.1 the sensitivity is $B/n = 100/10{,}000 = 0.01$ year, so one patient can move the mean by at most a hundredth of a year, however old they are. For the diabetes count under add/remove, row 1 gives a sensitivity of 1.

20.2. The Laplace mechanism

The Laplace mechanism is the first mechanism to try (Dwork, McSherry, Nissim & Smith 2006). It adds independent Laplace noise to each coordinate, with scale proportional to the ℓ_1 sensitivity. Section A.3 in the appendices derives the same result from scratch for a single count, with every number shown.

Everything rests on the **privacy loss** of the definition of differential privacy. For an output y, it is the log of how much more likely y is when the data are D than when they are D',

$$L_{D,D'}(y) = \ln \frac{p_{M(D)}(y)}{p_{M(D')}(y)}, \tag{20.4}$$

where $p_{M(D)}$ is the density of the published output on dataset D. Write P and Q for the two output distributions $M(D)$ and $M(D')$. That chapter proved that a mechanism whose loss is at

most ε at every output, for every neighbouring pair, is ε-DP, in its section on pure DP being pointwise. The Laplace mechanism is proved private exactly this way.

For additive noise the loss has a simple shape. On neighbouring datasets the mechanism outputs $f(D) + Z$ and $f(D') + Z$, the same noise placed around two different centres, so the density of Q is the density of P slid over by the shift $f(D') - f(D)$. How far apart two distributions are, at a factor $\gamma \geq 1$, is measured by the **hockey-stick divergence** of Divergences, $E_\gamma(P\|Q)$, the largest value of $\Pr_P[S] - \gamma \Pr_Q[S]$ over events S. At $\gamma = e^\varepsilon$ it is the smallest δ that works for the pair. The first result says that under this measure the true answer drops out, and only the shift matters.

Lemma 20.1 (Additive noise reduces to one shifted pair)**.** *Let $M(D) = f(D) + Z$, where Z has a density on $\mathbb{R}^d$, and let $v = f(D') - f(D)$ be the shift between the two answers on a neighbouring pair. Then for every $\gamma \geq 1$,*

$$E_\gamma(M(D)\|M(D')) = E_\gamma(Z\|Z + v). \tag{20.5}$$

Proof.

1. The map $y \mapsto y - f(D)$ sends $M(D)$ to Z and $M(D')$ to $Z + v$, and it is a bijection: every output corresponds to exactly one relabelled output, and back.
2. So an event S about M's output is the same as the event $S - f(D)$ about the relabelled output, with the same probability under each dataset. The hockey-stick divergence is a maximum of $\Pr_P[S] - \gamma \Pr_Q[S]$ over events, and both sides range over the same values, so they are equal.

□

For the hospital's count, the true value 1234 drops out and only the shift $v = 1$ remains. Privacy is a property of the noise and of the set of shifts that neighbouring datasets can produce, which Section 20.1 bounded. The Laplace mechanism chooses its scale so that the largest shift one record can cause, divided by the scale, is exactly ε.

Theorem 20.1 (The Laplace mechanism)**.** *The **Laplace distribution** $\mathrm{Lap}(b)$ with scale $b > 0$ has density $\frac{1}{2b}e^{-|z|/b}$, a two-sided exponential peaked at 0. Let $f\colon \mathcal{X}^n \to \mathbb{R}^d$ have ℓ_1 sensitivity $\Delta_1 f$ and let $\varepsilon > 0$. The **Laplace mechanism***

$$M(D) = f(D) + (Z_1, \dots, Z_d), \qquad Z_i \overset{i.i.d.}{\sim} \mathrm{Lap}(b), \quad b = \frac{\Delta_1 f}{\varepsilon}, \tag{20.6}$$

is ε-DP (i.i.d. means independent and identically distributed). Its error per coordinate is about b, and for every failure probability $\beta \in (0, 1)$ the largest error over the d coordinates obeys

$$\mathbb{E}[|Z_i|] = b, \qquad \mathrm{Var}(Z_i) = 2b^2, \qquad \Pr\Big[\max_i |Z_i| > b \ln \frac{d}{\beta}\Big] \leq \beta. \tag{20.7}$$

The scale is the smallest that works in general: for a count, $\mathrm{Lap}(b)$ noise with $b < 1/\varepsilon$ is not ε-DP.

Proof. The plan is to write the privacy loss down and bound it at every output by the triangle inequality, then to read the error off the Laplace distribution, and finally to exhibit an event on which the privacy bound is reached.

1. *Write the two densities.* Fix $D \sim D'$ and write $a = f(D)$ and $a' = f(D')$ for the two true answers. The coordinates of the noise are independent, so the density of $M(D)$ at y is the product $\prod_i \frac{1}{2b} e^{-|y_i - a_i|/b}$, and that of $M(D')$ is the same with a' in place of a.
2. *Take the log-ratio.* The constants $\frac{1}{2b}$ cancel, and the log of a product of exponentials is the sum of the exponents, so
$$L_{D,D'}(y) = \frac{1}{b} \sum_{i=1}^{d} \left(|y_i - a'_i| - |y_i - a_i| \right). \tag{20.8}$$
3. *Bound each term.* The distance from y_i to a'_i is at most the distance from y_i to a_i plus the distance from a_i to a'_i, by the triangle inequality $|y_i - a'_i| \le |y_i - a_i| + |a_i - a'_i|$. So each term of the sum is at most $|a_i - a'_i|$, whatever y is.
4. *Add the terms.* Summing over i gives the ℓ_1 norm of the shift, which is at most the sensitivity, so for every y
$$L_{D,D'}(y) \le \frac{\|a - a'\|_1}{b} \le \frac{\Delta_1 f}{b} = \varepsilon. \tag{20.9}$$
The privacy loss is at most ε at every output, so the mechanism is ε-DP by the pointwise criterion recalled above.
5. *Accuracy.* The absolute value $|Z_i|$ has density $\frac{1}{b} e^{-z/b}$ on $z \ge 0$, an exponential distribution with mean b and second moment $2b^2$; since Z_i has mean 0, that gives $\mathbb{E}[|Z_i|] = b$ and $\mathrm{Var}(Z_i) = 2b^2$. Integrating the same density from t to infinity gives the tail $\Pr[|Z_i| > t] = e^{-t/b}$.
6. *All coordinates at once.* Give each coordinate a share β/d of the failure probability: setting $e^{-t/b} = \beta/d$ gives $t = b \ln(d/\beta)$. The probability that at least one of the d coordinates fails is at most the sum of their failure probabilities, by the union bound, which is $d \cdot \beta/d = \beta$.
7. *Tightness.* The outputs where the loss is largest are those left of both answers, so take a count with $f(D) = 0$ and $f(D') = 1$ and the event $S = \{y \le 0\}$. Under $\mathrm{Lap}(b)$ noise, $\Pr[M(D) \in S] = \Pr[Z \le 0] = \frac{1}{2}$ by the symmetry of the noise about 0, and $\Pr[M(D') \in S] = \Pr[Z \le -1] = \frac{1}{2} e^{-1/b}$ from the tail of step 5. So the ratio of the two probabilities is exactly $e^{1/b}$, and on S the bound of step 4 holds with equality at every point. If $b < 1/\varepsilon$, the ratio exceeds e^{ε} and the definition fails on this event.

□

The noise does not depend on n. A count gets noise of scale $1/\varepsilon$ whether the database has a hundred records or a hundred million, because one record moves a count by 1 either way. The *relative* error of a count of size n is therefore about $1/(n\varepsilon)$, so large populations are cheap to protect and small subgroups are expensive. The worst case is not rare, either: the privacy loss equals ε on the event S of step 7, which has probability $\frac{1}{2}$ (Figure 20.1, left), so the guarantee is tight in the strongest sense and not just at some unlikely output.

Two more facts about the Laplace mechanism matter later, and the exercise book derives both. Drawn as a random number, the privacy loss of an output from $M(D)$ never leaves $[-\varepsilon, \varepsilon]$. It has an atom of probability $\frac{1}{2}$ at $+\varepsilon$, an atom of probability $\frac{1}{2} e^{-\varepsilon}$ at $-\varepsilon$, and a continuous ramp between them (Figure 20.2, left, and Exercise 7 in the exercise book), and Part 4's accountants

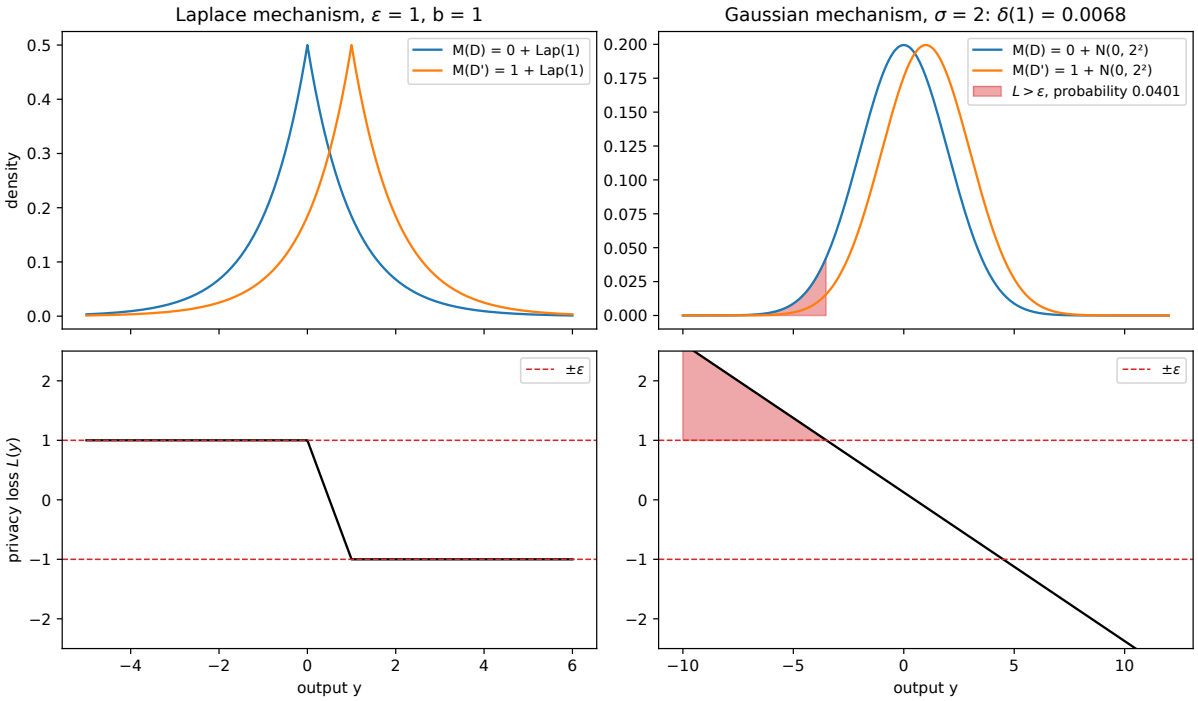

Figure 20.1.: Left column: a count released with Lap(1) noise on neighbouring datasets with true counts 0 and 1, and the privacy loss $L(y)$. It equals $+\varepsilon$ for every $y \leq 0$ and $-\varepsilon$ for every $y \geq 1$, never more. Right column: the same count with $\mathcal{N}(0, 2^2)$ noise. The privacy loss is a straight line, and exceeds $\varepsilon = 1$ on the shaded tail, which has probability 0.0401 under $M(D)$. The exact $\delta(1) = 0.0068$ is smaller, because the hockey-stick subtracts e^{ε} times the mass of $M(D')$ on the same tail.

track exactly this distribution. The mechanism also satisfies a whole curve of weaker guarantees. For every $\varepsilon' < \varepsilon$ it is (ε', δ)-DP with $\delta = 1 - e^{-(\varepsilon - \varepsilon')/2}$, the dashed curve of Figure 20.3 (Exercise 2 in the exercise book). As for the shape of the noise, the proof used only that the log-density changes by at most $\varepsilon/\Delta_1 f$ per unit of shift, and the Laplace log-density $-|z|/b$ has exactly that slope everywhere. Other shapes are slightly better for large ε (Geng & Viswanath's staircase mechanism), but the Laplace is within a small factor and is the standard choice.

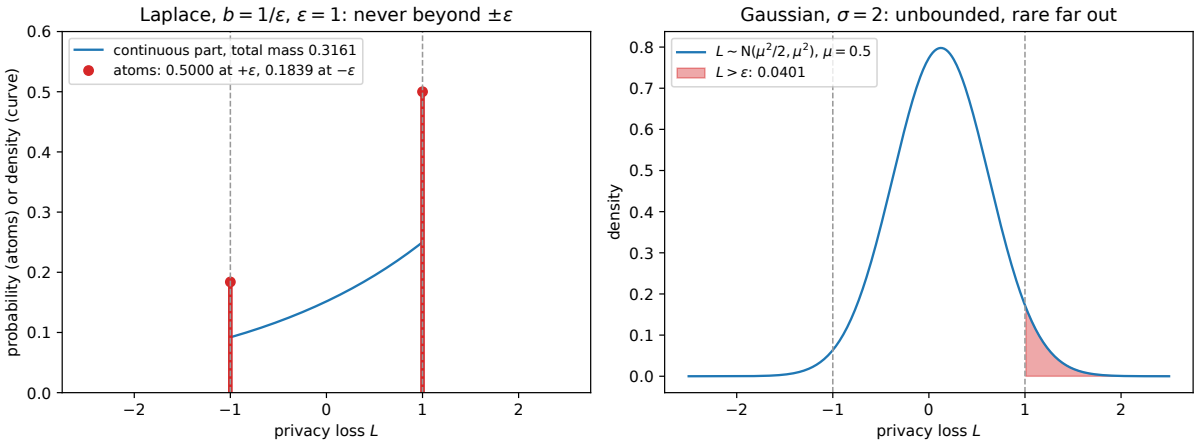

Figure 20.2.: The privacy loss distribution under $M(D)$ for a count, with $\varepsilon = 1$. Left: Laplace noise of scale $1/\varepsilon$. The loss never leaves $[-\varepsilon, \varepsilon]$; it has an atom of probability 0.5000 at $+\varepsilon$, an atom of 0.1839 at $-\varepsilon$, and a continuous ramp of total probability 0.3161 in between (density shown). Right: Gaussian noise of standard deviation 2. The loss is normal with mean $\mu^2/2$ and variance μ^2, here $\mu = 0.5$, and exceeds ε with probability 0.0401 (shaded).

Example 20.2. Release the diabetes count, 1,234 of $n = 10{,}000$ patients, with $\varepsilon = 0.1$ under add/remove. The sensitivity is 1, so the noise is Lap(10) and the expected absolute error is $b = 10$ (simulated over a million releases: 9.978). For a 95% guarantee take $d = 1$ and $\beta = 0.05$ in the accuracy bound. With probability 0.95 the error is then below $b \ln 20 = 29.96$ (simulated 95th percentile: 29.85), a relative error of $29.96/1234 = 0.0243$.

To see the privacy loss itself, take a count with $b = 1$, so $\varepsilon = 1$, and true answers 0 and 1. Table 20.2 evaluates the two densities and the loss at a few outputs. Left of both true answers the ratio of the densities is stuck at e, right of them at e^{-1}, and in between the loss falls linearly from 1 to -1. Once y is past both centres, moving it further away multiplies both densities by the same factor, so however far out an output lands, it never favours one dataset by more than a factor of e. A million simulated draws reproduce the tight event's probabilities to three decimals (Table 20.7).

Table 20.2.: The Laplace mechanism for a count with $b = 1$: densities and privacy loss at five outputs.

Output y	-2	0	0.5	1	3
$p_{M(D)}(y) = \frac{1}{2}e^{-\lvert y\rvert}$	0.0677	0.5	0.3033	0.1839	0.0249
$p_{M(D')}(y) = \frac{1}{2}e^{-\lvert y-1\rvert}$	0.0249	0.1839	0.3033	0.5	0.0677
$L(y) = \lvert y-1\rvert - \lvert y\rvert$	1	1	0	-1	-1

The hospital's histogram of diagnoses, with 20 bins, $\varepsilon = 1$ and add/remove, has $\Delta_1 = 1$, so each bin gets Lap(1) noise. With $d = 20$ and $\beta = 0.05$, every bin is within $\ln(20/0.05) = 5.99$ of its true count with probability 0.95. In 20,000 simulated releases the maximum error exceeded 5.99 in a fraction 0.0464 of them, just under β: independent coordinates rarely fail together, so the union bound is nearly exact.

20.3. The Gaussian mechanism: classic calibration

Gaussian noise is the other natural choice. It has lighter tails than Laplace noise, a sum of independent Gaussians is again Gaussian, and it is calibrated to the ℓ_2 sensitivity, which can be much smaller than the ℓ_1 sensitivity. The price is that its privacy loss is a straight line in the output and so is unbounded (Figure 20.1, right), so the pointwise criterion never applies and Gaussian noise cannot give pure DP. Instead you accept a small probability δ that the loss exceeds ε. This section derives the calibration found in the textbook of Dwork & Roth and in many papers and libraries, and shows where it is loose; Section A.6 in the appendices derives the same formula from scratch, with worked numbers.

The smallest δ that works for one pair is its hockey-stick divergence at $\gamma = e^{\varepsilon}$, and the largest of these over all pairs, as a function of ε, is the **privacy profile** $\delta_M(\varepsilon)$ of M. The first tool says which event is the worst one: the set of outputs where the loss is too large.

Lemma 20.2 (The bad event and the exact δ)**.** *Fix a neighbouring pair, write P and Q for the distributions of $M(D)$ and $M(D')$, with densities p and q, and let L be the privacy loss. Call $B = \{y : L(y) > \varepsilon\}$ the **bad event**, the outputs that favour D over D' by more than a factor e^{ε}. Then*

$$E_{e^{\varepsilon}}(P\|Q) = \Pr_{P}[B] - e^{\varepsilon}\Pr_{Q}[B] \le \Pr_{P}[B] = \Pr_{y\sim P}[L(y) > \varepsilon]. \tag{20.10}$$

Equivalently, writing $(x)_+ = \max(x, 0)$ for the positive part,

$$E_{e^{\varepsilon}}(P\|Q) = \mathbb{E}_Q[(e^L - e^{\varepsilon})_+] = \mathbb{E}_P[(1 - e^{\varepsilon - L})_+]. \tag{20.11}$$

Proof.

1. The quantity $\Pr_P[S] - e^\varepsilon \Pr_Q[S]$ is the integral over S of $p(y) - e^\varepsilon q(y)$. To make the integral as large as possible, include every output where the integrand is positive and no other. The integrand is positive exactly where $p > e^\varepsilon q$, that is where $L > \varepsilon$, which is B. This is the argument of Divergences for the worst event of a hockey-stick divergence, and it gives the equality.
2. The inequality drops the term $e^\varepsilon \Pr_Q[B]$, which is never negative.
3. For the expectation forms, the hockey-stick is the integral of $(p - e^\varepsilon q)_+$. Factoring out q gives $q\,(e^L - e^\varepsilon)_+$, and factoring out p gives $p\,(1 - e^{\varepsilon - L})_+$; integrating each against its density is the stated expectation.

□

So the bad event's probability is always a valid δ, though usually a loose one, and the last form needs only the distribution of the loss under P, the starting point of Numerical accounting. For Gaussian noise that distribution is itself normal.

Lemma 20.3 (The privacy loss of Gaussian noise)**.** *Let $M(D) = f(D) + Z$ with $Z \sim \mathcal{N}(0, \sigma^2 I_d)$, that is d independent normal coordinates with mean 0 and standard deviation σ, and let $v = f(D') - f(D)$ be the shift of a neighbouring pair. Write $\mu = \|v\|_2/\sigma$ for the shift measured in standard deviations of the noise. Under $M(D)$ the privacy loss is normal,*

$$L \sim \mathcal{N}\Big(\frac{\mu^2}{2}, \mu^2\Big), \tag{20.12}$$

and under $M(D')$ it is $\mathcal{N}(-\mu^2/2, \mu^2)$.

Proof.

1. Under $M(D)$, write the output as $y = f(D) + z$, where z is the noise. The density of $M(D)$ at y is proportional to $e^{-\|z\|^2/(2\sigma^2)}$, and that of $M(D')$ to $e^{-\|z-v\|^2/(2\sigma^2)}$, since y sits at distance $z - v$ from $f(D')$. The log of their ratio is the difference of the exponents, and expanding $\|z - v\|^2 = \|z\|^2 - 2\langle z, v\rangle + \|v\|^2$ gives
$$L(y) = \frac{\|v\|^2 - 2\langle z, v\rangle}{2\sigma^2}. \tag{20.13}$$
2. The loss depends on z only through the inner product $\langle z, v\rangle = \sum_i z_i v_i$, the component of the noise along the shift. That is a sum of independent normals, so it is normal, with mean 0 and variance $\sum_i \sigma^2 v_i^2 = \sigma^2\|v\|^2$.
3. A constant minus a multiple of a normal is normal, so L is normal with mean $\|v\|^2/(2\sigma^2) = \mu^2/2$ and variance $4\sigma^2\|v\|^2/(4\sigma^4) = \mu^2$. The other $d - 1$ directions of z, perpendicular to v, do not enter.
4. Under $M(D')$ the noise is centred one shift further along v, which lowers $\langle z, v\rangle$ by $\|v\|^2$ on average and so lowers the loss by μ^2; the variance is unchanged.

□

Unlike the Laplace loss, the Gaussian loss has no atoms and no largest value (Figure 20.2, right). The classic calibration bounds δ by the probability that it exceeds ε and chooses σ to make that tail small.

Theorem 20.2 (Classic Gaussian calibration)**.** *Let f have ℓ_2 sensitivity $\Delta_2 f$, and let $\varepsilon \in (0,1)$ and $\delta \in (0,1)$. The* ***Gaussian mechanism*** *$M(D) = f(D) + Z$ with $Z \sim \mathcal{N}(0, \sigma^2 I_d)$ and*

$$\sigma = \frac{\Delta_2 f \sqrt{2\ln(1.25/\delta)}}{\varepsilon} \tag{20.14}$$

is (ε, δ)-DP (Dwork & Roth 2014, Theorem A.1).

Proof. The plan is to bound δ by the bad-event probability of Lemma 20.2, which by Lemma 20.3 is a normal tail, and to show with a standard tail bound that this tail is below δ for the σ above. The route is Dwork & Roth's, in a one-sided form that is a little shorter. Write $c = \sqrt{2\ln(1.25/\delta)}$, so $\sigma = c\,\Delta_2 f/\varepsilon$.

1. *Bound δ by the bad event.* By Lemma 20.2, $\delta \le \Pr_P[L > \varepsilon]$. By Lemma 20.3 the loss is normal with mean $\mu^2/2$ and standard deviation μ, so $L > \varepsilon$ exactly when a standard normal exceeds $(\varepsilon - \mu^2/2)/\mu = \frac{\varepsilon}{\mu} - \frac{\mu}{2}$. Writing Φ for the standard normal cumulative distribution function (CDF), and using its symmetry $\Phi(-t) = 1 - \Phi(t)$,
$$\Pr_P[L > \varepsilon] = \Phi(-t), \qquad t = \frac{\varepsilon}{\mu} - \frac{\mu}{2}. \tag{20.15}$$
2. *Take the worst shift.* A larger shift makes the bad event more likely, because t decreases as μ grows. So the worst neighbouring pair has the largest shift, $\|v\|_2 = \Delta_2 f$, that is $\mu = \Delta_2 f/\sigma = \varepsilon/c$, and then $t = c - \frac{\varepsilon}{2c}$.
3. *Bound the normal tail.* The Mills-ratio bound of Concentration inequalities says $\Phi(-t) \le \varphi(t)/t$ for $t > 0$, where $\varphi(t) = e^{-t^2/2}/\sqrt{2\pi}$ is the standard normal density. The reason is that beyond t every point z has $z/t \ge 1$, so $\int_t^\infty \varphi(z)\,\mathrm{d}z \le \int_t^\infty \frac{z}{t}\varphi(z)\,\mathrm{d}z$, and since the derivative of φ is $-z\varphi(z)$ the right side integrates to $\varphi(t)/t$.
4. *Expand t^2.* Squaring $t = c - \varepsilon/(2c)$ gives $t^2 = c^2 - \varepsilon + \frac{\varepsilon^2}{4c^2} \ge c^2 - \varepsilon$, dropping the last term because it is positive. By the definition of c, $e^{-c^2/2} = \delta/1.25$, so
$$e^{-t^2/2} \le \frac{\delta}{1.25}\, e^{\varepsilon/2}. \tag{20.16}$$
5. *Combine.* Steps 3 and 4 give $\Pr_P[L > \varepsilon] \le \delta\, e^{\varepsilon/2}/(1.25\sqrt{2\pi}\,t)$, which is at most δ when $t \ge e^{\varepsilon/2}/(1.25\sqrt{2\pi})$. For $\varepsilon \le 1$ the right side is at most $e^{1/2}/(1.25\sqrt{2\pi}) = 0.5262$.
6. *Check that t is large enough.* For $\varepsilon \le 1$, $t = c - \varepsilon/(2c) \ge c - 1/(2c)$, and this lower bound grows with c. It equals 0.5262 at the positive root of $c^2 - 0.5262c - \frac{1}{2} = 0$, which is where $\delta = 0.7448$; since c grows as δ shrinks, $t \ge 0.5262$ for every $\delta \le 0.7448$, and every δ of practical interest qualifies.

□

The constant 1.25 absorbs $e^{\varepsilon/2} \le e^{1/2}$ and the $1/(t\sqrt{2\pi})$ factor of step 5, and the condition $\varepsilon < 1$ keeps $e^{\varepsilon/2}$ under control. The proof made three approximations in a row, the bad-event bound, the Mills ratio and the constants, and the example follows the chain to see what each one costs.

Example 20.3. Release the diabetes count with $\varepsilon = 1$ and $\delta = 10^{-5}$. The sensitivity is 1, so $c = \sqrt{2\ln(1.25 \times 10^5)}$ gives $\sigma = 4.8448$ and $t = c - 1/(2c) = 4.7416$. Table 20.3 follows the proof step by step.

Table 20.3.: The classic proof at $\varepsilon = 1$, $\delta = 10^{-5}$, step by step.

Quantity	Value	What was dropped to get the next line
Exact $\delta(\varepsilon)$, the hockey-stick	4.11×10^{-8}	the term $e^{\varepsilon} \Pr_Q[B]$ of Equation 20.10
$\Pr[L > \varepsilon] = \Phi(-t)$	1.06×10^{-6}	the Mills-ratio approximation
Mills bound $\varphi(t)/t$	1.10×10^{-6}	the constants $e^{\varepsilon/2}$, 1.25 and $t\sqrt{2\pi}$
Target δ	10^{-5}	

The classic σ delivers a δ about 240 times smaller than asked for, since $10^{-5}/(4.11 \times 10^{-8}) \approx 243$. Most of the slack is in two places. The bad-event bound throws away the $e^{\varepsilon} \Pr_Q[B]$ correction, a factor of $1.06 \times 10^{-6}/(4.11 \times 10^{-8}) \approx 26$ here, and the constants of steps 4 and 5 lose another factor of $10^{-5}/(1.10 \times 10^{-6}) \approx 9$. The Mills ratio itself costs almost nothing.

Equivalently, you could use less noise for the same (ε, δ), and Section 20.4 finds exactly how much less. The classic theorem is stated for $\varepsilon < 1$, and its constants are designed for that range. The formula does not fail immediately above 1: at $\delta = 10^{-5}$ the classic σ still gives a valid guarantee up to $\varepsilon = 8.42$ and violates it beyond (Figure 20.4, right), because the classic σ shrinks like $1/\varepsilon$ while the exact one shrinks more slowly. Nothing in the classic proof tells you that, so for $\varepsilon \geq 1$ you need the exact curve.

20.4. The exact privacy profile of the Gaussian mechanism

Lemma 20.2 says that the smallest valid δ is the bad-event probability minus the correction $e^{\varepsilon} \Pr_Q[B]$, and Lemma 20.3 says that for Gaussian noise both terms are normal tail probabilities. So the exact δ has a closed form, the one Divergences computed for two Gaussians with the same variance. Balle & Wang (2018) turned that observation into a calibration: instead of bounding δ, compute it exactly, and pick the smallest σ for which it is below the target. Section A.7 in the appendices derives the formula from scratch, with worked numbers.

Theorem 20.3 (Exact privacy profile of the Gaussian mechanism)**.** *Let f have ℓ_2 sensitivity $\Delta_2 f$, reached by some neighbouring pair, and let $M(D) = f(D) + Z$ with $Z \sim \mathcal{N}(0, \sigma^2 I_d)$. Write $\mu = \Delta_2 f/\sigma$. Then M is (ε, δ)-DP if and only if $\delta \geq \delta_\mu(\varepsilon)$, where*

$$\delta_\mu(\varepsilon) = \Phi\Big(\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) - e^{\varepsilon}\, \Phi\Big(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big). \tag{20.17}$$

The function $\delta_\mu(\varepsilon)$ is strictly decreasing in ε and strictly increasing in μ. At $\varepsilon = 0$ it is the total variation (TV) distance $2\Phi(\mu/2) - 1$ between the two output distributions, and it tends to 0 as $\varepsilon \to \infty$.

Proof. The plan is to reduce the worst pair to one dimension, apply the two lemmas there, and show that the largest shift is the worst one; the monotonicity claims then follow from the formula.

1. *Reduce to a shifted pair.* By Lemma 20.1, for a neighbouring pair with shift v the smallest δ at this ε is $E_{e^\varepsilon}(\mathcal{N}(0,\sigma^2 I_d)\|\mathcal{N}(v,\sigma^2 I_d))$.
2. *Reduce to one dimension.* Rotate coordinates so that v points along the first axis. A rotation is a bijection, so as in Lemma 20.1 it changes no divergence, and the normal distribution with independent equal-variance coordinates looks the same after any rotation (Section E.1 in the appendices proves it). Now both distributions are products: the first coordinate is $\mathcal{N}(0,\sigma^2)$ or $\mathcal{N}(\|v\|_2,\sigma^2)$, and the other $d-1$ coordinates have the same density h under both. The hockey-stick is the integral of $(p-\gamma q)_+$, and $(p_1 h-\gamma q_1 h)_+ = h\,(p_1-\gamma q_1)_+$ because $h\ge 0$, so integrating out the last $d-1$ coordinates leaves E_γ of the first coordinate alone. Coordinates that are identical under both hypotheses carry no evidence.
3. *Use the two lemmas.* By Lemma 20.2, $E_{e^\varepsilon} = \Pr_P[B] - e^\varepsilon \Pr_Q[B]$ with $B=\{L>\varepsilon\}$. By Lemma 20.3 with $\mu_v = \|v\|_2/\sigma$, the loss is $\mathcal{N}(\mu_v^2/2,\mu_v^2)$ under P and $\mathcal{N}(-\mu_v^2/2,\mu_v^2)$ under Q, so standardizing each tail gives

$$\Pr_P[B] = \Phi\Big(\frac{\mu_v}{2}-\frac{\varepsilon}{\mu_v}\Big), \qquad \Pr_Q[B] = \Phi\Big(-\frac{\mu_v}{2}-\frac{\varepsilon}{\mu_v}\Big). \tag{20.18}$$

   This is Equation 20.17 with μ_v in place of μ.
4. *The worst pair has the largest shift.* A smaller shift is harder to detect, and the proof shows that the pair with a smaller shift is a post-processing of the pair with a larger one, which cannot help anyone tell them apart. Let $\mu' < \mu_v$, take Y from the unit-variance pair with shift μ_v, and output $Y' = \frac{\mu'}{\mu_v}Y + W$ with independent $W\sim\mathcal{N}(0,1-\mu'^2/\mu_v^2)$. If $Y\sim\mathcal{N}(0,1)$ then Y' has mean 0 and variance $\mu'^2/\mu_v^2 + (1-\mu'^2/\mu_v^2) = 1$; if $Y\sim\mathcal{N}(\mu_v,1)$ the mean becomes μ' and the variance is still 1. By the data-processing inequality of Divergences, the hockey-stick of the post-processed pair is no larger, so $\delta_{\mu_v}(\varepsilon)$ is non-decreasing in μ_v and the maximum over neighbours is at $\|v\|_2 = \Delta_2 f$, that is at μ.
5. *If and only if.* The hockey-stick at $\gamma = e^\varepsilon$ is the smallest δ that works for one pair, and steps 1 to 4 show that the pair at shift $\Delta_2 f$ is the worst. So $\delta \ge \delta_\mu(\varepsilon)$ is sufficient, since it covers the worst pair and hence all, and necessary, since any smaller δ fails on that pair.
6. *Monotone in ε and in μ.* Exercise 3 in the exercise book differentiates Equation 20.17 and finds $\frac{\mathrm{d}}{\mathrm{d}\varepsilon}\delta_\mu(\varepsilon) = -e^\varepsilon\Phi(-\frac{\mu}{2}-\frac{\varepsilon}{\mu}) < 0$ and $\frac{\mathrm{d}}{\mathrm{d}\mu}\delta_\mu(\varepsilon) = \varphi(\frac{\mu}{2}-\frac{\varepsilon}{\mu}) > 0$.
7. *The two ends.* At $\varepsilon = 0$ the factor e^ε is 1 and Equation 20.17 reads $\Phi(\frac{\mu}{2}) - \Phi(-\frac{\mu}{2}) = 2\Phi(\mu/2)-1$, which is the TV distance because the TV distance is the hockey-stick with $\gamma = 1$. As $\varepsilon\to\infty$ the first term $\Phi(\frac{\mu}{2}-\frac{\varepsilon}{\mu})$ goes to 0 and the second is non-negative, so $\delta_\mu(\varepsilon)\to 0$.

□

Because δ_μ grows with μ, less noise always means a larger δ, and there is a single noise level that hits the target exactly.

Corollary 20.1 (Analytic calibration)**.** *For $0<\delta<1$ the equation $\delta_\mu(\varepsilon)=\delta$ has exactly one root μ^* in μ, and*

$$\sigma^*(\varepsilon,\delta) = \frac{\Delta_2 f}{\mu^*} \tag{20.19}$$

is the smallest σ for which the Gaussian mechanism is (ε,δ)-DP.

Proof.

1. As a function of μ, $\delta_\mu(\varepsilon)$ is continuous, tends to 0 as $\mu \to 0$ (both arguments of Φ go to $-\infty$, since there is no signal) and to 1 as $\mu \to \infty$ (the first Φ goes to 1 and the second to 0), and is strictly increasing by Theorem 20.3. So it crosses every $\delta \in (0,1)$ exactly once.
2. By Theorem 20.3, a noise level σ works exactly when $\delta_{\Delta_2 f/\sigma}(\varepsilon) \le \delta$, that is when $\Delta_2 f/\sigma \le \mu^*$, so the smallest such σ is $\Delta_2 f/\mu^*$.

□

The root is found by bisection: start with an interval of μ whose ends put $\delta_\mu(\varepsilon)$ on either side of δ, evaluate at the midpoint, and keep the half where the sign changes. Monotonicity is what makes this safe, since there is exactly one crossing to find. The script halves in $\ln \mu$, because μ^* ranges over several orders of magnitude, and 60 halvings pin it to machine precision; Exercise 4 in the exercise book runs it by hand.

Example 20.4. Release the diabetes count at $\varepsilon = 0.1$, $\delta = 10^{-5}$ with Gaussian noise. The sensitivity is 1, so the analytic calibration gives $\sigma^* = 30.75$, the row $\varepsilon = 0.1$ of Table 20.5. A normal variable stays within 1.96 standard deviations of its mean with probability 0.95, so the 95% error is $1.96\sigma^* = 60.27$, against 29.96 for Laplace noise with $\delta = 0$: for a single count, Laplace noise is better on both error and guarantee, and Section 20.5 says when the Gaussian earns its place.

To see the two terms of Equation 20.10 at work, take $\mu = 1$ and $\varepsilon = 1$ and measure the noise z in units of σ. With $\mu = 1$ the loss is $L = \frac{1}{2} - z$, so the bad event $B = \{L > 1\}$ is $\{z < -\frac{1}{2}\}$. Under $M(D)$ the noise is standard normal, so $\Pr_P[B] = \Phi(-0.5)$; under $M(D')$ the output is centred one unit higher, so in the same coordinates z is $\mathcal{N}(1,1)$ and $\Pr_Q[B] = \Phi(-1.5)$. Table 20.4 evaluates both, and the integration and Monte Carlo checks of Table 20.7 agree with the result.

Table 20.4.: The exact δ at $\mu = 1$, $\varepsilon = 1$ as the bad-event probability minus its correction.

Term	Formula	Value
$\Pr_P[B]$, the bad-event bound	$\Phi(\frac{\mu}{2} - \frac{\varepsilon}{\mu}) = \Phi(-0.5)$	0.3085
$e^\varepsilon \Pr_Q[B]$, the correction	$e\,\Phi(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}) = e\,\Phi(-1.5)$	0.1816
$\delta_1(1)$, the exact δ	difference	0.1269

One Gaussian mechanism gives a whole curve of guarantees, not one: it is $(\varepsilon, \delta_\mu(\varepsilon))$-DP for every $\varepsilon \ge 0$ simultaneously, trading a larger ε for a smaller δ (Figure 20.3). At $\sigma = \Delta_2 f$, so $\mu = 1$, the curve passes through $\delta = 0.3829$ at $\varepsilon = 0$ (the TV distance), 0.1269 at $\varepsilon = 1$, 0.0209 at $\varepsilon = 2$ and 4.71×10^{-5} at $\varepsilon = 4$, and reaches 10^{-5} at $\varepsilon = 4.3772$. The whole curve, not a single point, is what composes tightly in Part 4. Only the ratio $\mu = \Delta_2 f/\sigma$ matters, because Equation 20.17 depends on $\Delta_2 f$ and σ only through it: doubling the sensitivity and doubling the noise give the same curve. Read μ as a signal-to-noise ratio: it is the parameter of the Gaussian trade-off curve in Hypothesis testing.

The exact σ is 1.3 to 1.7 times smaller than the classic one. Table 20.5 compares the two calibrations at $\delta = 10^{-5}$. Over the rows with $\varepsilon \le 1$ the classic formula uses between 1.30 and 1.68 times the necessary noise, and the gap grows as ε shrinks. Since variance is σ^2, the factor at $\varepsilon = 1$ means 69% more variance than needed, which you could instead spend on a smaller ε. The last column shows the other failure: beyond $\varepsilon = 8.42$ the true δ at the classic σ exceeds the target.

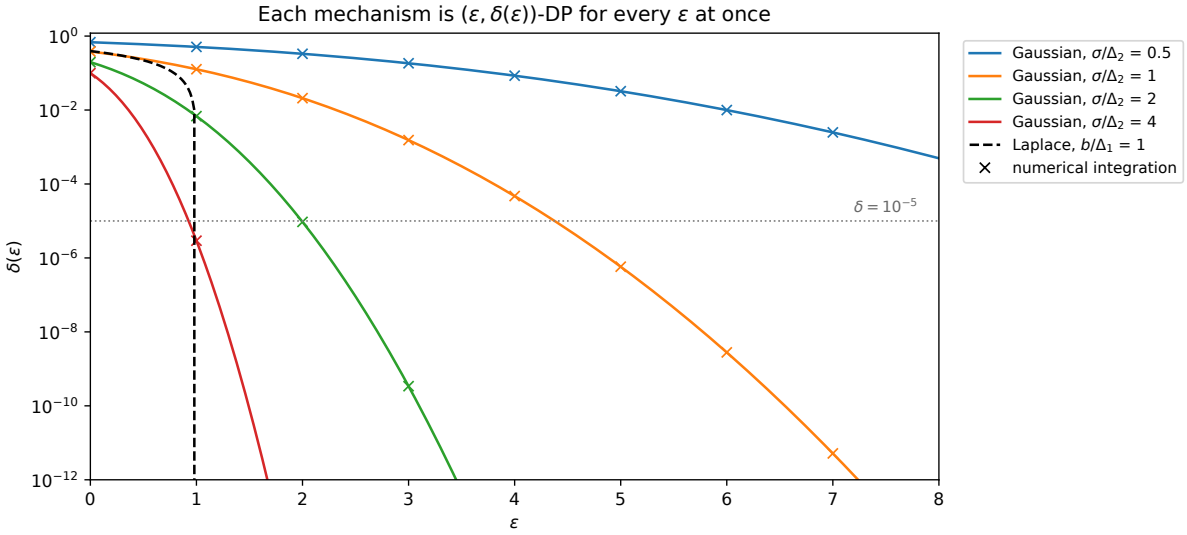

Figure 20.3.: The privacy profile $\delta(\varepsilon)$ of the Gaussian mechanism for four noise levels $\sigma/\Delta_2 f$, on a log scale, and of the Laplace mechanism with $b = \Delta_1 f$ (dashed). Crosses are the hockey-stick divergence computed by numerical integration. The Laplace curve drops to zero at $\varepsilon = 1$, its pure-DP level; every Gaussian curve stays positive but falls faster than exponentially. The dotted line marks $\delta = 10^{-5}$.

Table 20.5.: Classic against analytic calibration of the Gaussian mechanism at $\delta = 10^{-5}$. The last column is Equation 20.17 evaluated at the classic σ.

ε	Classic $\sigma/\Delta_2 f$	Analytic $\sigma^*/\Delta_2 f$	Ratio	True δ at the classic σ
0.05	96.8961	57.7707	1.677	1.29×10^{-9}
0.1	48.4481	30.7496	1.576	2.64×10^{-9}
0.25	19.3792	13.2855	1.459	7.10×10^{-9}
0.5	9.6896	7.0318	1.378	1.61×10^{-8}
1	4.8448	3.7306	1.299	4.11×10^{-8}
2	2.4224	1.9938	1.215	1.34×10^{-7}
4	1.2112	1.0812	1.120	6.84×10^{-7}
8	0.6056	0.6002	1.009	7.97×10^{-6}

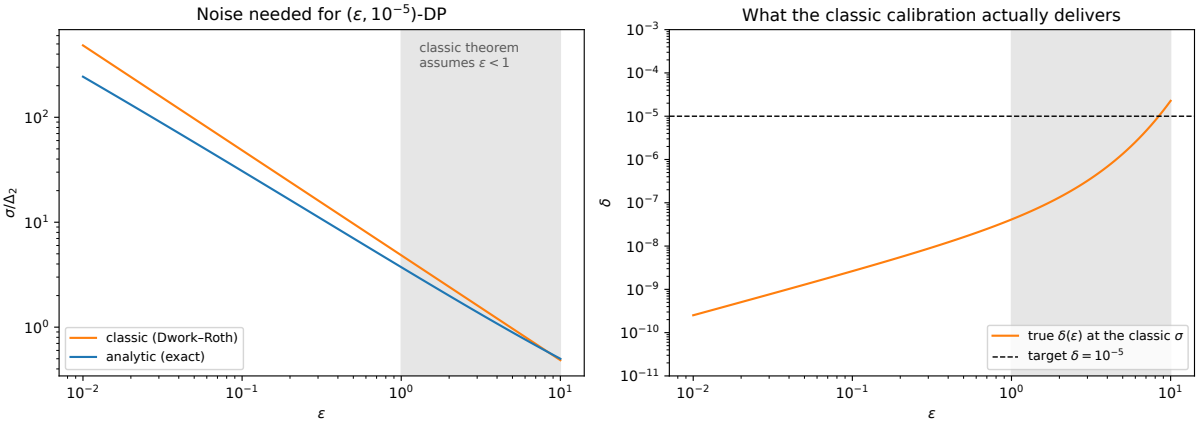

Figure 20.4.: Left: the noise needed for $(\varepsilon, 10^{-5})$-DP by the classic formula and by the analytic calibration. Right: the true δ that the classic σ delivers, from Equation 20.17. It is orders of magnitude below the target for small ε and crosses the target at $\varepsilon = 8.42$, in the shaded region where the classic theorem makes no claim.

20.5 Laplace against Gaussian in many dimensions

*For a **sparse query**, where one record moves one coordinate, $\Delta_1 f = \Delta_2 f$, and Laplace noise is more accurate whenever $\sqrt{2} < \varepsilon\,\sigma_1(\varepsilon, \delta)$, whatever d is. For a **dense query**, where one record moves every coordinate by 1, $\Delta_1 f = d$ and $\Delta_2 f = \sqrt{d}$, and Laplace noise is more accurate only while*

$$d < \frac{\left(\varepsilon\,\sigma_1(\varepsilon, \delta)\right)^2}{2}. \tag{20.21}$$

Proof.

1. *Laplace error.* A Lap(b) coordinate has mean 0 and variance $2b^2$ by Theorem 20.1, so its root-mean-square error is $\sqrt{2}\,b$, which with $b = \Delta_1 f/\varepsilon$ is $\sqrt{2}\,\Delta_1 f/\varepsilon$.
2. *Gaussian error.* A Gaussian coordinate has variance σ^2, so its root-mean-square error is σ. The analytic calibration gives $\sigma^* = \Delta_2 f\,\sigma_1(\varepsilon, \delta)$, because only $\mu = \Delta_2 f/\sigma$ enters Equation 20.17, so scaling the sensitivity scales the solution by the same factor.
3. *Sparse queries.* With $\Delta_1 f = \Delta_2 f$, Laplace is better when $\sqrt{2}\,\Delta_2 f/\varepsilon < \Delta_2 f\,\sigma_1$; dividing by $\Delta_2 f$ and multiplying by ε leaves $\sqrt{2} < \varepsilon\sigma_1$, with no d.
4. *Dense queries.* Substituting $\Delta_1 f = d$ and $\Delta_2 f = \sqrt{d}$, Laplace is better when $\sqrt{2}\,d/\varepsilon < \sqrt{d}\,\sigma_1$. Dividing both sides by $\sqrt{d}$ and rearranging gives $\sqrt{d} < \varepsilon\sigma_1/\sqrt{2}$, and squaring both sides gives the bound on d.

□

So use Laplace noise for sparse queries and Gaussian noise for dense ones. When a record touches one coordinate, the two sensitivities agree, and the stronger guarantee of Laplace, with $\delta = 0$, comes with less noise too. When a record touches all coordinates, $\Delta_1 f$ pays d while $\Delta_2 f$ pays $\sqrt{d}$, and the Gaussian wins by a factor that grows like $\sqrt{d}$ (Figure 20.5). This is why private training of neural networks uses Gaussian noise: one example's gradient moves every coordinate of a model with millions of parameters, the densest query there is, and clipping bounds its ℓ_2 norm, which is exactly what the Gaussian mechanism is calibrated to.

Keep in mind that the comparison is at equal ε but unequal guarantees, since the Laplace release is ε-DP and the Gaussian release has an extra δ. The Gaussian mechanism also has a second advantage that the comparison does not show: many Gaussian releases compose into another Gaussian mechanism, exactly, because stacking independent Gaussian answers gives one Gaussian answer whose ℓ_2 sensitivity is the root-sum-of-squares of theirs (Exercise 5 in the exercise book).

Example 20.5. The hospital releases the empirical cumulative distribution function (CDF) of its patients' ages, read off at d thresholds, at $\varepsilon = 1$ and $\delta = 10^{-5}$. There $\sigma_1 = 3.7306$, the value found by bisection in Section 20.4. For one count, Laplace noise has root-mean-square error $\sqrt{2} = 1.4142$ against 3.7306 for Gaussian noise, so Laplace wins. For threshold counts the crossover is at $d = (3.7306)^2/2 = 6.96$. Table 20.6 shows the errors, exactly (from $\sqrt{2}\,d$ and $3.7306\sqrt{d}$) and by simulation: at 100 thresholds Gaussian noise is 3.79 times more accurate, and at 1,000 thresholds 11.99 times.

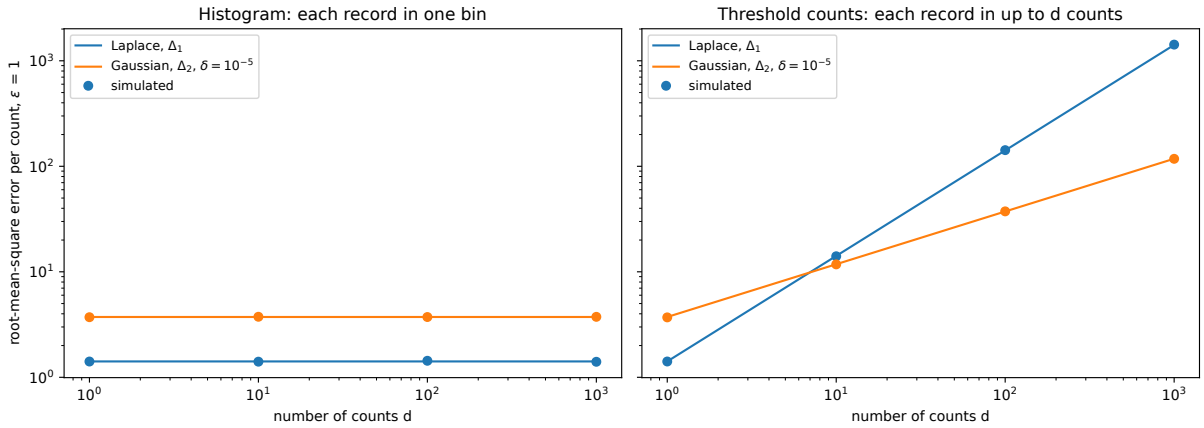

Figure 20.5.: Root-mean-square error per count at $\varepsilon = 1$ for the Laplace mechanism (calibrated to Δ_1) and the Gaussian mechanism (analytic calibration to Δ_2, $\delta = 10^{-5}$), as the number of released counts d grows; dots are simulations. Left: a histogram, where each record falls in one bin, so neither error depends on d and Laplace noise is smaller. Right: threshold counts, where a record can move all d counts; the Laplace error grows like d, the Gaussian like $\sqrt{d}$, and they cross near $d = 7$.

Table 20.6.: Root-mean-square error per count for d threshold counts at $\varepsilon = 1$, $\delta = 10^{-5}$.

d	Laplace, exact	Laplace, simulated	Gaussian, exact	Gaussian, simulated	Laplace / Gaussian
1	1.41	1.42	3.73	3.73	0.38
10	14.14	14.09	11.80	11.78	1.20
100	141.42	141.07	37.31	37.28	3.79
1000	1414.21	1412.90	117.97	118.11	11.99

20.6. Code

The script code/laplace_gaussian.py computes every number in this chapter and draws every figure. Sensitivities are found by brute force over every dataset of one to three records with values in $\{0, 1, 2, 3\}$. The Laplace mechanism's privacy and accuracy are checked by simulation. For the Gaussian mechanism, the closed form Equation 20.17 is checked against Simpson's rule on the two densities and against a Monte Carlo average of the privacy loss, and the analytic calibration is solved by bisection on $[e^{-12}, e^{8}]$. From the repository root:

```
uv run python code/part03-dp-foundations/laplace_gaussian.py
```

Table 20.7.: The script's output with the default seed.

Experiment	Result
Sensitivities, brute force over datasets of up to 3 records	Every row of Table 20.1, e.g. threshold counts $\ell_1 = 3$, $\ell_2 = 1.7321$
Laplace privacy loss, count, $\varepsilon = 1$	Ranges over exactly $[-1, 1]$
Laplace tight event	$\Pr[M(D) \le 0] = 0.5002$, $\Pr[M(D') \le 0] = 0.1838$, ratio 2.7221 against $e = 2.7183$
Laplace privacy loss distribution, $\varepsilon = 1$	Atoms 0.5000 and 0.1839 (simulated 0.5007, 0.1841), ramp 0.3161; mean 0.3679 (simulated 0.3682)
Laplace count, $\varepsilon = 0.1$	Mean absolute error 9.978 (exact 10); 95th percentile 29.85 (bound 29.96)
Laplace histogram, 20 bins	Maximum error above 5.99 in a fraction 0.0464 of releases ($\beta = 0.05$)
Classic proof chain, $\varepsilon = 1$, $\delta = 10^{-5}$	Exact δ 4.11×10^{-8}; $\Pr[L > \varepsilon]$ 1.06×10^{-6}; Mills bound 1.10×10^{-6}
Gaussian closed form vs integration	Largest relative difference 3.1×10^{-6} over 24 pairs (ε, μ) with $\delta > 10^{-12}$
Gaussian, $\mu = 1$, $\varepsilon = 1$	$\delta = 0.1269$ (integrated 0.1269, Monte Carlo 0.1270)
Analytic calibration, $\varepsilon = 1$, $\delta = 10^{-5}$	$\sigma^* = 3.7306$, classic 4.8448
Classic σ fails at $\delta = 10^{-5}$	For $\varepsilon > 8.42$
Laplace vs Gaussian, threshold counts	Crossover at $d = 6.96$; Table 20.6

tests/test_laplace_gaussian.py checks that the output still matches.

20.7. Summary

Table 20.8.: The results of this chapter, and where each is used.

Result	Statement	Use
Definition 20.1	$\Delta_p f = \max_{D \sim D'} \lVert f(D) - f(D') \rVert_p$	Compute it first, from the domain, and say which neighbouring relation it is for
Proposition 20.1	$\Delta_2 f \le \Delta_1 f \le \sqrt{d}\,\Delta_2 f$	Sparse queries sit at the left end, dense ones at the right
Proposition 20.2	Count 1; sum in $[0, B]$: B; mean with public n: B/n; histogram 1, or 2 and $\sqrt{2}$ under replace	Calibrating every release

Result	Statement	Use
Lemma 20.1	$E_\gamma(M(D)\|M(D')) = E_\gamma(Z\|Z+v)$	Only the shift matters, so analyse the noise against a shifted copy of itself
Theorem 20.1	$f(D) + \mathrm{Lap}(\Delta_1 f/\varepsilon)^d$ is ε-DP, tightly; error b per coordinate, $b\ln(d/\beta)$ for all at once	Counts, histograms, low-dimensional statistics; report-noisy-max
Lemma 20.2	$\delta_{\text{exact}} = \Pr_P[L > \varepsilon] - e^\varepsilon \Pr_Q[L > \varepsilon] \le \Pr_P[L > \varepsilon]$	The exact δ of any mechanism from its privacy loss; Numerical accounting
Lemma 20.3	$L \sim \mathcal{N}(\mu^2/2, \mu^2)$ under $M(D)$, with $\mu = \|v\|_2/\sigma$	Unbounded, so no pure DP; the object Part 4's accountants compose
Theorem 20.2	$\sigma = \Delta_2 f\sqrt{2\ln(1.25/\delta)}/\varepsilon$ for $\varepsilon < 1$	Reading papers and libraries that still use it; 1.3 to 1.7 times too much noise, and wrong for large ε
Theorem 20.3	(ε,δ)-DP iff $\delta \ge \Phi(\frac{\mu}{2} - \frac{\varepsilon}{\mu}) - e^\varepsilon \Phi(-\frac{\mu}{2} - \frac{\varepsilon}{\mu})$	Every Gaussian release; quote the profile, or μ, not one (ε,δ) pair
Corollary 20.1	$\sigma^* = \Delta_2 f/\mu^*$ with $\delta_{\mu^*}(\varepsilon) = \delta$, one bisection	At $\varepsilon = 1$, $\delta = 10^{-5}$: $\sigma^* \approx 3.73\,\Delta_2 f$
Proposition 20.3	Per coordinate: $\sqrt{2}\,\Delta_1 f/\varepsilon$ against $\Delta_2 f\,\sigma_1(\varepsilon,\delta)$	One number or a sparse vector: Laplace, pure DP. A dense vector: Gaussian, calibrated to Δ_2; gradients in Part 5

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

21. Advanced and optimal composition

A differentially private system rarely answers one query: a dashboard refreshes a hundred counts, and a training run takes thousands of noisy gradient steps. Each step satisfies (ε, δ)-differential privacy (DP) on its own, and you need a guarantee for the whole run. Post-processing, group privacy and composition gave the first answer, **basic composition**: k mechanisms that are each ε-DP are together $k\varepsilon$-DP. For large k that answer is far too pessimistic. A hundred queries at $\varepsilon = 0.1$ give $k\varepsilon = 10$, which lets an observer multiply its odds between two neighbouring datasets by up to $e^{10} \approx 22{,}000$. Yet at $\delta = 10^{-5}$ the same hundred queries are $(4.31, 10^{-5})$-DP, and no analysis that knows only each query's ε can say less.

The one idea behind the gap is that the privacy loss of a composition is a sum. Each output is evidence for one dataset or the other, measured by the logarithm of how much likelier the output is under D than under its neighbour D', and the evidence of k outputs adds up. Basic composition charges the largest value that sum can take, as if every step produced its worst output. But a sum of k bounded random terms rarely strays from its mean by more than a multiple of $\sqrt{k}$. Allowing a small δ lets you ignore the rare extreme sums and charge for the typical one, and that is **advanced composition**. The best bound of this kind, **optimal composition**, can be computed exactly, because randomized response is the mechanism whose composition is hardest to protect. Both survive an analyst who chooses each query after seeing the earlier answers, which is **adaptive composition**.

The running example is the dashboard: $k = 100$ counts, each released by a mechanism that is 0.1-DP, under add/remove neighbours. Basic composition charges $\varepsilon = 10$, advanced composition 5.85 at $\delta' = 10^{-5}$, and optimal composition 4.31, and the chapter derives all three from the distribution of the total privacy loss.

21.1. The privacy loss of a composition

Every bound in this chapter is a statement about one random variable, the total privacy loss of the run. This section defines it, shows that it is a sum over the steps, and works out its distribution for composed randomized response, which Section 21.3 proves is the worst case.

The evidence an output carries is the logarithm of how much likelier it is under D than under D': positive when it favours D, negative when it favours D', zero when it says nothing.

Definition 21.1 (The privacy loss random variable)**.** Let M be a mechanism and $D \sim D'$ two neighbouring datasets. Write $P = M(D)$ and $Q = M(D')$ for the two output distributions, with mass functions or densities p and q. The **privacy loss** of an output y is the log-ratio

$L_{D,D'}(y) = \ln\big(p(y)/q(y)\big)$, which is $+\infty$ where $q(y) = 0 < p(y)$, and the **privacy loss random variable** is the loss of a random output drawn under D,

$$L = L_{D,D'}(Y) = \ln \frac{p(Y)}{q(Y)}, \qquad Y \sim P. \tag{21.1}$$

Its distribution is the **privacy loss distribution** of the pair. Once the pair is fixed, $L(y)$ is short for $L_{D,D'}(y)$.

(ε, δ)-DP asks that $\Pr_P[S] \le e^{\varepsilon} \Pr_Q[S] + \delta$ for every set of outputs S; with $\delta = 0$ this says $|L| \le \varepsilon$ for every output (The definition of differential privacy). For one ordered pair of datasets, the smallest δ that works at a given ε is the largest gap $\Pr_P[S] - e^{\varepsilon} \Pr_Q[S]$, which Divergences shows is reached on the outputs with $p(y) > e^{\varepsilon} q(y)$. That largest gap is the **hockey-stick divergence**,

$$\delta(\varepsilon) = E_{e^{\varepsilon}}(P \| Q) = \sum_y \big(p(y) - e^{\varepsilon} q(y)\big)_+, \qquad (x)_+ = \max\{x, 0\}, \tag{21.2}$$

and as a function of ε it is the **privacy profile** of the pair in one direction. DP asks for it in both directions, for every pair of neighbours.

The smallest case is **randomized response** at level ε (The definition of differential privacy), which reports a person's bit truthfully with probability $t = e^{\varepsilon}/(1 + e^{\varepsilon})$ and flips it otherwise. For a person whose bit is 0 in D and 1 in D', at $\varepsilon = \ln 3$, a report of 0 has probability $\frac{3}{4}$ under D and $\frac{1}{4}$ under D', so its loss is $\ln 3$, and a report of 1 has loss $-\ln 3$. The first lemma says that the profile is an average of a function of the loss, so a composition theorem only has to control the distribution of the total loss.

Lemma 21.1 (The privacy profile is an average of the privacy loss)**.** *For every pair (P, Q) and every $\varepsilon \ge 0$,*

$$\delta(\varepsilon) = E_{e^{\varepsilon}}(P \| Q) = \sum_y \big(p(y) - e^{\varepsilon} q(y)\big)_+ = \mathbb{E}\big[(1 - e^{\varepsilon - L})_+\big] \le \Pr[L > \varepsilon], \tag{21.3}$$

where the expectation and the probability are over $Y \sim P$. In particular, $\delta(\varepsilon)$ depends on the pair only through the distribution of L under P.

Proof.

1. *Factor out p.* Each term of the hockey-stick sum is $(p - e^{\varepsilon} q)_+ = p\,(1 - e^{\varepsilon} q/p)_+$, and the ratio in the bracket is $e^{\varepsilon} q/p = e^{\varepsilon - \ln(p/q)} = e^{\varepsilon - L(y)}$. A sum of $p(y)$ times a function of y is the expectation of that function when $Y \sim P$, which gives the equality with the expectation. An output with $q = 0$ has $L = +\infty$ and bracket 1, as it should.
2. *Bound the bracket.* When $L \le \varepsilon$ the exponent $\varepsilon - L$ is non-negative, so $e^{\varepsilon - L} \ge 1$ and the bracket is 0. When $L > \varepsilon$ the bracket is $1 - e^{\varepsilon - L}$, which lies strictly between 0 and 1. So the bracket is at most the indicator $\mathbf{1}[L > \varepsilon]$, and its average is at most $\Pr[L > \varepsilon]$.

□

An output whose loss is at most ε contributes nothing to $\delta(\varepsilon)$, and an output that is impossible under D' contributes its whole probability. For randomized response at $\ln 3$, the lemma at $\varepsilon = 0$ gives $\delta(0) = \frac{3}{4}(1 - \frac{1}{3}) = \frac{1}{2}$, the total variation distance $\frac{3}{4} - \frac{1}{4}$, as it should. Advanced composition uses the tail bound of the lemma, and optimal composition uses the equality.

Now run k mechanisms. The probability of a whole sequence of outputs is built one step at a time, and the logarithm turns that product into a sum.

Lemma 21.2 (The privacy loss of a composition is a sum)**.** *Run $M_1, \dots, M_k$ in sequence, where M_i may depend on the earlier outputs $y_{<i} = (y_1, \dots, y_{i-1})$. Write $p_i(y_i \mid y_{<i})$ for the probability that step i outputs y_i on D after the history $y_{<i}$, and $q_i(y_i \mid y_{<i})$ for the same on D'. Then the privacy loss of the whole sequence is the sum of the per-step losses,*

$$L(y_1, \dots, y_k) = \sum_{i=1}^{k} L_i(y_i \mid y_{<i}), \qquad L_i(y_i \mid y_{<i}) = \ln \frac{p_i(y_i \mid y_{<i})}{q_i(y_i \mid y_{<i})}, \tag{21.4}$$

where L_i is the privacy loss of step i alone, for the mechanism that was run after that history. If step i is ε-DP for every history, then $|L_i| \le \varepsilon$, and so $|L| \le k\varepsilon$.

Proof.

1. *Chain rule.* The probability of a sequence of outputs is the probability of y_1, times the probability of y_2 given y_1, and so on. So the joint output has probability $p(y_1, \dots, y_k) = \prod_i p_i(y_i \mid y_{<i})$ on D, and likewise with q_i on D'.
2. *Log of a ratio of products.* The ratio of the two products is the product of the step-by-step ratios, and the logarithm of a product is the sum of the logarithms, which is Equation 21.4.
3. *Basic composition.* If step i is ε-DP whatever the history, each term lies in $[-\varepsilon, \varepsilon]$, and adding k such bounds gives $|L| \le k\varepsilon$.

□

Table 21.1 shows the sum for two independent rounds of randomized response at $\varepsilon = \ln 3$: the output $(0, 1)$ has loss 0 because one report favours D as much as the other favours D'.

Table 21.1.: Two rounds of randomized response at $\varepsilon = \ln 3$. The privacy loss of each output is the sum of the two per-round losses.

Output (y_1, y_2)	$(0,0)$	$(0,1)$	$(1,0)$	$(1,1)$
p (bit 0)	9/16	3/16	3/16	1/16
q (bit 1)	1/16	3/16	3/16	9/16
$L = \ln(p/q)$	$2\ln 3$	0	0	$-2\ln 3$

For randomized response the sum is a random walk with steps $\pm\varepsilon$, and its whole distribution can be written down. A report of 0 is the truth under D, so it **points to** D; under D a report points to D' only when it is a lie.

Proposition 21.1 (The loss of composed randomized response)**.** *Compose k independent rounds of randomized response at level ε, on a person whose bit is 0 in D and 1 in D', and let J be the number of rounds whose report points to D'. Under D,*

$$J \sim \mathrm{Bin}(k, 1-t), \qquad L = (k-2J)\varepsilon, \tag{21.5}$$

and the loss has mean, variance and worst-case probability

$$\mathbb{E}[L] = k\varepsilon \tanh(\varepsilon/2), \qquad \mathrm{Var}(L) = k\varepsilon^2(1-\tanh^2(\varepsilon/2)), \qquad \Pr[L = k\varepsilon] = t^k. \tag{21.6}$$

Proof. The plan is to find the loss of one round, add k of them, and then compute the mean and variance of one round and multiply by k.

1. *One round.* A truthful report has probability t under D and $1-t$ under D', so its loss is $\ln \frac{t}{1-t} = \ln e^{\varepsilon} = \varepsilon$, because $t/(1-t) = e^{\varepsilon}$ by the definition of t. A lie has the two probabilities swapped and loss $-\varepsilon$.
2. *k rounds.* By Lemma 21.2 the total is the sum of the k per-round losses. The J rounds that point to D' contribute $-\varepsilon$ each and the other $k-J$ contribute $+\varepsilon$, so $L = (k-J)\varepsilon - J\varepsilon = (k-2J)\varepsilon$. Each round points to D' exactly when it lies, independently with probability $1-t$, so J counts the successes in k independent trials and is binomial.
3. *Mean.* One round has mean $\varepsilon t - \varepsilon(1-t) = \varepsilon(2t-1)$. Substituting t gives $2t-1 = \frac{e^{\varepsilon}-1}{e^{\varepsilon}+1}$, and this is $\tanh(\varepsilon/2)$, because $\tanh x = \frac{e^{2x}-1}{e^{2x}+1}$. The mean of a sum is the sum of the means, so multiply by k.
4. *Variance.* One round takes the two values $\pm\varepsilon$, so its square is always ε^2 and its variance is $\varepsilon^2 - (\text{mean})^2 = \varepsilon^2(1-\tanh^2(\varepsilon/2))$. Variances of independent terms add, so the total variance is k times this.
5. *The worst case.* The value $L = k\varepsilon$ needs $J = 0$, every report truthful, which has probability t^k.

□

For small ε, $\tanh(\varepsilon/2) \approx \varepsilon/2$, so the mean is about $k\varepsilon^2/2$ and the standard deviation about $\sqrt{k}\,\varepsilon$, both far below the worst case $k\varepsilon$, which needs all k reports to be truthful. Basic composition guards against an event that will never happen.

By the central limit theorem the total loss is nearly normal (Figure 21.1), the starting point of the Gaussian view of privacy in Privacy accounting. Advanced composition bounds its tail, and optimal composition evaluates Equation 21.3 on the binomial exactly.

Example 21.1. Release each of the dashboard's $k = 100$ counts by randomized response at $\varepsilon = 0.1$, the worst 0.1-DP mechanism by Section 21.3. Each round is truthful with probability $t = e^{0.1}/(1+e^{0.1}) = 0.5250$. By Proposition 21.1 the total loss has mean $100 \times 0.1 \tanh(0.05) = 0.4996$ and standard deviation 0.9988. Basic composition's $k\varepsilon = 10$ sits $(10 - 0.50)/1.00 = 9.5$ standard deviations above the mean, and it needs all 100 reports to be truthful, which has probability $t^{100} = 1.0 \times 10^{-28}$. The loss $(100 - 2J) \times 0.1$ exceeds 4 only when $J < 30$, about 3.5 standard deviations of J (which are 5) below its mean $100(1-t) = 47.5$. The optimal ε' at $\delta' = 10^{-5}$ that Section 21.4 computes, 4.3068, sits $(4.3068 - 0.4996)/0.9988 = 3.8$ standard deviations above the mean of the loss.

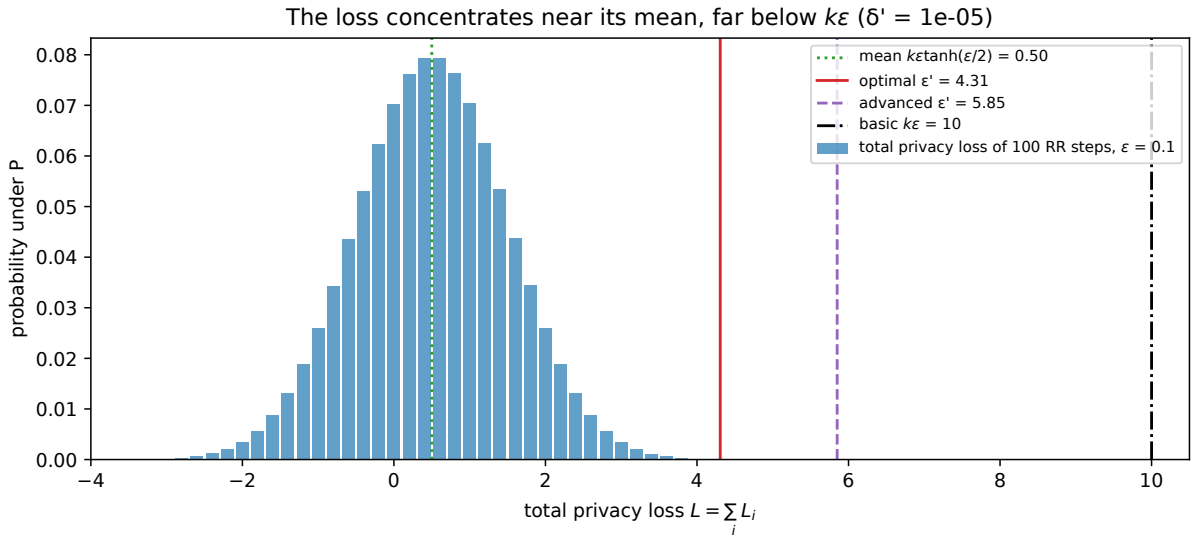

Figure 21.1.: The total privacy loss of 100 rounds of randomized response at $\varepsilon = 0.1$, under D, with its mean, the optimal and advanced ε' at $\delta' = 10^{-5}$, and basic composition's $k\varepsilon = 10$.

21.2. Advanced composition

Advanced composition, due to Dwork, Rothblum & Vadhan (2010), charges for the typical value of the sum rather than its largest: it needs only each step's ε, holds for mechanisms chosen in any adaptive way, and grows like $\sqrt{k}$. Its tool is Azuma's inequality, a version of Hoeffding's inequality for sums whose terms may depend on the earlier terms. Azuma controls how far the sum strays from its mean, so the theorem also needs a bound on the mean of each term, the drift of the sum, and that bound comes first.

The loss can be as large as ε, but on average it is much smaller: when ε is small, positive and negative losses nearly cancel, and what is left is of order ε^2. The average loss under P is $\sum_y p(y)\ln(p(y)/q(y))$, the Kullback–Leibler (KL) divergence $D_{\mathrm{KL}}(P\|Q)$ of Divergences.

Lemma 21.3 (The mean privacy loss of an ε-DP pair is second order in ε)**.** *If $|L| \le \varepsilon$ for every output, then*

$$\mathbb{E}[L] = D_{\mathrm{KL}}(P\|Q) \le \varepsilon(e^{\varepsilon} - 1). \tag{21.7}$$

Proof.

1. *Symmetrize.* The KL divergence is never negative (Divergences): by Jensen's inequality for the concave logarithm, $-D_{\mathrm{KL}}(Q\|P) = \sum_y q\ln(p/q) \le \ln\sum_y q\,(p/q) = \ln 1 = 0$. So adding $D_{\mathrm{KL}}(Q\|P) \ge 0$ to $\mathbb{E}[L]$ can only increase it, and the two sums combine term by term:

$$\mathbb{E}[L] \le \sum_y p\ln\frac{p}{q} + \sum_y q\ln\frac{q}{p} = \sum_y (p-q)\ln\frac{p}{q}. \tag{21.8}$$

2. *Use the bound on the loss.* Each $|\ln(p/q)|$ is at most ε, so the sum is at most $\varepsilon\sum_y |p-q|$, and the total difference $\sum_y |p-q|$ is itself small when P and Q are close.

3. *Bound the total difference.* Write $\sum_y |p-q| = \sum_y q\,|p/q-1|$. The ratio p/q lies in $[e^{-\varepsilon}, e^{\varepsilon}]$, and on that interval $|p/q-1|$ is largest at the upper end, where it is $e^{\varepsilon}-1$ (at the lower end it is $1-e^{-\varepsilon}$, which is smaller). Since the $q(y)$ sum to 1, $\sum_y |p-q| \le e^{\varepsilon}-1$, and the bound follows.

□

So the mean is of order ε^2: at $\varepsilon = 0.1$ the bound is $0.1(e^{0.1}-1) = 0.0105$, but it is not tight: Theorem 21.3 in Section 21.3 gives the best bound, $\varepsilon\tanh(\varepsilon/2)$, which is 0.0050 at $\varepsilon = 0.1$ and 0.4621 at $\varepsilon = 1$, where the lemma gives 1.7183. Section B.2 in the appendices derives the same bound from scratch for a single count, with every number shown.

Theorem 21.1 (Advanced composition (Dwork, Rothblum & Vadhan 2010))**.** *Fix k and $\varepsilon > 0$ in advance, and let $M_1, \dots, M_k$ be mechanisms, each chosen after seeing the earlier outputs, such that every M_i is ε-DP for every history. Then for every $\delta' > 0$ the composition is (ε', δ')-DP with*

$$\varepsilon' = \varepsilon\sqrt{2k\ln(1/\delta')} + k\varepsilon(e^{\varepsilon}-1). \tag{21.9}$$

Proof. The plan is to write the loss as a sum, centre each term by its conditional mean to get a martingale, bound the fluctuation of the martingale by Azuma's inequality and the drift by Lemma 21.3, and convert the tail bound into a δ by Lemma 21.1.

1. *The loss is a sum.* By Lemma 21.2, $L = \sum_i L_i$, where L_i is the loss of step i given the history $y_{<i}$.
2. *Each term is bounded, given the past.* For every fixed history, step i is ε-DP, so $L_i \in [-\varepsilon, \varepsilon]$.
3. *Each term has a small conditional mean.* Given the history, the average of L_i over step i's output is $m_i = \mathbb{E}[L_i \mid y_{<i}] = \sum_{y_i} p_i \ln(p_i/q_i)$, the KL divergence of step i's pair. So $m_i \le \varepsilon(e^{\varepsilon}-1)$ by Lemma 21.3.
4. *Centre the terms to get a martingale.* A **martingale** is a running sum whose next increment has mean zero given everything that happened before. Subtracting each term's conditional mean makes one: $W_k = \sum_i (L_i - m_i)$ has increments with conditional mean zero. Given the past, $L_i - m_i$ lies in $[-\varepsilon - m_i, \varepsilon - m_i]$, an interval of length $c_i = 2\varepsilon$, whose position depends on the past but whose length does not.
5. *Azuma.* The Azuma–Hoeffding inequality of Concentration inequalities says that if each increment of a martingale has conditional mean zero and lies, given the past, in an interval of length c_i fixed in advance, then the sum exceeds s with probability at most $\exp(-2s^2/\sum_i c_i^2)$. It holds because Hoeffding's lemma bounds each increment's conditional moment generating function using only its mean and the length of its range, and these bounds multiply one step at a time. With $c_i = 2\varepsilon$, so that $\sum_i c_i^2 = 4k\varepsilon^2$,
$$\Pr[W_k \ge s] \le \exp\left(-\frac{2s^2}{4k\varepsilon^2}\right) = \exp\left(-\frac{s^2}{2k\varepsilon^2}\right). \tag{21.10}$$
6. *Choose the level.* Setting the right side to δ' and solving, $s^2 = 2k\varepsilon^2\ln(1/\delta')$, gives $s = \varepsilon\sqrt{2k\ln(1/\delta')}$. The loss is the fluctuation plus the drift, $L = W_k + \sum_i m_i \le W_k + k\varepsilon(e^{\varepsilon}-1)$. So if L exceeds $\varepsilon' = s + k\varepsilon(e^{\varepsilon}-1)$, then W_k must exceed s, and $\Pr[L > \varepsilon'] \le \delta'$.
7. *Convert.* By Lemma 21.1, $\delta(\varepsilon') \le \Pr[L > \varepsilon'] \le \delta'$. The same argument with D and D' swapped gives the other direction, so the composition is (ε', δ')-DP.

□

The gain is $\sqrt{k}$ instead of k. The price is δ' and the factor $\sqrt{2\ln(1/\delta')}$, which is $\sqrt{2 \times 11.51} = 4.80$ at $\delta' = 10^{-5}$, so the theorem beats basic composition only once k is large. Dividing both bounds by ε and squaring, which needs $\varepsilon < \ln 2$ so that $2 - e^{\varepsilon} > 0$, gives the crossover (Exercise 2 in the exercise book):

$$k > \frac{2\ln(1/\delta')}{(2 - e^{\varepsilon})^2}. \tag{21.11}$$

Setting the leading term equal to a target $\varepsilon_{\text{total}}$ gives each step $\varepsilon \approx \varepsilon_{\text{total}}/\sqrt{2k\ln(1/\delta')}$, where basic composition would allow only $\varepsilon_{\text{total}}/k$. Corollary 21.1 in Section 21.4 extends the theorem to (ε, δ)-DP steps at a cost of $k\delta$, with the sharper drift $k\varepsilon\tanh(\varepsilon/2)$.

The bound is loose in three places: Azuma assumes each increment has the largest variance its range allows, the mean bound of Lemma 21.3 is a factor 2 too large for small ε, and the tail bound of Lemma 21.1 counts every output above ε' in full. At $k = 100$ and $\varepsilon = 0.1$, the exact δ at the advanced $\varepsilon' = 5.85$ is 1.96×10^{-9}, not 10^{-5}.

Example 21.2. Take the dashboard's $k = 100$ counts at $\varepsilon = 0.1$ and $\delta' = 10^{-5}$. The Azuma term is $0.1\sqrt{200\ln 10^5} = 0.1\sqrt{2302.6} = 4.7985$, and the mean term is $100 \times 0.1(e^{0.1} - 1) = 1.0517$, so $\varepsilon' = 5.8502$, against 10 for basic composition. The crossover is $23.03/0.8948^2 = 28.8$, so advanced composition wins from $k = 29$ on (Figure 21.2, and Table 21.4 in Section 21.4). At $k = 10{,}000$ the mean term dominates: it costs 105 of the total 153, against 48 for the Azuma term, and the sharper drift of Corollary 21.1 costs 50 instead.

Laplace noise in many dimensions. The same arithmetic explains why the Gaussian mechanism wins in high dimension. Take d dense counts, where one record can move every count by 1, at $\varepsilon = 1$ and $\delta = 10^{-5}$. Laplace noise of scale b has root-mean-square error $\sqrt{2}\,b$, and on the whole vector it must use the ℓ_1 sensitivity d, so $b = d/\varepsilon$. Composing d separate Laplace mechanisms instead, at the largest ε_0 whose composition stays at 1, gives error $\sqrt{2}/\varepsilon_0$: for $d = 1000$, $\varepsilon_0 = 0.00645$ by Equation 21.9, or 0.00849 by the optimal composition of Section 21.4. Table 21.2 adds the Gaussian mechanism of the Laplace and Gaussian mechanisms. Composed Laplace noise grows like $\sqrt{d}$ and stays within a factor of 1.9 of the Gaussian, while pure-DP Laplace noise falls behind by a factor of 38 at $d = 10{,}000$. So the $\sqrt{d}$ gain comes from allowing $\delta > 0$, not from the Gaussian density.

Table 21.2.: Root-mean-square error per count for d dense counts at $\varepsilon = 1$ and, except in the first column, $\delta = 10^{-5}$.

d	Laplace, pure DP	Laplace, advanced composition	Laplace, optimal composition	Gaussian
100	141.4	69.3	52.3	37.3
1,000	1,414.2	219.2	166.6	118.0
10,000	14,142.1	693.0	527.5	373.1

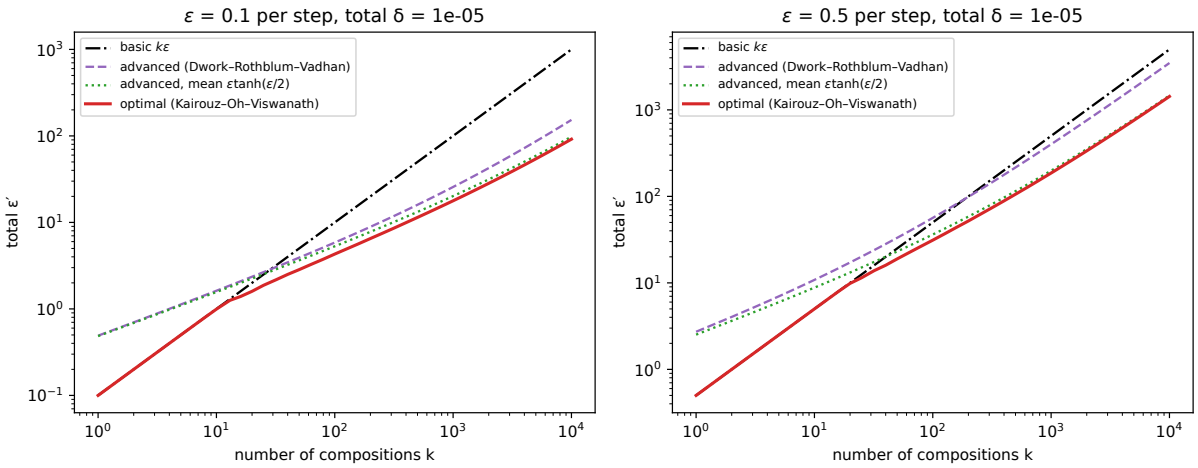

Figure 21.2.: Total ε' at $\delta = 10^{-5}$ after k steps that are each ε-DP, for $\varepsilon = 0.1$ (left) and 0.5 (right), on log axes. Basic composition grows like k, the others like $\sqrt{k}$ until the mean term takes over.

21.3. The worst mechanism

Advanced composition is one bound among many, and the question is which is best. Kairouz, Oh & Viswanath (2015) answered it with post-processing: every (ε, δ)-DP mechanism is a post-processing of one version of randomized response, so no composition of such mechanisms can be worse than composed randomized response. This section builds that mechanism and proves the reduction, and Section 21.4 composes it.

A **channel** K is a table of probabilities $K(y \mid z)$: given an input z, it draws an output y without looking at the data, and feeding a distribution $P^\star$ through it gives $P^\star K(y) = \sum_z P^\star(z)K(y \mid z)$. The data-processing inequality of Divergences says that a channel never increases the hockey-stick divergence or the KL divergence. For the hockey-stick the reason is short: the gap $P^\star K(S) - e^{\varepsilon'} Q^\star K(S)$ on a set S is $\sum_z K(S \mid z)(P^\star(z) - e^{\varepsilon'} Q^\star(z))$ with weights in $[0, 1]$, so it is at most the sum of the positive brackets, which is the hockey-stick before the channel.

The worst mechanism must spend both parameters. It spends δ by announcing, with probability δ, which dataset it ran on, and ε by otherwise running randomized response at level ε.

Definition 21.2 (The four-point randomized response)**.** The **four-point pair** $(P^\star, Q^\star)$ at level (ε, δ) is the pair of output distributions in Table 21.3: with probability δ the mechanism announces its dataset outright, and otherwise it reports the person's bit through randomized response at level ε, with $t = e^\varepsilon/(1 + e^\varepsilon)$.

Table 21.3.: The four-point randomized response of Kairouz, Oh & Viswanath at level (ε, δ).

Output	"flag D"	0	1	"flag D'"
$P^\star$ (on D)	δ	$(1-\delta)t$	$(1-\delta)(1-t)$	0
$Q^\star$ (on D')	0	$(1-\delta)(1-t)$	$(1-\delta)t$	δ
Privacy loss	$+\infty$	$+\varepsilon$	$-\varepsilon$	$-\infty$

Every (ε, δ)-DP pair can be produced from the four-point pair by one channel, and for $\delta = 0$ the channel has a closed form.

Theorem 21.2 (Randomized response is the worst (ε, δ)-DP mechanism)**.** *Let (P, Q) be a pair of distributions on a common set of outputs that satisfies (ε, δ)-DP in both directions. Then there is a channel K with $P = P^\star K$ and $Q = Q^\star K$, where $(P^\star, Q^\star)$ is the four-point pair of Definition 21.2. For $\delta = 0$ the channel is*

$$K(y \mid 0) = \frac{e^\varepsilon p(y) - q(y)}{e^\varepsilon - 1}, \qquad K(y \mid 1) = \frac{e^\varepsilon q(y) - p(y)}{e^\varepsilon - 1}. \tag{21.12}$$

Proof. For $\delta = 0$, solve for the channel and check that it reproduces the pair; for $\delta > 0$, the last step says why the channel exists and where it is built.

1. *Solve for the channel.* Plain randomized response outputs 0, the report that points to D, with probability t on D and $1 - t$ on D'. So the channel must satisfy, for every output y of the target pair, $p(y) = tK(y \mid 0) + (1-t)K(y \mid 1)$ and $q(y) = (1-t)K(y \mid 0) + tK(y \mid 1)$. These are two linear equations in the two unknowns $K(y \mid 0)$ and $K(y \mid 1)$, and solving them with $t/(1-t) = e^\varepsilon$ gives Equation 21.12.
2. *The rows are distributions.* A channel's rows must be non-negative and sum to 1. $K(y \mid 0) \geq 0$ exactly when $e^\varepsilon p(y) \geq q(y)$, and $K(y \mid 1) \geq 0$ exactly when $e^\varepsilon q(y) \geq p(y)$. Both hold for every y because the pair is ε-DP. Since p and q each sum to 1, each row sums to $(e^\varepsilon - 1)/(e^\varepsilon - 1) = 1$.
3. *They reproduce P.* Mixing the rows with randomized response's probabilities on D gives

$$t\,K(y \mid 0) + (1-t)K(y \mid 1) = \frac{(te^\varepsilon - (1-t))p(y) + ((1-t)e^\varepsilon - t)q(y)}{e^\varepsilon - 1}. \tag{21.13}$$

   With $t = e^\varepsilon/(1+e^\varepsilon)$, $(1-t)e^\varepsilon = t$, so the coefficient of q is 0. The coefficient of p is $\frac{te^\varepsilon - (1-t)}{e^\varepsilon - 1} = \frac{(e^{2\varepsilon}-1)/(1+e^\varepsilon)}{e^\varepsilon - 1} = 1$, since $e^{2\varepsilon} - 1 = (e^\varepsilon - 1)(e^\varepsilon + 1)$.
4. *They reproduce Q.* The same computation with t and $1 - t$ swapped.
5. *The case $\delta > 0$, cited.* The **trade-off function** of a pair gives, for each false positive rate, the smallest false negative rate any test between P and Q can reach. The definition of differential privacy shows that a pair is (ε, δ)-DP exactly when its trade-off function lies above a boundary $f_{\varepsilon,\delta}$ made of two straight lines, on which the four-point pair sits (Figure 21.3, left). So every (ε, δ)-DP pair is at least as hard to test as $(P^\star, Q^\star)$, at every level. Blackwell's theorem (1953) says that a pair is at least as hard to test as another at every level exactly when it is a post-processing of the other. Kairouz, Oh & Viswanath (2015) construct the channel, and Section J.1 in the appendices derives it step by step, by splitting each distribution into an ε-DP part of mass $1 - \delta$ and a leftover of mass δ.

□

The same reduction sharpens the drift term of advanced composition, because the KL divergence, like the hockey-stick, can only shrink under a channel.

Theorem 21.3 (The sharp mean loss)**.** *If the pair (P, Q) is ε-DP in both directions, then*

$$\mathbb{E}[L] = D_{\mathrm{KL}}(P \| Q) \leq \varepsilon \tanh(\varepsilon/2), \tag{21.14}$$

with equality for randomized response at level ε.

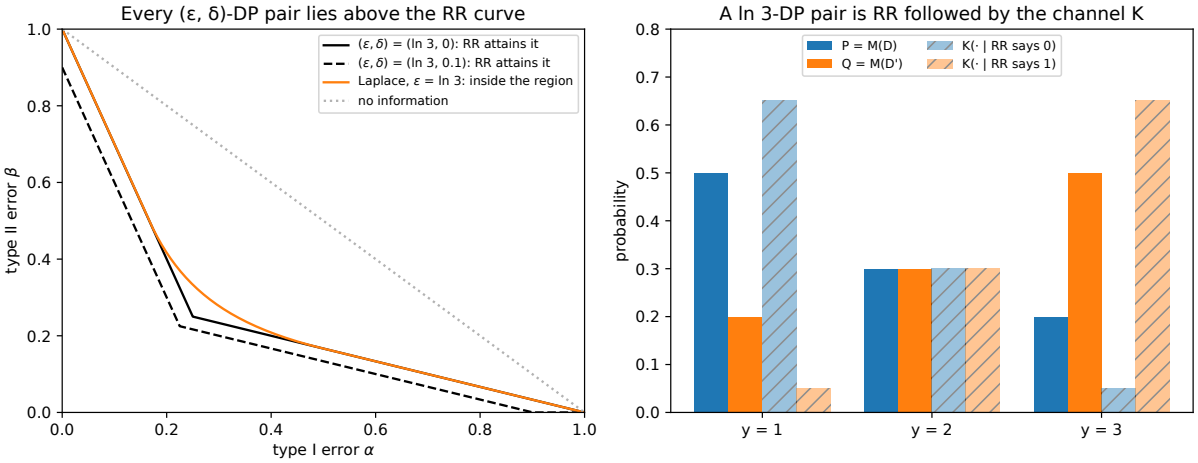

Figure 21.3.: Left: the boundaries $f_{\varepsilon,\delta}$ at $\varepsilon = \ln 3$ with $\delta = 0$ and 0.1, attained by randomized response, and a Laplace mechanism's trade-off curve inside the allowed region. Right: the pair of Example 21.3 and the two rows of its channel.

Proof.

1. *Reduce to randomized response.* By Theorem 21.2 with $\delta = 0$, the pair is a post-processing of randomized response at level ε through the channel Equation 21.12. Passing two distributions through the same channel can only make them more alike, which is the data-processing inequality for the KL divergence, so $D_{\mathrm{KL}}(P\|Q)$ is at most the KL divergence of randomized response.
2. *The KL divergence of randomized response.* Its mean loss is $\varepsilon t - \varepsilon(1-t) = \varepsilon \tanh(\varepsilon/2)$, by step 3 of the proof of Proposition 21.1 with $k = 1$, and randomized response itself reaches it.

□

Example 21.3. The dashboard's randomized-response steps need no channel, so take another pair: $P = (0.5, 0.3, 0.2)$ and $Q = (0.2, 0.3, 0.5)$ have largest loss $\ln(0.5/0.2) = \ln 2.5 = 0.9163$, below $\ln 3 = 1.0986$, so the pair is $\ln 3$-DP. With $e^{\varepsilon} = 3$, Equation 21.12 gives $K(\cdot \mid 0) = (3P - Q)/2 = (0.65, 0.30, 0.05)$ and $K(\cdot \mid 1) = (3Q - P)/2 = (0.05, 0.30, 0.65)$ (Figure 21.3, right). Randomized response at $\ln 3$ has $t = \frac{3}{4}$, and the first output comes back as $\frac{3}{4} \times 0.65 + \frac{1}{4} \times 0.05 = 0.5$. As Theorem 21.3 requires, the pair's KL divergence, $0.5 \ln 2.5 + 0.3 \ln 1 + 0.2 \ln 0.4 = 0.2749$, is below randomized response's $\ln 3 \times \frac{1}{2} = 0.5493$, and its $\delta(0)$, the total variation $0.5 - 0.2 = 0.3$, is below 0.5.

21.4. Optimal composition

With the worst mechanism in hand, the best bound for k mechanisms known only by their (ε, δ) is the exact profile of k copies of the four-point pair. Either some step raises a flag, and the output counts in full, or none does, and the loss is binomial by Equation 21.5. Lemma 21.1 turns that binomial loss into a δ, written $\delta_{\mathrm{RR}}(\varepsilon')$.

Theorem 21.4 (Optimal composition (Kairouz, Oh & Viswanath 2015))**.** *For every composition of k mechanisms that are each (ε, δ)-DP, adaptive or not, and every $\varepsilon' \geq 0$,*

$$\delta(\varepsilon') \leq 1 - (1-\delta)^k(1 - \delta_{\mathrm{RR}}(\varepsilon')), \qquad \delta_{\mathrm{RR}}(\varepsilon') = \sum_{j=0}^{k} \binom{k}{j} t^{k-j}(1-t)^j \left(1 - e^{\varepsilon' - (k-2j)\varepsilon}\right)_+, \tag{21.15}$$

with equality for k independent copies of the four-point pair. The binomial weight $\binom{k}{j}t^{k-j}(1-t)^j$ is the probability that exactly j of the k reports point to D'. At the points where ε' equals one of the values the loss can take, $\varepsilon' = (k-2i)\varepsilon$ for $i = 0, \dots, \lfloor k/2 \rfloor$, the positive part can be dropped and the sum becomes a ratio of exponentials,

$$\delta_{\mathrm{RR}}((k-2i)\varepsilon) = \frac{\sum_{\ell=0}^{i-1} \binom{k}{\ell}\left(e^{(k-\ell)\varepsilon} - e^{(k-2i+\ell)\varepsilon}\right)}{(1+e^{\varepsilon})^k}, \tag{21.16}$$

which is the formula of Kairouz, Oh & Viswanath's main theorem.

Proof. The plan is to show that a composition, adaptive or not, is a post-processing of k independent four-point pairs, so that the data-processing inequality reduces the bound to the four-point product, and then to evaluate Lemma 21.1 on that product.

1. *Non-adaptive.* If step i is $P_i = P^\star K_i$ and $Q_i = Q^\star K_i$ by Theorem 21.2, then the product $P_1 \times \cdots \times P_k$ is $(P^\star)^k$ followed by the channel that applies K_i to coordinate i, independently. So $\delta(\varepsilon')$ of the composition is at most that of $(P^\star)^k$ against $(Q^\star)^k$, by the data-processing inequality.
2. *Adaptive.* Now the mechanism of step i, and so its channel $K_i^{y_{<i}}$, may depend on the earlier outputs. The trick is to draw all the four-point outputs z_i first and apply the channels afterwards. Draw $z_1, \dots, z_k$ from $(P^\star)^k$, then $y_1 \sim K_1(\cdot \mid z_1)$, then $y_2 \sim K_2^{y_1}(\cdot \mid z_2)$, and so on. Given $y_{<i}$, z_i is still a fresh draw from $P^\star$, because it was drawn independently of $z_{<i}$ and $y_{<i}$ depends only on those. So y_i has law $P^\star K_i^{y_{<i}} = P_i(\cdot \mid y_{<i})$, and the sequence has exactly the law of the adaptive run on D. The same sampler fed with $(Q^\star)^k$ produces the run on D', so the adaptive run is still one post-processing of $(P^\star)^k$ against $(Q^\star)^k$.
3. *The four-point product.* With probability $1-(1-\delta)^k$ some coordinate of $(P^\star)^k$ shows "flag D", which $(Q^\star)^k$ never produces, so there $L = +\infty$, the bracket $(1 - e^{\varepsilon' - L})_+$ is 1, and the output contributes its full probability to Equation 21.3. Outputs with "flag D'" have probability 0 under $(P^\star)^k$. Otherwise, with probability $(1-\delta)^k$, all coordinates are plain randomized response; the factor $(1-\delta)$ per coordinate cancels in the ratio, so $L = (k-2J)\varepsilon$ by Equation 21.5, and Lemma 21.1 on this part gives $(1-\delta)^k\delta_{\mathrm{RR}}(\varepsilon')$. Adding the two parts gives $1-(1-\delta)^k + (1-\delta)^k\delta_{\mathrm{RR}}(\varepsilon')$, which is Equation 21.15.
4. *Equality.* The four-point pair is itself a mechanism, on a dataset of one bit, and it is (ε, δ)-DP. Composing k independent copies of it gives equality, so no better bound can hold for the whole class.
5. *The grid formula.* At $\varepsilon' = (k-2i)\varepsilon$, the terms of δ_{RR} with $j \geq i$ vanish, because their loss $(k-2j)\varepsilon$ is at most ε' and the bracket is 0. For $j = \ell < i$ the bracket is positive and the positive part can be dropped. Since $t = e^\varepsilon/(1+e^\varepsilon)$ and $1-t = 1/(1+e^\varepsilon)$, the weight is $\binom{k}{\ell}t^{k-\ell}(1-t)^\ell = \binom{k}{\ell}e^{(k-\ell)\varepsilon}/(1+e^\varepsilon)^k$. Multiplying it by $e^{\varepsilon' - (k-2\ell)\varepsilon} = e^{(2\ell-2i)\varepsilon}$ turns $e^{(k-\ell)\varepsilon}$ into $e^{(k-2i+\ell)\varepsilon}$, which is Equation 21.16.

□

"Optimal" means optimal for the class: Equation 21.15 is the best you can say about k mechanisms *if all you know about each is its* (ε, δ). A Laplace mechanism with the same ε does a little better, because its loss often lies strictly inside $(-\varepsilon, \varepsilon)$: its mean loss at $\varepsilon = 1$ is 0.3679, against 0.4621 for randomized response.

A single (ε, δ) also throws information away. The privacy loss of a Gaussian step is normal (The Laplace and Gaussian mechanisms), so k steps with noise σ on a sensitivity-1 query have exactly the loss of one step with noise $\sigma/\sqrt{k}$ (Exercise 6 in the exercise book). Figure 21.4 shows what a point summary costs: with $\sigma = 20$, $k = 1{,}000$ steps are exactly $(7.51, 10^{-5})$-DP, but the best per-step split of δ followed by optimal composition gives 62.7. Composing the curves themselves is the subject of Privacy accounting.

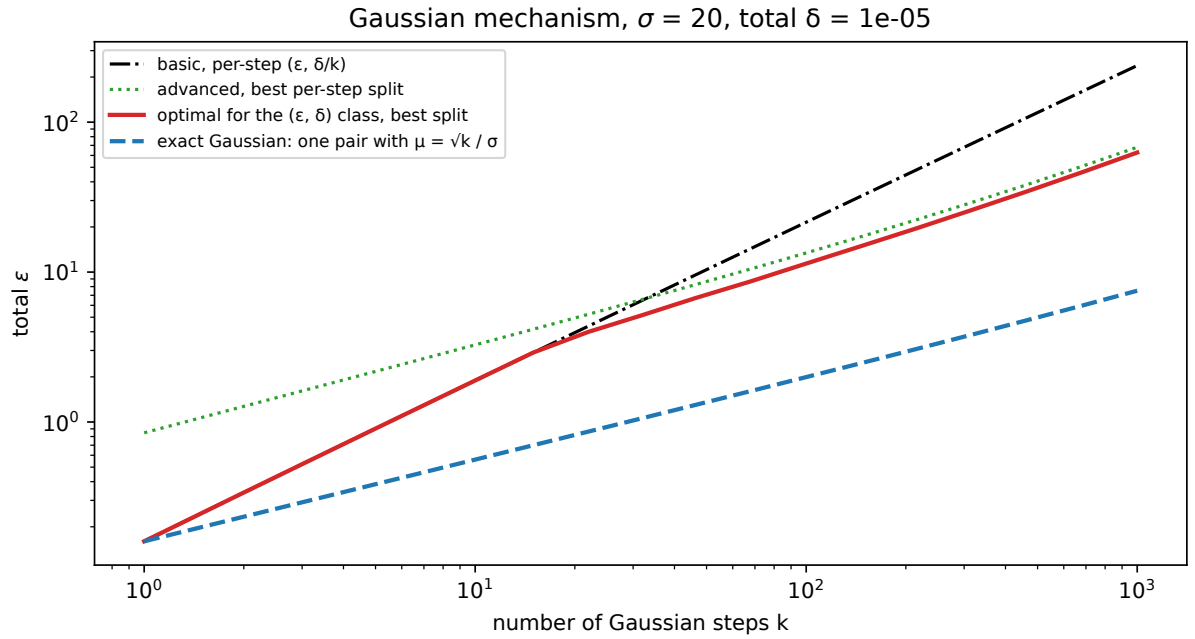

Figure 21.4.: Total ε at $\delta = 10^{-5}$ after k Gaussian steps with $\sigma = 20$ on a sensitivity-1 query. Three curves summarize each step by one (ε, δ) point and compose it with basic, advanced or optimal composition; the dashed curve is the exact composition, one Gaussian step with noise $\sigma/\sqrt{k}$.

The four-point product also extends advanced composition to steps with $\delta > 0$, and with the sharper drift: the flags cost their probability, and the rest is randomized response.

Corollary 21.1 (Advanced composition for (ε, δ)-DP steps, with the sharp drift)**.** *Fix k, $\varepsilon > 0$ and $\delta \geq 0$ in advance, and let $M_1, \ldots, M_k$ be mechanisms, each chosen after seeing the earlier outputs, such that every M_i is (ε, δ)-DP for every history. Then for every $\delta' > 0$ the composition is $(\varepsilon', k\delta + \delta')$-DP with ε' from Equation 21.9, and also with*

$$\varepsilon' = \varepsilon\sqrt{2k\ln(1/\delta')} + k\varepsilon\tanh(\varepsilon/2). \tag{21.17}$$

Proof.

1. *Reduce to the four-point product.* By step 2 of the proof of Theorem 21.4, the adaptive run is a post-processing of k independent copies of the four-point pair, and a channel never increases $\delta(\varepsilon')$, so it suffices to bound the k-fold four-point product.
2. *The flags.* Some coordinate shows "flag D" with probability $1-(1-\delta)^k$, which is at most $k\delta$ because the chance that at least one of k events happens is at most the sum of their chances (Exercise 4 in the exercise book proves the inequality). Those outputs are impossible under D' and contribute their whole probability to $\delta(\varepsilon')$, so the flags cost at most $k\delta$.
3. *The rest.* Otherwise all k coordinates are plain randomized response at level ε, which are k independent ε-DP steps, so Theorem 21.1 bounds their contribution at the ε' of Equation 21.9 by δ'. Their drift is exactly $k\varepsilon\tanh(\varepsilon/2)$ by Proposition 21.1, so step 6 of that proof with this drift in place of $k\varepsilon(e^{\varepsilon}-1)$ gives the same δ' at the ε' of Equation 21.17. Adding the two parts gives $k\delta+\delta'$.

□

Example 21.4. For the dashboard's $k=100$ steps at $\varepsilon=0.1$, the optimal ε' at $\delta'=10^{-5}$ is 4.3068, and the sharper advanced bound of Equation 21.17 is $4.7985+0.4996=5.2981$. The optimal value is 19% below it ($4.3068/5.2981=0.81$), 26% below the original advanced bound ($4.3068/5.8502=0.74$) and 57% below basic composition's 10. Table 21.4 compares the four bounds over k; at $k=10$, below the crossover, both advanced bounds are worse than basic composition, while the optimal bound is slightly better, 0.994 against 1. If each step also has $\delta=5\times10^{-8}$, the flags use up $1-(1-\delta)^{100}=5.0\times10^{-6}$ of a total $\delta=10^{-5}$, and the optimal ε' rises to 4.4469; advanced composition with the remaining $\delta'=5\times10^{-6}$ gives 5.9926.

Table 21.4.: Total ε' at $\delta'=10^{-5}$ for k mechanisms that are each 0.1-DP.

k	Basic $k\varepsilon$	Advanced, Equation 21.9	Advanced, Equation 21.17	Optimal
10	1.000	1.623	1.567	0.994
100	10.000	5.850	5.298	4.307
1,000	100.000	25.691	20.170	17.787
10,000	1,000.000	153.156	97.944	91.691

Computing the bound. Equation 21.16 as printed divides two numbers that overflow: at $\varepsilon=1$ and $k=1{,}000$, $(1+e)^{1000}\approx10^{570}$, beyond the largest double. The chapter's script (Section 21.6) adds the non-negative terms of Equation 21.15 in log space with a log-sum-exp, so nothing overflows and nothing cancels. Between two grid points $\delta_{\mathrm{RR}}(\varepsilon')=A-e^{\varepsilon'}B$, where A and B are the masses under P and Q of the outputs with loss above ε', so the optimal ε' for a target δ is found exactly. With a different ε_i per step the loss depends on which steps lied, not just how many, and the exact bound is #P-complete to compute (Murtagh & Vadhan, 2016); for a few steps you can still enumerate (Exercise 7 in the exercise book).

21.5. Adaptive composition

In practice the next query depends on the last answer: an analyst zooms into the largest bin of a noisy histogram, and a training loop computes each gradient at parameters that came from

earlier noisy gradients. The proofs above were written to cover this; this section makes the model explicit, collects the guarantees in one statement, and says where adaptivity does break things.

Definition 21.3 (The k-fold adaptive composition experiment)**.** An adversary plays k rounds against a hidden bit $b \in \{0, 1\}$, fixed for the whole run (Dwork, Rothblum & Vadhan 2010). In round i it looks at the outputs $y_1, \dots, y_{i-1}$ so far and, as any function of them, chooses a pair of neighbouring datasets $D_i^0 \sim D_i^1$ and a mechanism M_i from a class of (ε, δ)-DP mechanisms; it then receives $y_i \sim M_i(D_i^b)$. Everything the adversary sees, its **view**, is the sequence $V = (y_1, \dots, y_k)$. A composition theorem holds for the experiment when, for every adversary, the distributions of the view under $b = 0$ and under $b = 1$ satisfy its guarantee in both directions.

The claim is that every bound of this chapter holds in the experiment.

Theorem 21.5 (Every composition bound holds under adaptive choice)**.** *In the experiment of Definition 21.3, with k, ε and δ fixed before the interaction starts, the views under $b = 0$ and $b = 1$ satisfy basic composition, $(k\varepsilon, k\delta)$-DP; advanced composition, $(\varepsilon', k\delta + \delta')$-DP with ε' from Equation 21.9 or Equation 21.17; and optimal composition, Equation 21.15.*

Proof. Every argument above looked at one step at a time, given the history so far, and once the history is fixed, so is the adversary's choice.

1. *The loss of the view is a sum.* Lemma 21.2 applies with each term $L_i(y_i \mid y_{<i})$ computed for the mechanism and the pair of datasets chosen after $y_{<i}$. Nothing in Lemma 21.1, Lemma 21.2 or Lemma 21.3 needs the pair to be the same in every round; each step only needs its own pair to be neighbours.
2. *Basic composition.* For $\delta = 0$, $|L_i| \le \varepsilon$ for every history, so $|L| \le k\varepsilon$ by Lemma 21.2. For $\delta > 0$, step 1 of the proof of Corollary 21.1 reduces the run to k independent four-point pairs: a flag shows with probability at most $k\delta$, and otherwise $|L| \le k\varepsilon$, so $\delta(k\varepsilon) \le k\delta$.
3. *Advanced composition.* Azuma's inequality needs only conditional statements, given the past: a conditional mean of zero and a range of fixed length. That is the setting of steps 2 to 5 of the proof of Theorem 21.1, and the $\delta > 0$ extension goes through the same reduction as step 2.
4. *Optimal composition.* Step 2 of the proof of Theorem 21.4 builds the adaptive run from the four-point product with history-dependent channels.

□

Adaptivity does not allow choosing the privacy parameters on the fly. If the analyst picks ε_i after seeing earlier outputs, the range length $c_i = 2\varepsilon_i$ in the proof of Theorem 21.1 depends on the history, and Azuma's inequality needs it fixed in advance. A rule such as "keep querying until the budget is spent" needs its own theorem, a **privacy filter** (Rogers, Roth, Ullman & Vadhan, 2016), and reporting the privacy spent so far at every moment needs a **privacy odometer**; both are treated in Adaptive composition. For pure DP with basic composition the naive rule is fine, because $|L| \le \sum_i \varepsilon_i$ holds pointwise whatever order the ε_i came in.

Nor does adaptivity allow choices that depend on the data rather than the outputs. A system that answers private counts *until the true count of some group crosses a threshold* reveals that count through the number of answers it gives, so every answer can be ε-DP and the whole run

still not be DP for any finite ε. A rule that stops early within a fixed k, looking only at the noisy answers, is covered, because the stopping time is then a post-processing of the outputs.

Example 21.5. The script simulates an analyst who, at each of the dashboard's $k = 100$ steps, chooses the next mechanism from the last output. If the previous output pointed to D, meaning its privacy loss was positive, the analyst asks a Laplace query at $\varepsilon = 0.1$; otherwise a randomized-response query at $\varepsilon = 0.1$. Over 100,000 simulated runs on D, Table 21.5 estimates $\delta(2)$ through Equation 21.3, by averaging $(1 - e^{2-L})_+$ over the simulated total losses L. The exact Laplace mean is 100 times the per-step KL divergence of two Laplace densities whose centres are ε scale units apart, $e^{-\varepsilon} + \varepsilon - 1$.

Table 21.5.: The privacy loss of 100 steps of 0.1-DP mechanisms, composed non-adaptively and by an adaptive analyst.

Composition of 100 steps at $\varepsilon = 0.1$	Mean total loss	$\delta(\varepsilon' = 2)$
Randomized response, exact (Equation 21.15)	0.4996	0.0201
Randomized response, simulated	—	0.0198
Laplace, simulated	0.4838 (exact 0.4837)	0.0189
Adaptive mix, simulated	0.4971	0.0196

The adaptive analyst's $\delta(2)$ lies between the two non-adaptive compositions, and below the optimal bound, as Theorem 21.5 requires. Figure 21.5 shows the whole curves: the three compositions nearly coincide, and the advanced-composition points lie far to the right of them.

21.6. Code

The script code/composition.py computes every number in this chapter and draws every figure. It checks the log-space optimal bound against brute-force enumeration, in floating point and in exact fractions, and compares simulated Laplace and adaptive compositions with it. From the repository root:

```
uv run python code/part03-dp-foundations/composition.py
```

Table 21.6.: The script's output with the default seed.

Experiment	Result
One step, $\varepsilon = 0.1$	$t = 0.5250$; mean loss $\varepsilon \tanh(\varepsilon/2) = 0.004996$; bound $\varepsilon(e^{\varepsilon} - 1) = 0.010517$

Experiment	Result
One step, $\varepsilon = 1$	tanh form 0.4621; $\varepsilon(e^{\varepsilon} - 1) = 1.7183$; $\varepsilon^2/2 = 0.5$; Laplace mean loss 0.3679
Three-output pair	Largest loss 0.9163; channel rows $(0.65, 0.3, 0.05)$ and $(0.05, 0.3, 0.65)$; KL 0.2749 against 0.5493; $\delta(0)$ 0.3 against 0.5
100 rounds of randomized response, $\varepsilon = 0.1$	Mean 0.4996; standard deviation 0.9988; $k\varepsilon$ is 9.5 standard deviations above the mean; $t^k = 1.033 \times 10^{-28}$
100 steps, $\varepsilon = 0.1$, $\delta' = 10^{-5}$	Basic 10; advanced 5.8502; advanced (tanh) 5.2981; optimal 4.3068
Exact δ at the advanced ε'	1.956×10^{-9} at 5.8502; 6.249×10^{-8} at 5.2981
Crossover	Advanced beats basic from $k = 29$
Brute-force checks of Equation 21.15	4,096 sequences at $\varepsilon = 0.5$, $\delta = 0$, $k = 12$ and at $\varepsilon = 0.3$, $\delta = 10^{-3}$, $k = 6$; 1,024 at $\varepsilon = 1$, $\delta = 0.01$, $k = 5$: largest difference 3.9×10^{-16}
Exact fractions, $\varepsilon = \ln 3$, $k = 8$	$\delta(0) = 1759/2048$, error 2.2×10^{-16}
Overflow, $\varepsilon = 1$, $k = 1{,}000$	The grid formula raises `OverflowError`; log space gives $\delta(550) = 6.094 \times 10^{-4}$
$\varepsilon = 0.01$, $k = 100{,}000$, $\delta' = 10^{-6}$	Optimal 19.4228; advanced (tanh) 21.6225, 11% above
Gaussian, $\sigma = 5$, $k = 100$, $\delta = 10^{-5}$	Basic 93.178; advanced 89.843; optimal 76.223; exact 9.997
Gaussian, $\sigma = 20$, $k = 1{,}000$, $\delta = 10^{-5}$	Basic 238.578; advanced 68.008; optimal 62.720; exact 7.511
Dense counts, $\varepsilon = 1$, $\delta = 10^{-5}$	Table 21.2; per-count ε_0 at $d = 1000$: 0.00645 (advanced), 0.00849 (optimal)

tests/test_composition.py checks that the output still matches.

21.7. Summary

Table 21.7.: The results of this chapter, and where each is used.

Result	Statement	Use
Definition 21.1	$L = \ln \frac{p(Y)}{q(Y)}$ with $Y \sim P$	The object every accountant of Privacy accounting composes
Lemma 21.1	$\delta(\varepsilon) = \mathbb{E}[(1 - e^{\varepsilon - L})_+] \leq \Pr[L > \varepsilon]$	The exact δ from the loss distribution; the tail bound is the cheap version
Lemma 21.2	$L = \sum_i L_i(y_i \mid y_{<i})$	Any sequence, adaptive or not; $\lvert L\rvert \leq k\varepsilon$ is basic composition

Result	Statement	Use
Proposition 21.1	$L = (k - 2J)\varepsilon$, $J \sim \mathrm{Bin}(k, 1-t)$	Mean about $k\varepsilon^2/2$, spread about $\sqrt{k}\,\varepsilon$; the worst case $k\varepsilon$ has probability t^k
Lemma 21.3	$\mathbb{E}[L] \le \varepsilon(e^\varepsilon - 1)$ for an ε-DP pair	The drift of advanced composition; a factor 2 loose for small ε
Theorem 21.1	$\varepsilon' = \varepsilon\sqrt{2k\ln(1/\delta')} + k\varepsilon(e^\varepsilon - 1)$ at slack δ'	Beats basic composition from $k = 29$ at $\varepsilon = 0.1$, $\delta' = 10^{-5}$; budget $\varepsilon_{\text{total}}/\sqrt{2k\ln(1/\delta')}$ per step
Theorem 21.2	Every (ε, δ)-DP pair is a post-processing of the four-point pair of Table 21.3	Reduces any question about the class to randomized response
Theorem 21.3	$\mathbb{E}[L] \le \varepsilon\tanh(\varepsilon/2) \le \min\{\varepsilon^2/2,\ \varepsilon(e^\varepsilon - 1)\}$	The sharp drift; the mean loss of Concentrated DP
Theorem 21.4	$\delta(\varepsilon') \le 1-(1-\delta)^k(1-\delta_{\mathrm{RR}}(\varepsilon'))$, tight for the class	Knowing only each (ε, δ), compute it exactly in log space; knowing the mechanism, compose its whole profile, since the point summary can be off by a factor of 8 (62.7 against 7.51)
Corollary 21.1	$(\varepsilon', k\delta + \delta')$-DP with Equation 21.9 or Equation 21.17	The per-step δ is spent outright; composed Laplace steps cost like $\sqrt{d}$, and the $\sqrt{d}$ comes from δ
Theorem 21.5	Every bound holds when each mechanism is chosen from the earlier outputs, with k, ε, δ fixed in advance	Adaptive privacy parameters, or stopping rules that read the raw data, need the filters of Adaptive composition

22. Selection: exponential mechanism, report-noisy-max, sparse vector

Many questions ask you to pick something rather than to compute a number, such as the best of 50 trained models or the first statistic to cross an alarm level. The answer is a name from a list, and adding noise to a name makes no sense. The Laplace mechanism of differential privacy (DP) could release a noisy score for every candidate. But if one record can move each of the $|\mathcal{R}|$ candidates' scores by 1, it moves the vector by $|\mathcal{R}|$ in the ℓ_1 norm, so the noise would grow with the number of candidates.

This chapter shows that you never have to pay for the losers. The one idea is to release the position, not the values. Each mechanism adds noise to scores that are never published and reports only which candidate came out on top. The privacy proof asks how far one record can move the bar that the chosen candidate must clear. That bar is a maximum over the other candidates, and a maximum of numbers that each move by at most some amount moves by at most that amount, however many there are. So the number of candidates never enters the privacy cost, and enters the accuracy only through its logarithm.

The **exponential mechanism** samples a candidate with probability exponential in its score. **Report-noisy-max** adds noise to every score and names the winner. The **sparse vector technique** reports the first query of a stream above a threshold. The running example is model selection. Fifty models are scored on a private validation set of 1,000 examples, and model r gets $900 - r$ right. A vote of six people checks the exponential mechanism by hand, and the sparse vector technique watches 1,000 counts for an alarm. Neighbours differ by adding or removing one record.

22.1. The exponential mechanism

You want to output a good candidate, where "good" is measured by a score that one record can move only a little. The natural private answer is a random candidate tilted toward high scores, and this section finds how much tilting a budget of ε allows.

A selection problem has a finite set $\mathcal{R}$ of candidates, fixed before the data are seen, and a **score function** $u(D, r)$ saying how good candidate r is on the dataset D. Its **sensitivity** is the largest change of any one score between two neighbours,

$$\Delta u = \max_{r \in \mathcal{R}} \max_{D \sim D'} \big| u(D, r) - u(D', r) \big|, \tag{22.1}$$

written Δ when the score is clear. McSherry and Talwar (2007) weighted each candidate exponentially in its score, at a rate that lets one record change every weight by at most $e^{\varepsilon/2}$. Section A.5 in the appendices derives the mechanism and its utility from scratch.

Definition 22.1 (The exponential mechanism)**.** For $\varepsilon > 0$, the **exponential mechanism** M_E outputs candidate r with probability proportional to $\exp\left(\varepsilon u(D, r)/(2\Delta)\right)$. The total weight $Z(D)$ is the **normalizer**:

$$\Pr[M_E(D) = r] = \frac{\exp\left(\frac{\varepsilon\, u(D,r)}{2\Delta}\right)}{Z(D)}, \qquad Z(D) = \sum_{s \in \mathcal{R}} \exp\Big(\frac{\varepsilon\, u(D, s)}{2\Delta}\Big). \tag{22.2}$$

The scores are **monotone** if, for every pair of neighbours, either every score goes up from D to D' or every score goes down.

Counts under add/remove are monotone, because adding a record can only raise each count. A candidate's probability is a weight divided by a total, and one record can change both, so the proof bounds each part. With monotone scores the two parts cannot both grow, which lets the 2 go.

Theorem 22.1 (Privacy of the exponential mechanism)**.** *The exponential mechanism is ε-DP. If the scores are monotone, the mechanism with weights $\exp\left(\varepsilon u(D, r)/\Delta\right)$, without the 2, is also ε-DP.*

Proof. The plan is to split the ratio of the probabilities of one candidate into its own weight and the normalizer, and bound each factor by sensitivity.

1. *Reduce to single outputs.* The output set is finite, so by Proposition 18.1 it is enough that every single output's probability changes by at most e^{ε} between neighbours. Fix $D \sim D'$ and a candidate r. Dividing the two probabilities of Equation 22.2 separates the two effects of one record:
$$\frac{\Pr[M_E(D) = r]}{\Pr[M_E(D') = r]} = \exp\Big(\frac{\varepsilon\big(u(D, r) - u(D', r)\big)}{2\Delta}\Big) \cdot \frac{Z(D')}{Z(D)}. \tag{22.3}$$
2. *The candidate's own weight.* By sensitivity, $u(D, r) - u(D', r) \le \Delta$, so the first factor is at most $e^{\varepsilon/2}$.
3. *The normalizer.* For every candidate s, sensitivity gives $u(D', s) \le u(D, s) + \Delta$, so each term of $Z(D')$ is at most $e^{\varepsilon/2}$ times the matching term of $Z(D)$. Adding the terms gives $Z(D') \le e^{\varepsilon/2} Z(D)$, and the product is at most e^{ε}.
4. *Monotone scores.* With weights $e^{\varepsilon u/\Delta}$, each factor alone could reach e^{ε}. If every score goes up from D to D', the first factor is at most 1 and the normalizer ratio at most e^{ε}, by step 3 with Δ for 2Δ. If every score goes down, the first factor is at most e^{ε} and the normalizer ratio at most 1. Either way the product is at most e^{ε}.

□

The 2 pays for two effects that can act together. One record can raise the score of r and lower its competitors', so r's weight grows while the normalizer shrinks. Exercise 1 in the exercise book builds neighbours on which the ratio approaches $e^{2\varepsilon}$ without the 2. The mechanism is a softmax of the scores with temperature $2\Delta/\varepsilon$, uniform as $\varepsilon \to 0$ and the argmax as $\varepsilon \to \infty$ (Figure 22.1).

The candidate set must not depend on the data, because the proof compares the same list on D and D'. It may be infinite, though. On a continuous range the sum becomes an integral against

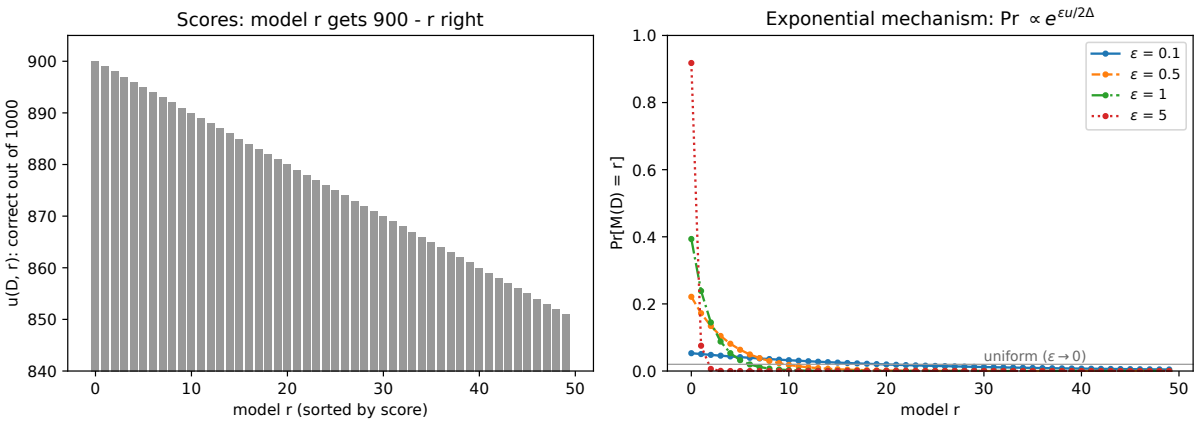

Figure 22.1.: Left: the scores of 50 models, model r getting $900 - r$ of 1,000 validation examples right. Right: the probability that the exponential mechanism selects each model, for four values of ε. Small ε spreads the probability toward uniform; large ε concentrates it on the best model.

a fixed base measure, such as length, and the two factors bound the ratio of densities at every point. Nothing else uses the structure of $\mathcal{R}$, so the candidates can be models, split points, strings or graphs.

Example 22.1. Six people vote among options A, B, C and X, with counts $(3, 2, 1, 0)$ on the dataset D. The neighbour D' has one more vote, for B, so $\Delta = 1$. With $\varepsilon = 1$ the weights are $e^{u/2}$, and Table 22.1 shows the output of the chapter's script (Section 22.8).

Table 22.1.: The exponential mechanism with $\varepsilon = 1$ on a vote and its neighbour with one extra vote for B.

Option	A	B	C	X
$\Pr[M_E(D) = r]$	0.4551	0.2760	0.1674	0.1015
$\Pr[M_E(D') = r]$	0.3859	0.3859	0.1420	0.0861
Ratio D/D'	1.1790	0.7151	1.1790	1.1790

The weights on D sum to $Z(D) = 9.8487$, and on D' the weight of B rises to $e^{1.5}$, so $Z(D') = 11.6121$. Only B's score changed, so for A, C and X the ratio is the normalizer ratio 1.1790, below its bound $e^{1/2} = 1.6487$. For B its own factor $e^{-1/2}$ multiplies that, giving 0.7151. The largest privacy loss is $|\ln 0.7151| = 0.3353$, a third of ε, because only one factor is at work for each option. Counts are monotone, so the weights e^u are also allowed, with largest privacy loss 0.6585.

22.2. Utility of the exponential mechanism

Privacy came for free in the number of candidates, but accuracy does not, because more candidates means more bad ones to pick by accident. This section bounds how far below the best score the

choice can fall. The idea is that a bad candidate weighs little next to the best one, whose weight is part of the normalizer.

Write $\mathrm{OPT}(D) = \max_r u(D, r)$ for the best score, and call the **gap** the difference between it and the score of the chosen candidate.

Theorem 22.2 (Utility of the exponential mechanism)**.** *For every dataset D and every $t > 0$,*

$$\Pr\left[u(D, M_E(D)) \le \mathrm{OPT}(D) - \frac{2\Delta}{\varepsilon}(\ln|\mathcal{R}| + t)\right] \le e^{-t}, \tag{22.4}$$

and the expected gap is at most $\frac{2\Delta}{\varepsilon}(\ln|\mathcal{R}| + 1)$. With monotone scores and weights $e^{\varepsilon u/\Delta}$, 2Δ can be replaced by Δ.

Proof. The plan is to bound the bad candidates' weight from above and the normalizer from below, solve for the gap, and integrate the tail. Write G for the gap. It is at least a exactly when the mechanism picks a candidate at least a below the best.

1. *Bad candidates are light.* The weight grows with the score, so each such candidate weighs at most $e^{\varepsilon(\mathrm{OPT}-a)/(2\Delta)}$.
2. *The normalizer is heavy.* It includes the weight of an optimal candidate, so $Z(D) \ge e^{\varepsilon\,\mathrm{OPT}/(2\Delta)}$.
3. *Divide.* There are at most $|\mathcal{R}|$ bad candidates, so dividing their total weight by the normalizer gives
$$\Pr[G \ge a] \le |\mathcal{R}|\, e^{-\varepsilon a/(2\Delta)}. \tag{22.5}$$
4. *Solve for the gap.* Setting the right side to e^{-t} and taking logarithms gives $a = \frac{2\Delta}{\varepsilon}(\ln|\mathcal{R}| + t)$, which is Equation 22.4.
5. *Expectation.* The mean of a non-negative quantity is the integral of its tail. Bound the tail by 1 up to $a_0 = \frac{2\Delta}{\varepsilon}\ln|\mathcal{R}|$, where step 3 reaches 1, and by step 3 beyond. The second piece is an exponential integral equal to $\frac{2\Delta}{\varepsilon}$, so $\mathbb{E}[G] \le a_0 + \frac{2\Delta}{\varepsilon}$. With monotone weights the same steps run with Δ for 2Δ.

□

Doubling the candidates adds only $\frac{2\Delta}{\varepsilon}\ln 2$ to the gap, and a lower bound shows that no ε-DP mechanism avoids the $\ln|\mathcal{R}|$. The proof counted every candidate as bad at the largest bad weight and kept one term of the normalizer. Both are nearly exact when one best candidate faces 49 runners-up all exactly a below it (Figure 22.2, right). At $\varepsilon = 1$ and $a = 20$ the bound is 0.0023 and the truth 0.0022.

When scores are spread out, most bad candidates sit far below the best and are much lighter than the bound assumes. Figure 22.2 (left) shows the bound orders of magnitude above the truth for the 50 models.

Example 22.2. Release the best of the 50 models. The score counts correct predictions, so one validation example changes each score by at most 1 and $\Delta = 1$. Table 22.2 shows the script's output.

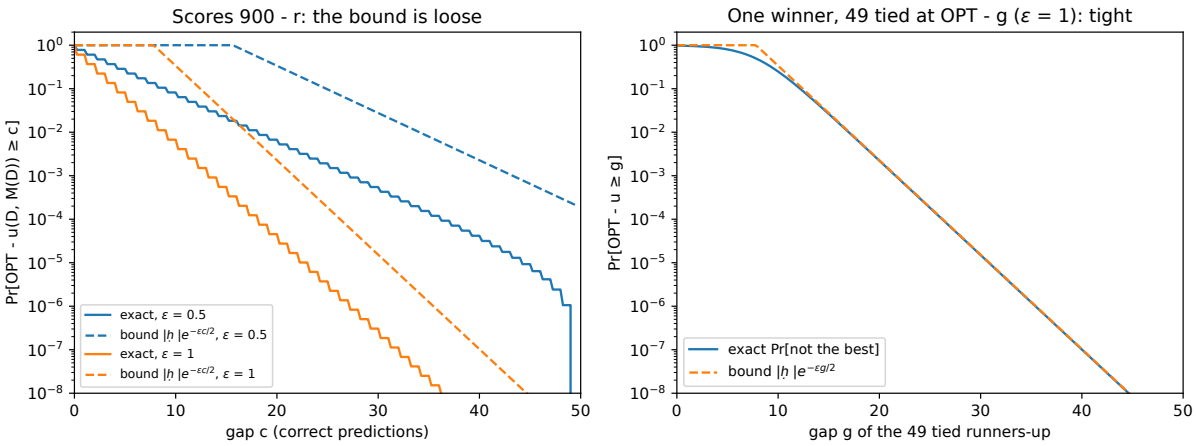

Figure 22.2.: Probability that the exponential mechanism's choice is at least a below the best score, exact against the bound $|\mathcal{R}|e^{-\varepsilon a/2\Delta}$. Left: the 50 models with scores $900 - r$, for $\varepsilon = 0.5$ and 1; the bound is loose because the scores are spread out. Right: one best model and 49 runners-up all the same distance below it, with $\varepsilon = 1$; the bound is tight.

Table 22.2.: The exponential mechanism selecting among 50 models with scores $900 - r$. The gap is in correct predictions out of 1,000.

ε	Pr[best]	$\mathbb{E}$[gap]	Bound $2(\ln 50 + 1)/\varepsilon$	$\mathbb{E}$[gap], monotone weights
0.1	0.0531	15.03	98.24	9.17
1	0.3935	1.54	9.82	0.58
5	0.9179	0.09	1.96	0.01

At $\varepsilon = 1$ you lose 1.54 correct predictions on average, although you pick the best model only 39% of the time, because the mechanism mostly picks a near-tie. The tail bound with $t = 3$ says the gap exceeds 13.82 with probability at most 0.0498, while the exact probability is 9.12×10^{-4}. The scores are monotone, since one more example can only add correct predictions, and the weights $e^{\varepsilon u}$ cut the expected gap at $\varepsilon = 1$ from 1.54 to 0.58.

22.3. Applications of the exponential mechanism

To use the exponential mechanism, you choose a fixed candidate set, a score and its sensitivity. This section makes those choices three times. The first recovers the Laplace mechanism and shows a second way to drop the 2. The second picks a classifier from a finite class, and the third finds a median over an interval, which private training in Part 5 uses to set its clipping norm.

22.3.1. The Laplace mechanism

Take a query f of sensitivity Δ, let every real number h be a candidate, and score it by $u(D,h) = -|f(D)-h|$. With length as the base measure, the density is proportional to $e^{-\varepsilon|f(D)-h|/(2\Delta)}$, a Laplace density of scale $2\Delta/\varepsilon$ centred at $f(D)$. Changing the data only slides it along the line, so the normalizer cannot change and cannot work against any candidate.

Proposition 22.1 (A data-independent normalizer allows the full rate)**.** *If $Z(D) = Z(D')$ for every pair of neighbours, the exponential mechanism with weights $e^{\varepsilon u(D,h)/\Delta}$ is ε-DP. For the score $-|f(D)-h|$ on the real line, the normalizer does not depend on the data, and the mechanism outputs $f(D) + \mathrm{Lap}(\Delta/\varepsilon)$.*

Proof.

1. *General claim.* When $Z(D) = Z(D')$, the ratio of the densities at h is the own factor of Theorem 22.1, now at most e^{ε}, and integrating bounds every event.
2. *Sensitivity.* By the triangle inequality, $\big||f(D)-h| - |f(D')-h|\big| \le |f(D)-f(D')| \le \Delta$.
3. *The normalizer.* Shifting the variable of integration by $f(D)$ removes the data:
$$Z(D) = \int_{-\infty}^{\infty} e^{-\varepsilon|f(D)-h|/\Delta}\,\mathrm{d}h = \int_{-\infty}^{\infty} e^{-\varepsilon|h|/\Delta}\,\mathrm{d}h = \frac{2\Delta}{\varepsilon}. \tag{22.6}$$
4. *It is the Laplace mechanism.* A density proportional to $e^{-\varepsilon|h-f(D)|/\Delta}$ is the $\mathrm{Lap}(\Delta/\varepsilon)$ density shifted to $f(D)$.

□

So monotone scores keep the two factors from both being large, and a data-independent normalizer makes the second one 1. A constant normalizer needs candidates that look the same after a shift and data that only shift the scores, which is why the Laplace mechanism needs only half the scale $2\Delta/\varepsilon$ of the exponential mechanism (Exercise 7 in the exercise book).

22.3.2. A private learner

A learning problem has a finite class $\mathcal{H}$ of classifiers and n labelled examples drawn independently from one unknown distribution. The **training error** $\mathrm{err}_D(h)$ is the fraction of training examples that h gets wrong, and the **population error** $\mathrm{err}(h)$ is its error probability on a fresh example. The learner of Kasiviswanathan, Lee, Nissim, Raskhodnikova and Smith (2008) is the exponential mechanism over $\mathcal{H}$ with score $-n\,\mathrm{err}_D(h)$, minus the number of mistakes. Its excess error over the best classifier has a sampling term, paid without privacy too, and a privacy term.

Theorem 22.3 (A private learner for a finite class)**.** *The learner is ε-DP. For a failure probability β, with probability at least $1-2\beta$ its choice $\hat{h}$ satisfies*

$$\mathrm{err}(\hat{h}) \le \min_{h\in\mathcal{H}} \mathrm{err}(h) + 2\sqrt{\frac{\ln(2|\mathcal{H}|/\beta)}{2n}} + \frac{2\ln(|\mathcal{H}|/\beta)}{\varepsilon n}. \tag{22.7}$$

Proof. The plan is to get privacy from Theorem 22.1, then chain two bounds: the choice is nearly the best on the training set, and training errors are close to population errors.

1. *Privacy.* One example changes every classifier's number of mistakes by at most 1, so $\Delta = 1$. This holds for any example, so privacy does not assume independence.
2. *Nearly the best on the training set.* Equation 22.4 with $t = \ln(1/\beta)$, divided by n, gives $\operatorname{err}_D(\hat{h}) \le \min_h \operatorname{err}_D(h) + c_E$ with $c_E = 2\ln(|\mathcal{H}|/\beta)/(\varepsilon n)$, with probability at least $1 - \beta$.
3. *Close to the population.* A training error is an average of n independent indicators, so Hoeffding's inequality (Concentration inequalities) bounds the chance that it strays by more than s by $2e^{-2ns^2}$. A union bound over the class and setting the total to β give $s = \sqrt{\ln(2|\mathcal{H}|/\beta)/(2n)}$ for all classifiers at once.
4. *Chain.* Let $h^\star$ have the smallest population error. On both events, step 3 moves to the training set, step 2 compares with $h^\star$, and step 3 moves back:

$$\operatorname{err}(\hat{h}) \le \operatorname{err}_D(\hat{h}) + s \le \operatorname{err}_D(h^\star) + c_E + s \le \operatorname{err}(h^\star) + c_E + 2s. \tag{22.8}$$

□

The sampling term falls like $1/\sqrt{n}$ and the privacy term like $1/n$, so for fine accuracy privacy costs little (Exercise 8 in the exercise book finds the records each needs). The class must be finite. Alon, Livni, Malliaris and Moran (2019) showed that thresholds at every real number cannot be learned privately in the probably approximately correct (PAC) sense.

22.3.3. A private median

Take records $x_1, \dots, x_n$ in an interval $[0, B]$ fixed before looking at the data, and score every point r by $-\big|\#\{i : x_i < r\} - \#\{i : x_i > r\}\big|$. The absolute value is the **imbalance** of r. Here the 2 stays, because a new record raises the scores on one side of the median and lowers them on the other. Assume no two records are equal, and write $x_{(1)} < \cdots < x_{(n)}$ for them in increasing order. They cut the interval into $n + 1$ **pieces**, with $x_{(0)} = 0$ and $x_{(n+1)} = B$ as end points. Write ℓ_j for the length of the piece from $x_{(j)}$ to $x_{(j+1)}$, and $\ell^\star$ for the total length of the best pieces.

Proposition 22.2 (The private median)**.** *Under add/remove the score has sensitivity 1, and the exponential mechanism with length as base measure is ε-DP. It picks piece j with probability proportional to $\ell_j e^{-\varepsilon|2j-n|/2}$, then a uniform point inside it. For even n and any $t > 0$, with probability at least $1 - e^{-t}$ its output r satisfies*

$$\big|\#\{i : x_i < r\} - \#\{i : x_i > r\}\big| \le \frac{2}{\varepsilon}\Big(\ln\frac{B}{\ell^\star} + t\Big). \tag{22.9}$$

For odd n the right side gains 1, because no point splits the data evenly.

Proof.

1. *Sensitivity.* One record changes the count below r or the count above it by 1, or neither, so the imbalance moves by at most 1. Theorem 22.1 gives privacy.
2. *Sampling.* Inside piece j, exactly j records lie below r and $n - j$ above, so the score is $-|2j - n|$ and the density is flat. The piece's probability is its length times its weight, over Z.

3. *Utility.* Repeat Theorem 22.2 with lengths for counts. The points at least a below the best have total length at most B, so they weigh at most $Be^{\varepsilon(\mathrm{OPT}-a)/2}$, while the best pieces weigh $\ell^\star e^{\varepsilon\,\mathrm{OPT}/2}$. Their ratio $(B/\ell^\star)e^{-\varepsilon a/2}$, set to e^{-t}, bounds the imbalance by the best imbalance plus $\frac{2}{\varepsilon}(\ln(B/\ell^\star)+t)$. The best imbalance is 0 for even n and 1 for odd n.

□

The range enters only through $\ln(B/\ell^\star)$, so a generous range is cheap, but it must be fixed without looking at the data, as a clamping range must be in Sensitivity. The guarantee controls the output's rank, not its value. For the quantile q, the score $-\big|(1-q)\#\{x_i < r\} - q\,\#\{x_i > r\}\big|$ works the same way.

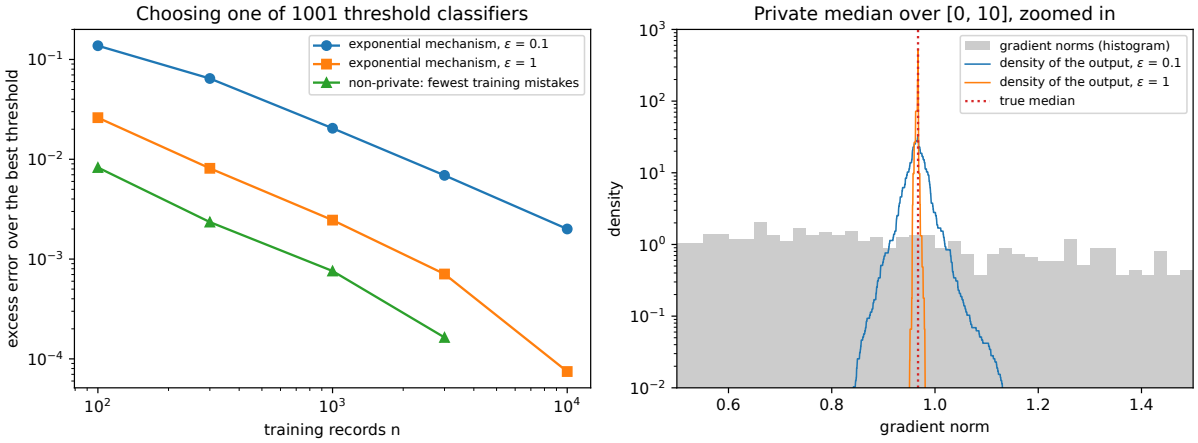

Figure 22.3.: Left: excess population error of the learner that picks one of 1,001 threshold classifiers with the exponential mechanism, against the non-private learner that picks the fewest training mistakes, averaged over 100 datasets per point (the text's numbers use 200); the non-private learner finds the best threshold exactly at $n = 10{,}000$, which a log axis cannot show. Right: 1,000 lognormal gradient norms (histogram) and the density of the private median over $[0, 10]$ for $\varepsilon = 0.1$ and $\varepsilon = 1$, zoomed in around the true median.

Example 22.3. *A threshold classifier.* The data are x uniform on $[0, 1]$, labelled 1 when $x \geq 0.3$, with each label flipped with probability 0.1. The class holds the 1,001 thresholds $0, 0.001, \ldots, 1$. Over 200 datasets of $n = 1{,}000$, the private learner's average excess error is 0.0024 at $\varepsilon = 1$ and 0.0206 at $\varepsilon = 0.1$, against 0.0008 without privacy (Figure 22.3, left). At $\beta = 0.05$, Equation 22.7 has a sampling term of 0.1456 and a privacy term of 0.0198, both far above the observed errors, because the union bound guards against all 1,001 classifiers at once.

A clipping norm. Take 1,000 gradient norms drawn from a lognormal distribution with median 1, capped at $B = 10$. Their median is 0.9804. At $\varepsilon = 1$ the private median is on average 0.0013 from it, and 0.0157 at $\varepsilon = 0.1$ (Figure 22.3, right). With $t = \ln 20$, Equation 22.9 allows an imbalance of 26.4 at $\varepsilon = 1$ and 264.5 at $\varepsilon = 0.1$.

22.4. Report-noisy-max

The obvious way to select privately is to add independent noise to every score and report only the index of the largest. This section proves that counts then need noise of scale $1/\varepsilon$, for any number of candidates, with the bar argument of the opening. Its three tools, used again for the sparse vector technique, come first as lemmas.

The proof looks at one candidate i and freezes the noise of all the others. The first lemma says that freezing is allowed when the frozen noise is drawn the same way on both datasets.

Lemma 22.1 (Fix the data-independent randomness)**.** *Let W be randomness inside a mechanism whose distribution does not depend on the data, and A an event. If $\Pr[A \mid D, W = w] \le e^{\varepsilon} \Pr[A \mid D', W = w]$ for every w, then $\Pr[A \mid D] \le e^{\varepsilon} \Pr[A \mid D']$.*

Proof. Both probabilities average the conditional ones (a sum, or an integral for continuous noise) with the same weights $\Pr[W = w]$, because W does not depend on the data. Bounding each term of the first average by e^{ε} times the matching term of the second bounds the averages. □

Once the other noise is frozen, candidate i wins when its own noise clears a bar built from a maximum over the others. The second lemma bounds how far one record moves that maximum.

Lemma 22.2 (A maximum moves no more than its terms)**.** *If $|v'_j - v_j| \le \Delta$ for every j, then $|\max_j v'_j - \max_j v_j| \le \Delta$, for any number of terms. If every $v'_j - v_j$ lies in $[0, \Delta]$, so does $\max_j v'_j - \max_j v_j$.*

Proof. Raising every term to its highest value gives $\max_j v'_j \le \max_j v_j + \Delta$, and swapping v and v' gives the other side. When every term moves up, the maximum cannot fall. □

The third lemma pays for the move. The Laplace density falls by $e^{-1/b}$ per unit of distance from 0, so sliding it by s changes its height anywhere by at most $e^{|s|/b}$.

Lemma 22.3 (Moving a Laplace threshold)**.** *For $Z \sim \mathrm{Lap}(b)$ and all real t and s,*

$$\Pr[Z > t - s] \le e^{|s|/b} \Pr[Z > t]. \tag{22.10}$$

Proof.

1. *Compare densities.* With $p(z) = \frac{1}{2b} e^{-|z|/b}$, the ratio $p(z-s)/p(z)$ is $e^{(|z|-|z-s|)/b}$. Two points s apart differ in distance from 0 by at most $|s|$, so $p(z-s) \le e^{|s|/b} p(z)$.
2. *Change variables.* Substituting $z \mapsto z - s$ writes $\Pr[Z > t - s]$ as $\int_t^{\infty} p(z-s)\,\mathrm{d}z$, which step 1 bounds by $e^{|s|/b} \Pr[Z > t]$.

□

With $b = s = 1$, the ratio of the two tails is 1.6321 at $t = 0$ and exactly $e = 2.7183$ at $t = 2$, where t and $t - s$ both lie above 0 and each tail is $\frac{1}{2} e^{-x/b}$.

Theorem 22.4 (Report-noisy-max)**.** ***Report-noisy-max*** *adds independent* $Z_r \sim \mathrm{Lap}(b)$ *to every score and outputs* $M_N(D) = \arg\max_r (u(D,r) + Z_r)$*. With* $b = 2\Delta/\varepsilon$ *it is* ε*-DP, and with monotone scores* $b = \Delta/\varepsilon$ *suffices (Dwork and Roth, Claim 3.9). With probability at least* $1-\beta$*, its gap is at most* $2b\ln(|\mathcal{R}|/\beta)$*.*

Proof. The plan is to freeze the other noise, write the output as one Laplace noise clearing a bar, bound how far the bar moves, and pay for the move.

1. *Freeze the others.* Fix $D \sim D'$, a candidate i and the noise z_{-i} of the others. By Lemma 22.1 it is enough to bound the conditional probability that i wins.
2. *A bar.* Candidate i wins on D exactly when $Z_i > t(D)$, with
$$t(D) = \max_{j \neq i} (u(D,j) + z_j) - u(D,i). \tag{22.11}$$
3. *The bar moves by at most* 2Δ. Each term $u(\cdot, j) + z_j$ moves by at most Δ, so the maximum does too by Lemma 22.2, however many terms it has. The score $u(\cdot, i)$ adds another Δ.
4. *Monotone scores.* If every score goes up by an amount in $[0, \Delta]$, then by Lemma 22.2 so does the maximum, and their difference lies in $[-\Delta, \Delta]$. The same holds when every score goes down.
5. *Pay.* Lemma 22.3 with $s = t(D) - t(D')$ gives a factor at most $e^{2\Delta/b} = e^{\varepsilon}$ in general and $e^{\Delta/b} = e^{\varepsilon}$ for monotone scores. Lemma 22.1 removes the conditioning, and Proposition 18.1 gives ε-DP.
6. *Accuracy.* By the accuracy bound of Theorem 20.1, a union bound over the candidates' Laplace tails, every $|Z_r|$ is below $x = b\ln(|\mathcal{R}|/\beta)$ with probability at least $1-\beta$. Then the winner's noisy score beat that of a best candidate, so $u(D,i) + x > \mathrm{OPT} - x$, and the gap is below $2x$.

□

Figure 22.4 draws steps 2 to 5 with $b = 1$ and a bar lowered from 0.7 by 1. The winning probability rises from 0.2483 to 0.6296, a ratio of 2.5357, below e because the lowered bar left the tail where Lemma 22.3 is exact.

The losers enter only through one maximum in step 3, which is why they cost nothing. The 2 is needed in general because competitors can rise while i falls. A histogram under replace neighbours, where one record is swapped for another, does exactly that, so it is not monotone.

Release only the index, because the winning noisy score would publish Z_i, the noise the proof averages over. Neither Laplace report-noisy-max nor the exponential mechanism always selects better (Exercise 6 in the exercise book).

Example 22.4. On the vote of Table 22.1 the counts are monotone, so $b = 1$ is allowed at $\varepsilon = 1$. The script's exact winning probabilities give a largest privacy loss of 0.6674, and 0.3626 with $b = 2$. On the 50 models at $\varepsilon = 1$, the general mechanism ($b = 2$) picks the best with probability 0.4241, against 0.3935 for the exponential mechanism, and has expected gap 1.40 against 1.54. The monotone one ($b = 1$) has expected gap 0.54. The accuracy bound at $\beta = 0.05$, 27.63 for $b = 2$, is loose for spread-out scores.

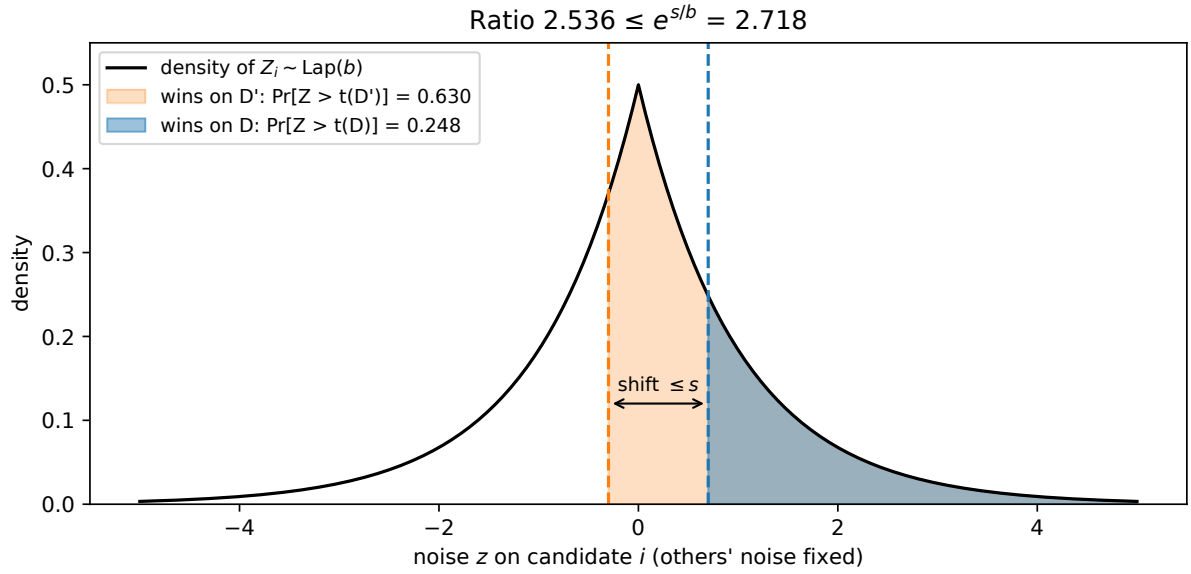

Figure 22.4.: The proof of report-noisy-max in one picture. With the other candidates' noise fixed, candidate i wins when its own noise $Z_i \sim \mathrm{Lap}(1)$ exceeds a bar t. Moving to a neighbouring dataset moves the bar by at most s, and the winning probability changes by at most a factor $e^{s/b}$.

22.5. Gumbel noise: report-noisy-max is the exponential mechanism

Report-noisy-max with Laplace noise is close to the exponential mechanism but not equal to it. This section shows that Gumbel noise makes the noisy argmax give exactly the probabilities of Equation 22.2. This is the **Gumbel-max trick**. The **Gumbel distribution** with scale κ, Gumbel(κ), has cumulative distribution function (CDF) $\Pr[G \le g] = \exp(-e^{-g/\kappa})$, and NumPy's `rng.gumbel(0, kappa)` samples it.

Theorem 22.5 (The Gumbel-max trick)**.** *For scores u_r and independent $G_r \sim \mathrm{Gumbel}(\kappa)$,*

$$\Pr\left[\arg\max_r \left(u_r + G_r\right) = i\right] = \frac{e^{u_i/\kappa}}{\sum_r e^{u_r/\kappa}}. \tag{22.12}$$

With $\kappa = 2\Delta/\varepsilon$ this is the exponential mechanism.

Proof. Conditioning on the winner's noise lets you multiply the chances that each other candidate falls short, and the integral can then be done exactly. Dividing everything by κ keeps the argmax, so take $\kappa = 1$, with CDF $H(g) = \exp(-e^{-g})$ and density $H'(g) = e^{-g}H(g)$.

1. *Condition.* If $G_i = g$, candidate i wins when every other $G_j < g + u_i - u_j$. These events are independent, so
$$\Pr[i \text{ wins}] = \int_{-\infty}^{\infty} H'(g) \prod_{j \ne i} H(g + u_i - u_j)\,\mathrm{d}g. \tag{22.13}$$

2. *Collect.* Each factor is $\exp(-e^{-g}e^{u_j-u_i})$, and the $H(g)$ inside $H'(g)$ is the factor for $j=i$. The product is $\exp(-e^{-g}A)$, with $A=e^{-u_i}\sum_j e^{u_j}$.
3. *Substitute* $w=e^{-g}$. The factor e^{-g} and $\mathrm{d}g$ together are $-\mathrm{d}w$, and the minus sign flips the limits, so

$$\Pr[i \text{ wins}] = \int_0^\infty e^{-wA}\,\mathrm{d}w = \frac{1}{A} = \frac{e^{u_i}}{\sum_j e^{u_j}}. \tag{22.14}$$

□

So the Gumbel noisy max inherits the privacy of Theorem 22.1. It works in score units, while $e^{\varepsilon u/(2\Delta)}$ overflows for scores in the thousands. Taking the c largest of u_r+G_r at once has the distribution of c exponential mechanisms run in turn without replacement, at $c\varepsilon$ (Durfee and Rogers 2019; Section J.6 derives it).

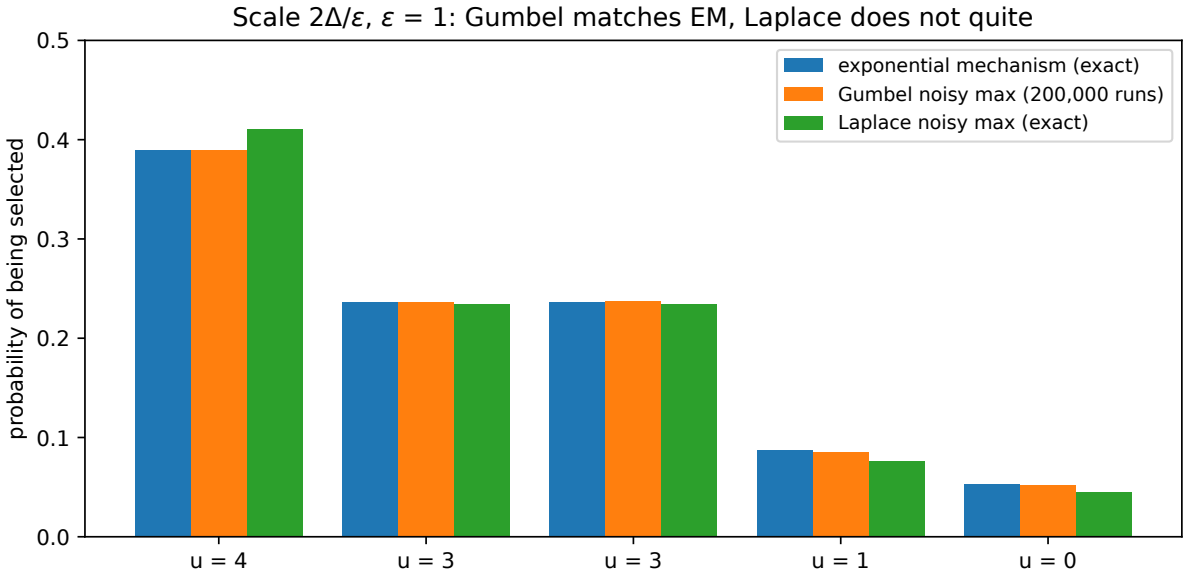

Figure 22.5.: Selection probabilities for five candidates with scores $(4,3,3,1,0)$ and noise scale $2\Delta/\varepsilon$ with $\varepsilon=1$: the exponential mechanism's exact probabilities, the frequencies of the Gumbel noisy max in 200,000 runs, and the exact probabilities of the Laplace noisy max.

Example 22.5. Take five candidates with scores $(4,3,3,1,0)$ and noise scale 2, which is $\varepsilon=1$ and $\Delta=1$. Table 22.3 and Figure 22.5 compare the three mechanisms.

Table 22.3.: Selection probabilities with noise scale 2 for five candidates.

Candidate score	4	3	3	1	0
Exponential mechanism, exact	0.3889	0.2359	0.2359	0.0868	0.0526
Gumbel noisy max, 10^6 runs	0.3891	0.2351	0.2362	0.0871	0.0525
Laplace noisy max, exact	0.4105	0.2341	0.2341	0.0764	0.0449

The Gumbel frequencies are within 0.0008 of the exponential mechanism, about the sampling error of a million draws. The Laplace noisy max is at total variation distance 0.0216, the extra probability it puts on the top candidate.

22.6. The sparse vector technique

Now the queries arrive one at a time, and you care only about the first one above a threshold, such as the first statistic to cross an alarm level. Answering each with the Laplace mechanism would cost ε per query. Report-noisy-max needs the whole list in advance, but here each query must be answered before the next is seen. The **sparse vector technique** (Dwork, Naor, Reingold, Rothblum and Vadhan 2009) compares each query with one noisy threshold and pays only for the one above it. Its basic form is Algorithm 1 of Dwork and Roth (2014).

Definition 22.2 (AboveThreshold)**.** The input is a dataset D, a stream of k queries f_i of sensitivity Δ, possibly adaptive, a threshold τ and budgets $\varepsilon_1, \varepsilon_2 > 0$. Draw $\rho \sim \mathrm{Lap}(\Delta/\varepsilon_1)$ once. For each query, draw fresh $\nu_i \sim \mathrm{Lap}(2\Delta/\varepsilon_2)$. If $f_i(D) + \nu_i \geq \tau + \rho$, output $\top$ (“above”) and halt; otherwise output $\bot$ (“below”). The output $\bot^{j-1}\top$ stops at query j.

The output “stop at query j” says that the noisy threshold is above every earlier noisy answer and at or below the j-th. The proof slides ρ by however much the largest earlier answer moved, which costs at most Δ by Lemma 22.2, and slides ν_j to keep query j in place, which costs at most 2Δ.

Theorem 22.6 (AboveThreshold)**.** *AboveThreshold is $(\varepsilon_1 + \varepsilon_2)$-DP for any number of queries (Dwork and Roth, Theorem 3.23; Lyu, Su and Li 2017). For monotone queries, which all move the same way between neighbours as counts under add/remove do, $\nu_i \sim \mathrm{Lap}(\Delta/\varepsilon_2)$ suffices. With $\varepsilon_1 = \varepsilon_2 = \varepsilon/2$ and k fixed before the run, with probability at least $1 - \beta$ every $\bot$ query has $f_i(D) < \tau + \alpha$ and the $\top$ query has $f_j(D) > \tau - \alpha$, where*

$$\alpha = \frac{8\Delta(\ln k + \ln(2/\beta))}{\varepsilon}. \tag{22.15}$$

Proof. The plan is to freeze the earlier noise, write the output as two conditions on (ρ, ν_j), shift both noises to turn the conditions for D into those for D', and pay with the Laplace density; accuracy then comes from Laplace tails. Fix $D \sim D'$ and write $g(D) = \max_{i<j} (f_i(D) + \nu_i)$.

1. *Freeze.* Fix $\nu_1, \dots, \nu_{j-1}$, which do not depend on the data, and use Lemma 22.1. Adaptive queries are then fixed too, since they depend only on earlier answers, all $\perp$.
2. *Two conditions.* The earlier queries say $\perp$ exactly when $g(D) < \tau + \rho$, and query j says $\top$ when $f_j(D) + \nu_j \geq \tau + \rho$. With noise densities p_ρ and p_ν, the output has probability
$$\iint p_\rho(\rho)\, p_\nu(\nu)\, \mathbf{1}[g(D) < \tau + \rho]\, \mathbf{1}[f_j(D) + \nu \geq \tau + \rho]\, \mathrm{d}\rho\, \mathrm{d}\nu. \tag{22.16}$$
3. *Shift both noises.* Substitute $\rho = \rho' + g(D) - g(D')$ and $\nu = \nu' + (g(D) - g(D')) - (f_j(D) - f_j(D'))$. After cancelling, the indicators are those for D', and a translation leaves $\mathrm{d}\rho\, \mathrm{d}\nu$ unchanged, so only the densities are evaluated at shifted points.
4. *Size of the shifts.* Each term of g moves by at most Δ, so $|g(D) - g(D')| \leq \Delta$ by Lemma 22.2, whatever j is. The shift of ν is a difference of two such terms, at most 2Δ.
5. *Pay.* By step 1 of the proof of Lemma 22.3, a Laplace density of scale b changes by at most $e^{|x|/b}$ when its argument moves by x. That is e^{ε_1} for ρ and e^{ε_2} for ν. The output $\perp^k$ has only the first indicator and costs e^{ε_1}. Lemma 22.1 and Proposition 18.1 conclude.
6. *Monotone queries.* If all queries move the same way, g and f_j move the same way by Lemma 22.2, so the shift of ν is at most Δ.
7. *Accuracy.* With the equal split, the Laplace tail of Theorem 20.1 gives $\Pr[|\rho| \geq \alpha/2] = e^{-\alpha\varepsilon/(4\Delta)}$, and a union bound over the k query noises gives $k\, e^{-\alpha\varepsilon/(8\Delta)}$. Setting the second to $\beta/2$ gives Equation 22.15, and the first is then smaller. The union bound needs k fixed in advance, because the index where the run stops depends on the noise.
8. *Read off.* If all noises are below $\alpha/2$, a $\perp$ means $f_i < \tau + \rho - \nu_i < \tau + \alpha$, and the $\top$ means $f_j \geq \tau + \rho - \nu_j > \tau - \alpha$.

□

To find c queries above the threshold, the algorithm Sparse of Dwork and Roth restarts AboveThreshold with fresh threshold noise after each $\top$ and halts after the c-th. Each run gets a share of the budget and of the failure probability.

Corollary 22.1 (Sparse: c answers above)**.** *With c runs at budget ε/c each, Sparse is ε-DP, and with probability $1 - \beta$ all its answers are accurate to within*
$$\alpha_c = \frac{8c\Delta(\ln k + \ln(2c/\beta))}{\varepsilon}. \tag{22.17}$$
With runs at the largest ε_0 whose c-fold advanced composition (Advanced and optimal composition) is at most ε at slack δ, it is (ε, δ)-DP, with margin Equation 22.15 at ε_0 and β/c.

Proof.

1. *Privacy.* The runs form an adaptive composition of c AboveThresholds, so basic composition at ε/c gives ε, and advanced composition at ε_0 gives (ε, δ).
2. *Accuracy.* Apply Theorem 22.6 to each run at its budget and failure probability β/c, and take a union bound over the runs.

□

The advanced margin grows like $\sqrt{c}$ instead of c, and Exercise 9 in the exercise book finds where it starts to win.

The $\perp$ answers are free because step 4 pays for all of them through one maximum, whether there are 3 or 3 million. The run must halt because that payment covers one $\top$, and each further $\top$ against the same ρ needs its own shift. Query noise $\mathrm{Lap}(2c\Delta/\varepsilon_2)$ pays for c shifts at once (Section J.5). The split of ε matters only for accuracy (Exercise 4 in the exercise book). The proof is tight in the limit. On the pair of $2m$ queries built in Section 22.7, the largest privacy loss is 0.994011, 0.999981 and 1.000000 at $m = 10$, 20 and 40. Figure 22.6 shows one run.

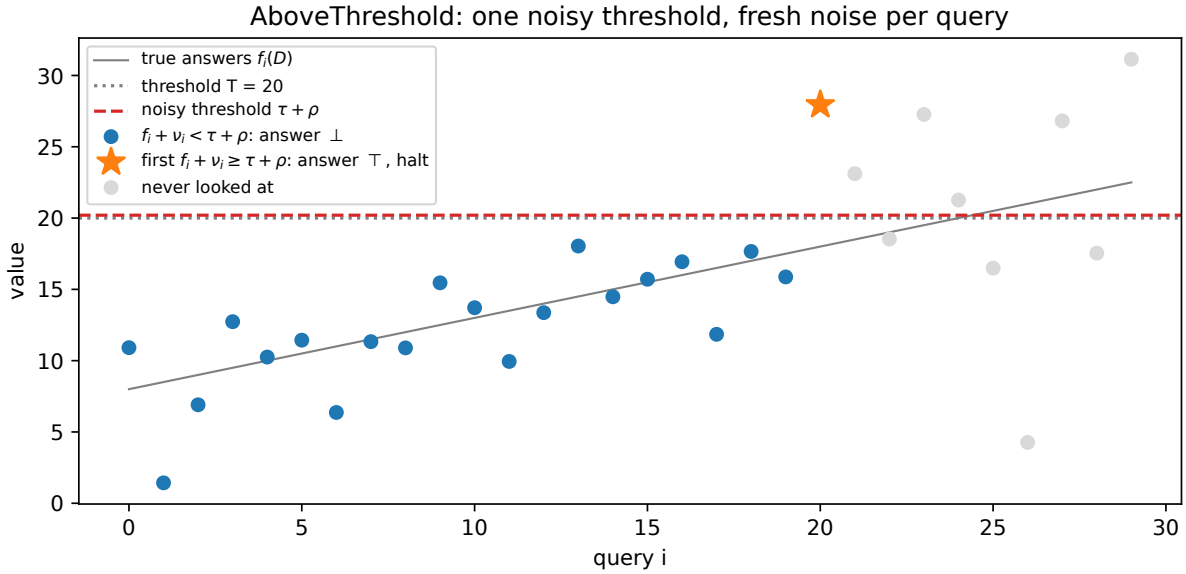

Figure 22.6.: One run of AboveThreshold with $\varepsilon = 1$ on 30 queries whose true answers rise from 8 to 22.5, with threshold $\tau = 20$. Each query's noisy answer is compared with the same noisy threshold. The first one above it is reported and the run halts; later queries are never looked at.

Example 22.6. You monitor $k = 1000$ counts ($\Delta = 1$) with threshold $\tau = 500$ at $\varepsilon = 1$. With $\beta = 0.05$, Equation 22.15 gives $\alpha = 8(\ln 1000 + \ln 40) = 84.77$. In the script's stream every count is 400, below $500 - \alpha$, except query 700, at 600, above $500 + \alpha$. So with probability at least 0.95 the output is query 700. In 10,000 simulated runs it always was, and the margin the noises needed had a 95% quantile of 78.59, so the union bound is nearly tight. For the first c alarms, Equation 22.17 gives a margin of 1,032 at $c = 10$. Advanced composition at $\delta = 10^{-6}$ gives the worse 1,746 there, and wins only at $c = 100$, with 6,506 against 12,161.

22.7. When the sparse vector technique goes wrong

The sparse vector technique is easy to break. Lyu, Su and Li (2017) found several published variants, each a harmless-looking optimization of AboveThreshold, that were not private at all

(Table 22.4). Each removes an ingredient that one step of the proof of Theorem 22.6 needs, and finding that step is how to review an implementation.

Table 22.4.: Variants of the sparse vector technique and their actual privacy, from Lyu, Su & Li (2017).

Variant (as numbered by Lyu, Su & Li)	What it changes	Privacy shown by Lyu, Su & Li
Algorithm 1 (theirs); Algorithm 2 (Dwork & Roth)	Correct, with c answers above	ε
Algorithm 3 (Roth's 2011 lecture notes)	Outputs the noisy value $f_i + \nu_i$ for each $\top$	∞
Algorithm 4 (Lee & Clifton 2014)	Query noise does not grow with c	$\frac{1+6c}{4}\varepsilon$
Algorithm 5 (Stoddard et al. 2014)	No noise on the queries	∞
Algorithm 6 (Chen et al. 2015)	Never halts	∞

The **no-halt variant** keeps the noise of AboveThreshold at the equal split but answers every query. One pair of neighbours and one output with too large a ratio suffice to break it. The pair below makes each answer of $\perp^m\top^m$ a little more likely under D, and without a halt the $2m$ factors multiply. Take $\Delta = 1$ and

$$f(D) = (\underbrace{0,\dots,0}_{m},\underbrace{1,\dots,1}_{m}), \qquad f(D') = (\underbrace{1,\dots,1}_{m},\underbrace{0,\dots,0}_{m}). \tag{22.18}$$

Proposition 22.3 (Without the halt, the loss is unbounded)**.** *On this pair, the no-halt variant has*

$$\ln \frac{\Pr[\perp^m\top^m \mid D]}{\Pr[\perp^m\top^m \mid D']} \geq \frac{m\varepsilon}{4}, \tag{22.19}$$

so it is not ε'-DP for any ε'.

Proof. Once the shared threshold is fixed the answers are independent, so the plan is to fix it, multiply, bound the ratio at every threshold, and average. Let $b = 4/\varepsilon$ be the query-noise scale $2\Delta/\varepsilon_2$ at the equal split, F its Laplace CDF and $\bar{F} = 1 - F$.

1. *Fix the threshold.* Given $\tau + \rho = t$, a query of value f says $\perp$ with probability $F(t - f)$ and $\top$ with probability $\bar{F}(t - f)$.
2. *Multiply.* Under D the output needs m zeros below and m ones above, and under D' the values swap:

$$a_D(t) = F(t)^m\,\bar{F}(t-1)^m, \qquad a_{D'}(t) = F(t-1)^m\,\bar{F}(t)^m. \tag{22.20}$$

3. *A power.* Their ratio is $\omega(t)^m$, with $\omega(t) = \frac{F(t)}{F(t-1)} \cdot \frac{\bar{F}(t-1)}{\bar{F}(t)}$, and both factors are at least 1.
4. *Bound ω.* The CDF is $\frac{1}{2}e^{x/b}$ for $x \leq 0$ and the survival function $\frac{1}{2}e^{-x/b}$ for $x \geq 0$. So the first factor is $e^{1/b}$ when $t \leq 0$, and the second is $e^{1/b}$ when $t \geq 1$. For $0 < t < 1$, $F(t) \geq \frac{1}{2}$ makes the first factor at least $e^{(1-t)/b}$, and likewise the second is at least $e^{t/b}$. So $\omega(t) \geq e^{1/b}$ at every threshold.

5. *Average.* The threshold has the same distribution under both datasets, so averaging $a_D \geq e^{m/b} a_{D'}$ gives Equation 22.19. The pair exists for every m, so the loss is unbounded.

□

AboveThreshold's proof fails here because each $\top$ after the first needs its own shift, and the halt is what limits them to one. Without query noise (Algorithm 5), even the halting version fails, because two queries can give an output that is impossible on D' (Exercise 5 in the exercise book). Publishing $f_j + \nu_j$ (Algorithm 3) releases the noise the proof integrates over. The no-halt variant adds as much noise per query as AboveThreshold, so a reviewer who checks only noise scales will not find the bug. An audit will find it. Under ε-DP every test, a rule that says "D" or "D'" from the output, fires at most e^{ε} times as often under D as under D', by the definition, and a simple sign test breaks that (Figure 22.7, right).

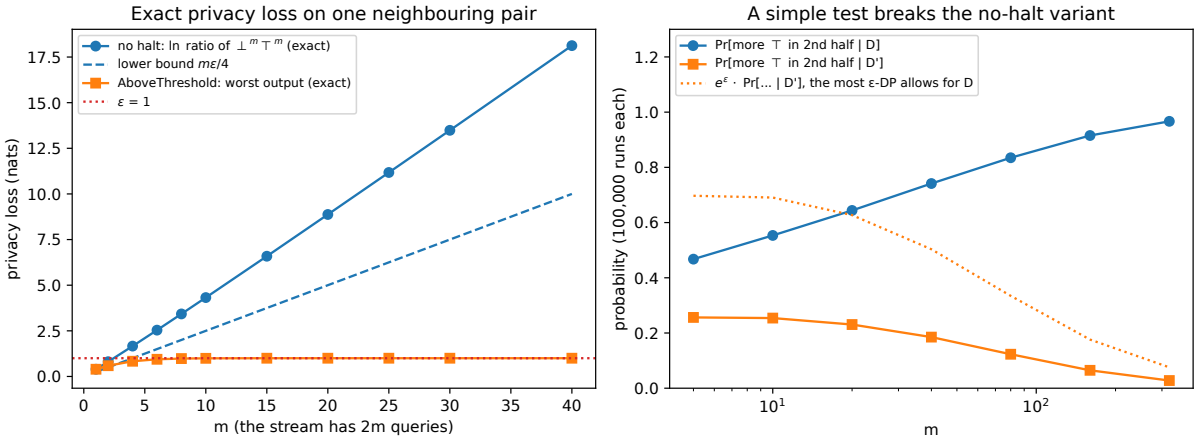

Figure 22.7.: Left: privacy loss on the neighbouring pair $f(D) = (0^m, 1^m)$, $f(D') = (1^m, 0^m)$ with $\varepsilon = 1$, computed exactly by integrating over the threshold noise. For the no-halt variant, the loss of the output $\perp^m\top^m$ grows linearly in m, above the lower bound $m\varepsilon/4$. For AboveThreshold, the largest loss over all outputs levels off at ε. Right: the no-halt variant under a simple test, the probability that the second half has more $\top$ answers than the first. Once the probability under D exceeds e^{ε} times the probability under D' (dotted), no ε-DP mechanism could produce it.

Example 22.7. Table 22.5 gives the script's exact values for $\varepsilon = 1$ and $\tau = 0$: the largest loss over all outputs for AboveThreshold, and the loss of $\perp^m\top^m$ for the no-halt variant.

Table 22.5.: Exact privacy loss of AboveThreshold and of its no-halt variant on the counterexample, with $\varepsilon = 1$.

m	1	5	10	20	40
AboveThreshold, largest loss over outputs	0.3958	0.8998	0.9940	1.0000	1.0000
No halt, loss of $\bot^m\top^m$	0.3958	2.0985	4.3220	8.8741	18.1246
Lower bound $m\varepsilon/4$	0.25	1.25	2.50	5.00	10.00

At $m = 1$ the two coincide, because AboveThreshold halts after the $\top$ anyway. Then the no-halt loss grows by about 0.45 nats (units of natural logarithm) per pair of queries. The lower bound is loose by a factor of a little under 2, because step 4 bounded ω at its smallest. The sign test asks whether the second half has more $\top$ answers. Its log-ratio is 0.77 at $m = 10$ and 1.40 at $m = 40$, so from $m = 40$ on it alone proves that the variant is not 1-DP.

22.8. Code

The script code/selection.py computes every number in this chapter and draws every figure. Exponential-mechanism probabilities are exact sums, the noisy max and the sparse vector technique are integrated on a grid over one noise variable, and simulations check the integrals. From the repository root:

```
uv run python code/part03-dp-foundations/selection.py
```

Table 22.6.: The script's output with the default seed.

Experiment	Result
Laplace threshold shift, $b = s = 1$	Ratio 1.6321 at $t = 0$, 2.5357 at $t = 0.7$, 2.7183 at $t = 1$ and $t = 2$
Exponential mechanism on the vote, $\varepsilon = 1$	Table 22.1; normalizer ratio 1.1790; largest loss 0.3353 (monotone weights: 0.6585)
Exponential mechanism on 50 models	Table 22.2; $\Pr[\text{gap} \geq 13.82] = 9.12 \times 10^{-4}$ against $e^{-3} = 0.0498$; tied profile at gap 20: 0.0022 against 0.0023
Laplace report-noisy-max, 50 models, $\varepsilon = 1$	$b = 2$: Pr[best] 0.4241, expected gap 1.40 (simulated 1.39). $b = 1$: 0.6463 and 0.54
Laplace report-noisy-max on the vote, $b = 1$	Largest loss 0.6674 ($b = 2$: 0.3626)

Experiment	Result
Gumbel-max, five candidates	Within 0.0008 of the exponential mechanism over 10^6 runs; Laplace at total variation 0.0216
AboveThreshold, $k = 1000$, $\beta = 0.05$	$\alpha = 84.77$; simulated 95% quantile 78.59; alarm stream correct in 10,000 of 10,000 runs
AboveThreshold against no halt	Table 22.5; sign test log-ratios 0.77, 1.40, 2.63 at $m = 10, 40, 160$
Sparse, $k = 1000$, $\beta = 0.05$	Margin 1,032 ($c = 10$) and 12,161 ($c = 100$); with advanced composition at $\delta = 10^{-6}$, 1,746 and 6,506
Threshold learner, $n = 1000$	Excess error 0.0024 ($\varepsilon = 1$), 0.0206 ($\varepsilon = 0.1$), 0.0008 non-private; records for $\alpha = 0.05$: 33,913 (sampling), 793 (privacy at $\varepsilon = 1$)
Private median of 1,000 gradient norms	Median 0.9804; mean distance 0.0013 ($\varepsilon = 1$) and 0.0157 ($\varepsilon = 0.1$); imbalance bound 26.4 and 264.5

tests/test_selection.py checks that the output still matches.

22.9. Summary

Table 22.7.: The results of this chapter, and where each is used.

Result	Statement	Use
Theorem 22.1	Pick r with probability $\propto e^{\varepsilon u(D,r)/(2\Delta)}$; ε-DP, and $e^{\varepsilon u/\Delta}$ for monotone scores	Model selection; private multiplicative weights; fix the candidates first
Theorem 22.2	Gap $\leq \frac{2\Delta}{\varepsilon}(\ln\lvert\mathcal{R}\rvert + t)$ w.p. $1 - e^{-t}$	Candidates cost $\ln\lvert\mathcal{R}\rvert$ in accuracy, nothing in privacy
Proposition 22.1	A data-independent normalizer allows $e^{\varepsilon u/\Delta}$	Why the Laplace mechanism needs no factor 2
Theorem 22.3	Excess error $\leq 2\sqrt{\ln(2\lvert\mathcal{H}\rvert/\beta)/(2n)} + 2\ln(\lvert\mathcal{H}\rvert/\beta)/(\varepsilon n)$	A finite class from $O(\ln\lvert\mathcal{H}\rvert)$ records
Proposition 22.2	Piece j w.p. $\propto \ell_j e^{-\varepsilon\lvert 2j-n\rvert/2}$; imbalance $\leq \frac{2}{\varepsilon}(\ln(B/\ell^\star) + t)$	A private clipping norm or quantile; fix the range first
Lemma 22.1, Lemma 22.2, Lemma 22.3	Freeze data-independent noise; a maximum moves by at most Δ; a shifted Laplace tail changes by at most $e^{\lvert s\rvert/b}$	Every noisy-max proof

Result	Statement	Use
Theorem 22.4	$\arg\max_r(u + \mathrm{Lap}(2\Delta/\varepsilon))$ is ε-DP; $\mathrm{Lap}(\Delta/\varepsilon)$ for monotone scores	Vote counts in private prediction; release the index only
Theorem 22.5	A Gumbel noisy max is the exponential mechanism	Stable sampling; top-c at $c\varepsilon$
Theorem 22.6	AboveThreshold is $(\varepsilon_1 + \varepsilon_2)$-DP for any number of $\perp$; margin Equation 22.15	Monitoring; the reusable holdout of adaptive data analysis
Corollary 22.1	c runs: margin Equation 22.17, or $\sqrt{c}$ growth with advanced composition	Advanced composition once $c \gg 2\ln(1/\delta)$
Proposition 22.3	Without the halt the loss grows like $m\varepsilon/4$	Draw fresh query noise, keep one threshold per run, halt, never publish noisy values

23. Query release and private multiplicative weights

Many private releases are a large batch of simple statistics: every cross-tabulation of a census file, or the hundreds of counts on a dashboard. Each is a **linear query**, the average over the records of a function that gives each record a value between 0 and 1. Adding noise to every answer makes the noise grow with the number of queries, in proportion to it under pure differential privacy (DP) and like its square root under approximate DP (The Laplace and Gaussian mechanisms). With millions of queries, either is useless. Yet the reconstruction attack breaks privacy only when the answers are within about $1/\sqrt{n}$ of the truth, for n records. This chapter fills the gap with an error that grows only with the logarithms of the number of queries and of the number of possible records.

The one idea is to learn the data from its mistakes. Keep a public guess of the data, a histogram that starts out uniform, find a query that the guess gets badly wrong, measure that one query privately, and nudge the guess toward the answer. Each nudge is a step of the **multiplicative weights** method from online learning, and its guarantee says that about $\ln N/\alpha^2$ nudges suffice for error α on every query, where N is the number of possible records. The number of queries does not appear, so the privacy budget is spent on corrections instead of on queries, and the final guess can be published as a **synthetic dataset**.

The running example is a table of $n = 10{,}000$ records with eight yes/no attributes, drawn from a mixture of three groups, so there are $N = 2^8 = 256$ possible records. The queries are every cell of every marginal table: for each set of attributes and each combination of their values, the fraction of records with those values. That gives $2^8 - 1 = 255$ tables, and a cell fixes each attribute to 0 or 1 or leaves it out, which gives $3^8 - 1 = 6560$ cells. The uniform histogram, which uses no data, has a largest error of 0.232 over these queries.

23.1. Linear queries as inner products

Every algorithm in this chapter treats a dataset as a histogram and a query as a vector, so that answering a query is an inner product. This section fixes that view first, because it lets a guessed histogram answer every query.

Definition 23.1 (Universe, histogram and linear query)**.** The **universe** $\mathcal{X}$ is the set of all possible records, and $N = |\mathcal{X}|$ is its size. A dataset $D = (x_1, \dots, x_n)$ holds n records from the universe. Its **histogram** p gives, for each element x of the universe, the fraction $p(x)$ of the records that equal x. A **linear query** is a function $q\colon \mathcal{X} \to [0,1]$, and its answer on D is the average of its values over the records,

$$q(D) = \frac{1}{n}\sum_{i=1}^{n} q(x_i). \tag{23.1}$$

The set of queries to answer is the **workload** $\mathcal{Q}$, with $|\mathcal{Q}|$ queries. Neighbouring datasets $D \sim D'$ differ by replacing one record, so n is public.

The answer depends on the records only through how many of them take each value, which is what the histogram records.

Proposition 23.1 (A linear query is an inner product with the histogram)**.** *For every linear query q and dataset D with histogram p,*

$$q(D) = \sum_{x \in \mathcal{X}} q(x)\, p(x) = \langle q, p \rangle, \tag{23.2}$$

the inner product of two vectors indexed by the universe. Replacing one record moves the answer by at most $1/n$, so q has sensitivity $1/n$.

Proof.

1. Group the records by value. Each element x of the universe contributes $q(x)$ once for every record equal to it, and there are $np(x)$ such records, so $\sum_i q(x_i) = \sum_x np(x)q(x)$. Dividing by n gives Equation 23.2.
2. Replacing one record x_i by x_i' changes the sum by $q(x_i') - q(x_i)$, which lies in $[-1, 1]$ because q takes values in $[0, 1]$. Divided by n, the answer moves by at most $1/n$.

□

Two consequences carry the chapter. Any distribution $\hat{p}$ over the universe, not only the histogram of a real dataset, gives an answer $\langle q, \hat{p} \rangle$ to every query, so a histogram is a synthetic dataset. And the **error** of $\hat{p}$ on q, the distance between its answer and the true one, is $|\langle q, \hat{p} - p \rangle|$, which is linear in the difference of the two histograms. The target throughout is an error of at most α on every query of the workload, except with a small failure probability β, and all logarithms are natural.

Example 23.1. Take two yes/no attributes, so the universe is $\{00, 01, 10, 11\}$, and four records $01, 11, 11, 10$. Table 23.1 lists the histogram and the query "the first attribute is 1". The inner product is $0 + 0 + \frac{1}{4} + \frac{1}{2} = \frac{3}{4}$, and indeed three of the four records have a first attribute of 1. The running example is the same picture with 256 elements, where each marginal cell is a query with a 1 on the elements that match it, so the script answers all 6,560 queries at once with one matrix product.

Table 23.1.: A four-record dataset as a histogram, and one query.

Element x	00	01	10	11
Records equal to x	0	1	1	2
$p(x)$	0	1/4	1/4	1/2
$q(x)$: first attribute is 1	0	0	1	1

23.2. Noise on every answer

The direct way to release a workload is to add noise to each answer. Before improving on it, it helps to know what it costs, because the two sample sizes of this section are the targets that the rest of the chapter beats.

Write $f(D)$ for the vector of the $|\mathcal{Q}|$ answers. By Proposition 23.1, replacing one record moves each coordinate by at most $1/n$, so the ℓ_1 sensitivity of f is at most $|\mathcal{Q}|/n$ and its ℓ_2 sensitivity at most $\sqrt{|\mathcal{Q}|}/n$. The square root comes from the norm: the ℓ_1 norm adds the moves, while the ℓ_2 norm adds their squares and takes a square root. The Laplace mechanism adds noise of scale $b = \Delta_1 f/\varepsilon$ to every coordinate, and each noise exceeds t in absolute value with probability $e^{-t/b}$ (Theorem 20.1). The Gaussian mechanism is calibrated through $\mu = \mu(\varepsilon, \delta)$, the largest ratio of sensitivity to noise standard deviation that the exact calibration allows (Corollary 20.1).

Proposition 23.2 (Records needed with noise on every answer)**.** *Let the workload have $|\mathcal{Q}|$ queries, and let z be the number that a standard normal variable exceeds with probability $\beta/(2|\mathcal{Q}|)$. The Laplace mechanism on the answer vector, with scale $|\mathcal{Q}|/(n\varepsilon)$, is ε-DP, and with probability at least $1-\beta$ its largest error is at most α once*

$$n \geq \frac{|\mathcal{Q}| \ln(|\mathcal{Q}|/\beta)}{\alpha\varepsilon}. \tag{23.3}$$

The Gaussian mechanism with standard deviation $\sqrt{|\mathcal{Q}|}/(n\mu)$ on every answer is (ε, δ)-DP, and with probability at least $1-\beta$ its largest error is at most α once

$$n \geq \frac{\sqrt{|\mathcal{Q}|}\, z}{\mu\alpha}. \tag{23.4}$$

Proof.

1. *Laplace.* Each answer gets noise of scale $b = |\mathcal{Q}|/(n\varepsilon)$, which exceeds $b\ln(|\mathcal{Q}|/\beta)$ in absolute value with probability $\beta/|\mathcal{Q}|$. The union bound, which says that the probability that at least one of several events happens is at most the sum of their probabilities, gives probability at most β that some answer's noise exceeds that level. Setting $b\ln(|\mathcal{Q}|/\beta) = \alpha$ and solving for n gives Equation 23.3.
2. *Gaussian.* A normal variable exceeds z standard deviations in absolute value with probability $2\Phi(-z)$, where Φ is the standard normal cumulative distribution function, and the one-sided tail $\beta/(2|\mathcal{Q}|)$ that defines z makes this $\beta/|\mathcal{Q}|$. By the union bound, some answer's noise exceeds σz with probability at most β, where $\sigma = \sqrt{|\mathcal{Q}|}/(n\mu)$ is the standard deviation. Setting $\sigma z = \alpha$ and solving for n gives Equation 23.4.

□

The records needed grow like $|\mathcal{Q}|$ under pure DP and like $\sqrt{|\mathcal{Q}|}$, times a slowly growing z, under approximate DP. For a few hundred queries on a large dataset that is fine, and nothing in this chapter beats it there. But a table with 30 yes/no attributes has $3^{30} - 1 \approx 2 \times 10^{14}$ marginal cells, too many for independent noise.

A workload with structure does better. Replacing one record lowers one cell of a marginal table by $1/n$ and raises another by $1/n$, so each table contributes only $2/n$ to the ℓ_1 sensitivity, whatever its number of cells, and $2/n^2$ to the squared ℓ_2 sensitivity.

Example 23.2. With $n = 10{,}000$ and $\varepsilon = 1$, the 255 marginal tables give an ℓ_1 sensitivity of $2 \times 255/n = 0.0510$, so the Laplace mechanism adds noise of scale 0.0510 to each of the 6,560 cells. Its largest error, averaged over 20 runs, is 0.497, worse than the 0.232 of the uniform histogram, which uses no data. The Gaussian mechanism at $\delta = 10^{-6}$ has ℓ_2 sensitivity $\sqrt{2 \times 255}/n = 0.00226$. With $\mu = 0.2367$ its noise has standard deviation 0.0095, and its average largest error is 0.037. Both use the structure of the marginals: treated as 6,560 unrelated queries, the ℓ_1 sensitivity would be $|\mathcal{Q}|/n = 0.656$, about 13 times larger.

23.3. Multiplicative weights and its regret bound

Forget privacy for two sections. The method behind this chapter comes from a prediction game, and the question is how well a learner can do against any sequence of outcomes when all it may do is reweight a fixed set of advisers. The answer is a regret bound that depends on the number of advisers only through a logarithm, and it drives every algorithm that follows.

Each day, N **experts** predict a yes/no outcome, and you must decide whom to follow before you see it. If one expert is always right, the **halving algorithm** follows the majority of the experts who have never erred and drops each one that errs. Each of your mistakes drops at least half of them, so you err at most $\log_2 N$ times (Exercise 1 in the exercise book). In 20 simulated runs with 1,024 experts it never made more than 6 mistakes, against the bound $\log_2 1024 = 10$. Real experts are never perfect, so multiplicative weights keeps every expert but shrinks its weight each time it does badly.

Definition 23.2 (The experts game and multiplicative weights)**.** The game has T rounds. In round t the learner chooses a probability distribution p_t over the N experts. Then a **loss vector** ℓ_t is revealed, which gives each expert x a loss $\ell_t(x)$ in $[-1, 1]$, and the learner pays the average loss under its distribution, $\langle \ell_t, p_t \rangle$. The losses may be chosen by an adversary who knows the learner's rule. **Multiplicative weights** keeps a positive weight $w_t(x)$ on each expert, starting from $w_1(x) = 1$, and has a **learning rate** (step size) $\eta \le \frac{1}{2}$. In round t it plays $p_t(x) = w_t(x)/W_t$, where $W_t = \sum_x w_t(x)$ is the total weight, and after the losses are revealed it updates each weight by

$$w_{t+1}(x) = w_t(x)(1 - \eta \ell_t(x)). \tag{23.5}$$

The learner's **regret** against a distribution π over the experts, fixed in hindsight, is its total loss minus the total loss of π, that is $\sum_t \langle \ell_t, p_t \rangle - \sum_t \langle \ell_t, \pi \rangle$.

An expert with a positive loss loses weight, and one with a negative loss gains it. The proof of the regret bound takes the logarithm of factors $1 - x$ twice: from above, when it turns the total weight into the learner's loss, and from below, when it turns one expert's weight into that expert's loss. The next lemma supplies both bounds, and its range $|x| \le \frac{1}{2}$ is why the learning rate is at most $\frac{1}{2}$.

Lemma 23.1 (Two bounds on the logarithm)**.** *For every $x < 1$, $\ln(1 - x) \le -x$. For $|x| \le \frac{1}{2}$,*

$$\ln(1 - x) \ge -x - x^2. \tag{23.6}$$

Proof.

1. *Upper bound.* The logarithm is concave, so it lies below its tangent line at any point. The tangent of $\ln(1-x)$ at $x=0$ is $-x$, which gives $\ln(1-x) \le -x$.
2. *Lower bound.* Let $g(x) = \ln(1-x) + x + x^2$, so that $g(0) = 0$ and the claim is that g is never negative on the range. Its derivative is

$$g'(x) = -\frac{1}{1-x} + 1 + 2x = \frac{x(1-2x)}{1-x}. \tag{23.7}$$

   On $[0, \frac{1}{2}]$ every factor is non-negative, so g rises from 0 and stays non-negative. On $[-\frac{1}{2}, 0]$ the numerator is at most 0 and the denominator positive, so g falls toward $g(0) = 0$ and is non-negative there too.

□

At the end of the range the bound is close, since $\ln \frac{1}{2} = -0.6931$ lies just above -0.75. Outside the range it can fail, and at $x = 0.9$ it does, because $\ln 0.1 = -2.30$ lies below -1.71. A loss outside $[-1, 1]$ pushes $\eta\ell_t(x)$ out of the range in the same way, and at $\eta\ell_t(x) \ge 1$ a weight can even become zero or negative, so losses are rescaled into $[-1, 1]$ first.

Theorem 23.1 (The regret bound of multiplicative weights)**.** *Run multiplicative weights with learning rate $\eta \le \frac{1}{2}$ for T rounds against any sequence of loss vectors with entries in $[-1, 1]$. Then for every distribution π over the experts,*

$$\sum_{t=1}^{T} \langle \ell_t, p_t \rangle - \sum_{t=1}^{T} \langle \ell_t, \pi \rangle \le \eta T + \frac{\ln N}{\eta}. \tag{23.8}$$

When $T \ge 4 \ln N$, the learning rate $\eta = \sqrt{\ln N / T}$ is allowed and gives regret at most $2\sqrt{T \ln N}$.

Proof. The plan is to bound $\ln W_{T+1}$ from above by the learner's total loss and from below by any one expert's total loss, to compare the two bounds, and then to average the comparison over the experts.

1. *The total weight shrinks with the learner's loss.* Summing Equation 23.5 over the experts gives $W_{t+1} = \sum_x w_t(x) - \eta \sum_x w_t(x)\ell_t(x)$. Factoring out W_t turns each weight into $p_t(x)$, so

$$W_{t+1} = W_t(1 - \eta \langle \ell_t, p_t \rangle). \tag{23.9}$$

2. *Upper bound.* Unrolling step 1 from $W_1 = N$ makes W_{T+1} equal to N times the product of the factors. Each $\eta\langle \ell_t, p_t \rangle$ is below 1, so the upper bound of Lemma 23.1 applies to every factor:

$$\ln W_{T+1} = \ln N + \sum_{t=1}^{T} \ln\left(1 - \eta \langle \ell_t, p_t \rangle\right) \le \ln N - \eta \sum_{t=1}^{T} \langle \ell_t, p_t \rangle. \tag{23.10}$$

3. *Lower bound from one expert.* The total weight is at least the weight of any single expert x, and that weight is the product of its own factors. Each $\eta\ell_t(x)$ lies in $[-\frac{1}{2}, \frac{1}{2}]$, so the lower bound of Lemma 23.1 applies, and $\ell_t(x)^2 \le 1$ bounds each squared term:

$$\ln W_{T+1} \ge \ln w_{T+1}(x) = \sum_{t=1}^{T} \ln\left(1 - \eta \ell_t(x)\right) \ge -\eta \sum_{t=1}^{T} \ell_t(x) - \eta^2 T. \tag{23.11}$$

4. *Compare.* The upper bound of step 2 is at least the lower bound of step 3, so $\eta \sum_t \langle \ell_t, p_t \rangle \le \ln N + \eta \sum_t \ell_t(x) + \eta^2 T$. Dividing by η gives Equation 23.8 for the comparison with the single expert x.
5. *Any distribution.* The inequality of step 4 holds for every expert x, and its left side does not depend on x. Multiply it by $\pi(x)$ and add over the experts. The $\pi(x)$ sum to 1, so the left side and the constant terms are unchanged, and $\sum_x \pi(x)\ell_t(x) = \langle \ell_t, \pi \rangle$, which is Equation 23.8.
6. *Choose the learning rate.* A larger η raises ηT and lowers $\ln N/\eta$, so the bound is smallest where the two terms are equal, at $\eta = \sqrt{\ln N/T}$, where it equals $2\sqrt{T \ln N}$. The lemma needs $\eta \le \frac{1}{2}$, that is $T \ge 4 \ln N$.

□

The average regret per round, $2\sqrt{\ln N/T}$, goes to zero, so over many rounds the learner does as well as the best fixed distribution. Nothing in the proof assumed that the losses were random or independent of the weights, so an adversary who knows the rule gains nothing, and the number of experts enters only through $\ln N$. The sequences met in practice are rarely as hostile as the worst case, as Section 23.4 shows.

The weights also look familiar. Each factor $1 - \eta\ell$ is close to $e^{-\eta\ell}$ when η is small, so the distribution is close to a softmax of minus the cumulative losses, the shape of the exponential mechanism. The version with the factor $e^{-\eta\ell}$ exactly is called Hedge, and online learning also views it as follow the regularized leader (FTRL) with an entropy penalty; DP-FTRL uses a squared-norm penalty to train models privately.

Example 23.3. The smallest case shows the mechanics. Take $N = 2$ experts and $\eta = \frac{1}{2}$ over $T = 3$ rounds, with losses $\ell_1 = (1, 0)$, $\ell_2 = (0, 1)$ and $\ell_3 = (1, 0)$. Table 23.2 follows the weights. The learner pays $\frac{1}{2} + \frac{2}{3} + \frac{1}{2} = \frac{5}{3}$ in total. Expert 2 lost only 1, so the regret against it is $\frac{2}{3}$, and the bound Equation 23.8 is $\frac{1}{2} \times 3 + \ln 2/\frac{1}{2} = 1.5 + 1.386 = 2.886$. The running example enters in the next section, where the experts are the 256 elements of the universe.

Table 23.2.: Multiplicative weights on two experts with learning rate 1/2.

Round t	Weights w_t	Distribution p_t	Loss ℓ_t	Learner pays $\langle \ell_t, p_t \rangle$
1	$(1, 1)$	$(1/2, 1/2)$	$(1, 0)$	1/2
2	$(1/2, 1)$	$(1/3, 2/3)$	$(0, 1)$	2/3
3	$(1/2, 1/2)$	$(1/2, 1/2)$	$(1, 0)$	1/2

23.4. From regret to a mistake bound

Now turn the game into an algorithm for releasing answers, still without privacy. The question is how many corrections a guessed histogram needs before it answers every query to within α, and the answer must not depend on the number of queries. Let the experts be the elements of the universe, so that p_t is a guessed histogram, and compare it with the true histogram p, one particular distribution π. If each round's regret against p is the guess's error on one query, the regret bound limits the number of large errors.

Theorem 23.2 (The mistake bound)**.** *Run multiplicative weights over the universe, starting from the uniform histogram, with learning rate $\eta = \alpha/2$. In each round, look for a query $q_t \in \mathcal{Q}$ on which the current guess has error more than α. If there is none, stop: the guess is within α on every query. Otherwise let s_t be $+1$ if the guess's answer is too high and -1 if it is too low, and use the loss $\ell_t = s_t q_t$. The number U of rounds before the algorithm stops satisfies*

$$U < \frac{4 \ln N}{\alpha^2}, \tag{23.12}$$

whatever the workload and however the queries are chosen.

Proof. The plan is to show that the regret against the true histogram grows by more than α in every round, to bound the same regret by Equation 23.8, and to compare the two.

1. *Each round's regret is the error.* The regret bound holds for every distribution π, and the loss of p is the true answer times s_t, so by Equation 23.2 $\langle \ell_t, p_t - p \rangle = s_t(\langle q_t, p_t \rangle - \langle q_t, p \rangle)$. The sign s_t makes the bracket positive, so this is the error of p_t on q_t, more than α.
2. *Total regret is large.* Adding over the U rounds, the regret against p is more than αU.
3. *Total regret is small.* The losses $s_t q_t$ have entries in $[-1, 1]$, and $\eta = \alpha/2 \le \frac{1}{2}$, so Theorem 23.1 with $\pi = p$ and $T = U$ bounds the same regret by $\eta U + \ln N/\eta = \alpha U/2 + 2 \ln N/\alpha$.
4. *Combine.* The regret is more than αU by step 2 and at most $\alpha U/2 + 2 \ln N/\alpha$ by step 3, so

$$\alpha U < \frac{\alpha U}{2} + \frac{2 \ln N}{\alpha}. \tag{23.13}$$

   Subtracting $\alpha U/2$ from both sides and dividing by $\alpha/2$ gives Equation 23.12.

□

If the guess's answer is too high, the loss is $+q_t$, and the weights of the records that the query counts shrink, which lowers the answer. A few such corrections fix every query at once because each one moves the guess closer to the true histogram in relative entropy, a distance that starts at no more than $\ln N$. The algorithm never looks at the queries it gets right, so their number never enters, and doubling the universe adds only $4 \ln 2/\alpha^2$ corrections. Exercise 3 in the exercise book shows that $\alpha/2$ is the best learning rate.

The choice of query and its sign are the only places where the algorithm touches the data, and both use only answers of sensitivity $1/n$, which makes it easy to privatize. The bound is very loose, because in practice the first corrections fix errors several times larger than α, and many queries at once.

Example 23.4. With $\alpha = 0.05$ the bound Equation 23.12 allows $4 \ln 256/0.05^2 = 8872$ corrections. The algorithm needs 148 (Figure 23.1). The first three queries it corrects have errors 0.232, 0.228 and 0.226, more than four times α. After 148 rounds the regret is 16.70, against a bound of 225.5.

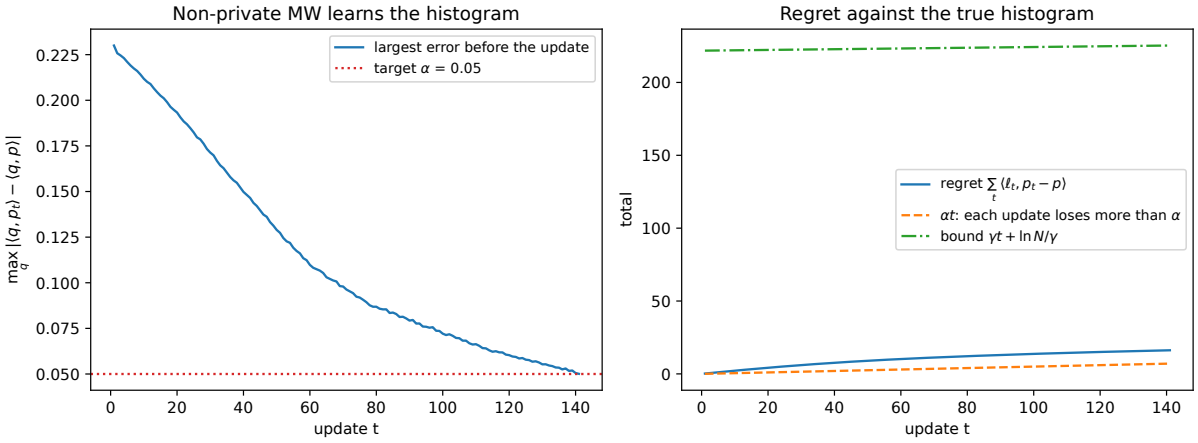

Figure 23.1.: Non-private multiplicative weights on the running example, $\alpha = 0.05$, $\eta = \alpha/2$. Left: the largest error over the 6,560 queries before each update. Right: the regret against the true histogram and its bound $\eta t + \ln N/\eta$.

23.5. Private multiplicative weights

The algorithm of Section 23.4 touches the data in two places, the choice of a badly answered query and the sign of its error. This section makes both private, which gives an error that grows only with the logarithms of $|\mathcal{Q}|$ and N. The exponential mechanism picks a query whose error is close to the largest, and the Laplace mechanism measures its answer, which gives the sign. Both can miss, so the algorithm cannot tell when to stop. Instead it runs a fixed number of rounds T and releases the average of its guesses. This is the **multiplicative weights exponential mechanism (MWEM)** of Hardt, Ligett & McSherry (2012), the practical form of private multiplicative weights (Hardt & Rothblum 2010).

Definition 23.3 (Private multiplicative weights, offline)**.** Input: the dataset D, the workload $\mathcal{Q}$, a number of rounds $T \geq 4 \ln N$ and a per-step budget ε_0. Start from the uniform histogram p_1 and set $\eta = \sqrt{\ln N / T}$. For $t = 1, \dots, T$:

1. *Select.* Run the exponential mechanism over $\mathcal{Q}$ with budget ε_0 and score $|\langle q, p_t \rangle - q(D)|$, the error of the current guess on q. Call the chosen query q_t.
2. *Measure.* Release $m_t = q_t(D) + \mathrm{Lap}(1/(n\varepsilon_0))$.
3. *Update.* Let $s_t = +1$ if $\langle q_t, p_t \rangle > m_t$ and -1 otherwise, and apply Equation 23.5 with the loss $s_t q_t$ to get p_{t+1}.

Output the average histogram $\bar{p} = \frac{1}{T} \sum_{t=1}^{T} p_t$.

The measurement needs its own budget, because the exponential mechanism releases only the index of the chosen query, never its exact score.

Three earlier results do the private work. The exponential mechanism over the $|\mathcal{Q}|$ queries, with a score of sensitivity $1/n$, is ε_0-DP, and except with probability β' the chosen score is within $\frac{2}{n\varepsilon_0}(\ln |\mathcal{Q}| + \ln(1/\beta'))$ of the best (Selection). The Laplace mechanism with scale $b = 1/(n\varepsilon_0)$ is ε_0-DP, and its noise exceeds $b \ln(1/\beta')$ in absolute value with probability β' (Theorem 20.1).

Advanced composition (Advanced and optimal composition) makes k adaptive ε_0-DP steps (ε', δ)-DP with $\varepsilon' = \varepsilon_0\sqrt{2k\ln(1/\delta)} + k\varepsilon_0\tanh(\varepsilon_0/2)$. The privacy step below needs a closed-form per-step budget from it.

Lemma 23.2 (A closed-form per-step budget)**.** *Let $\varepsilon > 0$ and $\delta \in (0,1)$ satisfy $\varepsilon \le 8\ln(1/\delta)$. If each of k adaptively chosen steps is ε_0-DP with*

$$\varepsilon_0 = \frac{\varepsilon}{2\sqrt{2k\ln(1/\delta)}}, \tag{23.14}$$

then the whole is (ε, δ)-DP.

Proof.

1. Substitute ε_0 into the advanced composition bound. The first term, $\varepsilon_0\sqrt{2k\ln(1/\delta)}$, is exactly $\varepsilon/2$.
2. The second term, $k\varepsilon_0\tanh(\varepsilon_0/2)$, is at most $k\varepsilon_0^2/2$, because tanh never exceeds its argument. Substituting ε_0 turns $k\varepsilon_0^2/2$ into $\varepsilon^2/(16\ln(1/\delta))$, and the condition $\varepsilon \le 8\ln(1/\delta)$ makes this at most $\varepsilon/2$.
3. The two terms add to at most ε, so the composition is (ε, δ)-DP.

□

The condition is mild, since at $\delta = 10^{-6}$ it allows any ε up to 110. When ε_0 is small the second term is far below $\varepsilon/2$, so the closed form leaves up to half the budget unspent (Example 23.5).

Theorem 23.3 (Privacy and accuracy of private multiplicative weights)**.** *The algorithm of Definition 23.3 is $2T\varepsilon_0$-DP. So $\varepsilon_0 = \varepsilon/(2T)$ makes it ε-DP, and ε_0 from Equation 23.14 with $k = 2T$ makes it (ε, δ)-DP when $\varepsilon \le 8\ln(1/\delta)$. With probability at least $1-\beta$, the largest error of the average histogram over the workload is at most*

$$\max_{q\in\mathcal{Q}} \left|\langle q, \bar{p}\rangle - q(D)\right| \le 2\sqrt{\frac{\ln N}{T}} + \frac{2}{n\varepsilon_0}\Big(\ln|\mathcal{Q}| + 2\ln\frac{2T}{\beta}\Big). \tag{23.15}$$

Proof. The plan is to check that each private step is ε_0-DP, to define the event on which every selection and every measurement works as intended, and on that event to run the regret argument of Theorem 23.2 with a deficit per round for the two private steps.

1. *Privacy.* Given the history, the guess p_t is a fixed histogram, so the score moves by at most $1/n$ between neighbours (Proposition 23.1) and the selection is ε_0-DP. The measurement is a Laplace mechanism of scale $1/(n\varepsilon_0)$ on an answer of sensitivity $1/n$, so it is ε_0-DP too. The update and the average are post-processing, and composition allows the $2T$ steps to be adaptive (Advanced and optimal composition).
2. *The good event.* Write $\mathrm{err}_t(q) = |\langle q, p_t\rangle - q(D)|$ for the error of round t's guess on query q. Give each of the $2T$ private steps the failure probability $\beta' = \beta/(2T)$. The utility bound of the exponential mechanism then says that the selection picks a query whose error is within

$$c_E = \frac{2}{n\varepsilon_0}\Big(\ln|\mathcal{Q}| + \ln\frac{2T}{\beta}\Big) \tag{23.16}$$

of the largest, except with probability $\beta/(2T)$. The Laplace tail says that the measurement's noise is below

$$c_L = \frac{1}{n\varepsilon_0} \ln \frac{2T}{\beta}, \tag{23.17}$$

also except with probability $\beta/(2T)$. The union bound over the $2T$ steps makes all of this hold at once except with probability β.

3. *Each round's regret is nearly the largest error.* If the sign s_t is right, then the round's regret $\langle s_t q_t, p_t - p\rangle$ is $\mathrm{err}_t(q_t)$, as in step 1 of Theorem 23.2. If it is wrong, the guess's answer lies between the measured and the true answers, which are at most c_L apart, so $\mathrm{err}_t(q_t) \le c_L$, and the regret $-\mathrm{err}_t(q_t)$ falls short of $\mathrm{err}_t(q_t)$ by at most $2c_L$. Either way the loss is at least $\mathrm{err}_t(q_t) - 2c_L$, and by step 2 the chosen query's error is within c_E of the largest, so

$$\langle s_t q_t, p_t - p\rangle \ge \max_q \mathrm{err}_t(q) - c_E - 2c_L. \tag{23.18}$$

4. *Sum and use the regret bound.* Adding over the T rounds, the regret against the true histogram is at least $\sum_t \max_q \mathrm{err}_t(q) - T(c_E + 2c_L)$. By Theorem 23.1 with $\eta = \sqrt{\ln N/T}$ it is at most $2\sqrt{T \ln N}$. Comparing the two and dividing by T,

$$\frac{1}{T}\sum_{t=1}^{T} \max_q \mathrm{err}_t(q) \le 2\sqrt{\frac{\ln N}{T}} + c_E + 2c_L. \tag{23.19}$$

5. *The average histogram.* For any query q, the error of the average is the average of the errors by Equation 23.2, $\langle q, \bar{p}\rangle - q(D) = \frac{1}{T}\sum_t \langle q, p_t - p\rangle$. Its absolute value is at most $\frac{1}{T}\sum_t \mathrm{err}_t(q)$, which is at most the left side of step 4. Finally $c_E + 2c_L = \frac{2}{n\varepsilon_0}(\ln|\mathcal{Q}| + 2\ln\frac{2T}{\beta})$, which gives Equation 23.15.

□

The algorithm releases the average guess because the regret bound controls the sum of the rounds' largest errors, and says nothing about any single round. The constants are poor: on the running example the bound is above 1, while the real error is far smaller (Example 23.5).

The first term of Equation 23.15 falls with more rounds, and the second grows, because each round gets less budget. Balancing the two turns the bound into a sample size.

Corollary 23.1 (Records needed by private multiplicative weights)**.** *Write $L = \ln|\mathcal{Q}| + 2\ln(2T/\beta)$ for the logarithmic term of Equation 23.15, treated as a constant because it depends on T only through a logarithm. Under (ε, δ)-DP with the budget of Equation 23.14 for $2T$ steps, there is a number of rounds T at which the error bound is at most α once*

$$n \ge \frac{64\sqrt{\ln N \, \ln(1/\delta)}\, L}{\alpha^2 \varepsilon}. \tag{23.20}$$

Proof.

1. *The shape of the bound.* With $k = 2T$ steps, Equation 23.14 gives $\varepsilon_0 = \varepsilon/(4\sqrt{T\ln(1/\delta)})$, so the second term of Equation 23.15 is $8\sqrt{\ln(1/\delta)}\, L\sqrt{T}/(n\varepsilon)$. The bound therefore has the shape $A/\sqrt{T} + B\sqrt{T}$, with $A = 2\sqrt{\ln N}$ from the regret and $B = 8\sqrt{\ln(1/\delta)}\, L/(n\varepsilon)$ from the noise.

2. *Balance.* A sum of this shape is smallest where its two terms are equal, at $T = A/B$, and there it equals $2\sqrt{AB}$. Substituting A and B,

$$2\sqrt{AB} = 8(\ln N \ln(1/\delta))^{1/4}\sqrt{\frac{L}{n\varepsilon}}. \tag{23.21}$$

3. *Solve for n.* Setting this to α and squaring gives $64\sqrt{\ln N \ln(1/\delta)}\, L/(n\varepsilon) = \alpha^2$, which rearranges to Equation 23.20.

□

Under pure DP the second term grows linearly in T, and the same balancing gives $n \geq 108\, L \ln N/(\alpha^3 \varepsilon)$ (Exercise 4 in the exercise book). The queries enter only through L, which grows like $\ln|\mathcal{Q}|$, where the baseline paid $|\mathcal{Q}|$ or $\sqrt{|\mathcal{Q}|}$. The price is accuracy, because at a fixed n the error falls like $n^{-1/2}$, or $n^{-1/3}$ under pure DP, against $1/n$ for independent noise, so the method wins only when the queries far outnumber the records. No method can do much better on every workload, since errors below about $1/\sqrt{n}$ on many queries let the reconstruction attack recover the data. Up to constants it is close to optimal, by the packing and fingerprinting arguments of Lower bounds (Bun, Ullman & Vadhan 2014).

The running time is proportional to N, which is 2^{50} for 50 attributes. Some such cost is unavoidable, since Ullman & Vadhan (2011) showed that under standard cryptographic assumptions no efficient algorithm releases private synthetic data accurate for every two-way marginal, with probabilistically checkable proof (PCP) techniques. Practical methods keep the select–measure–update loop with a compact model in place of the histogram (McKenna, Mullins, Sheldon & Miklau 2022).

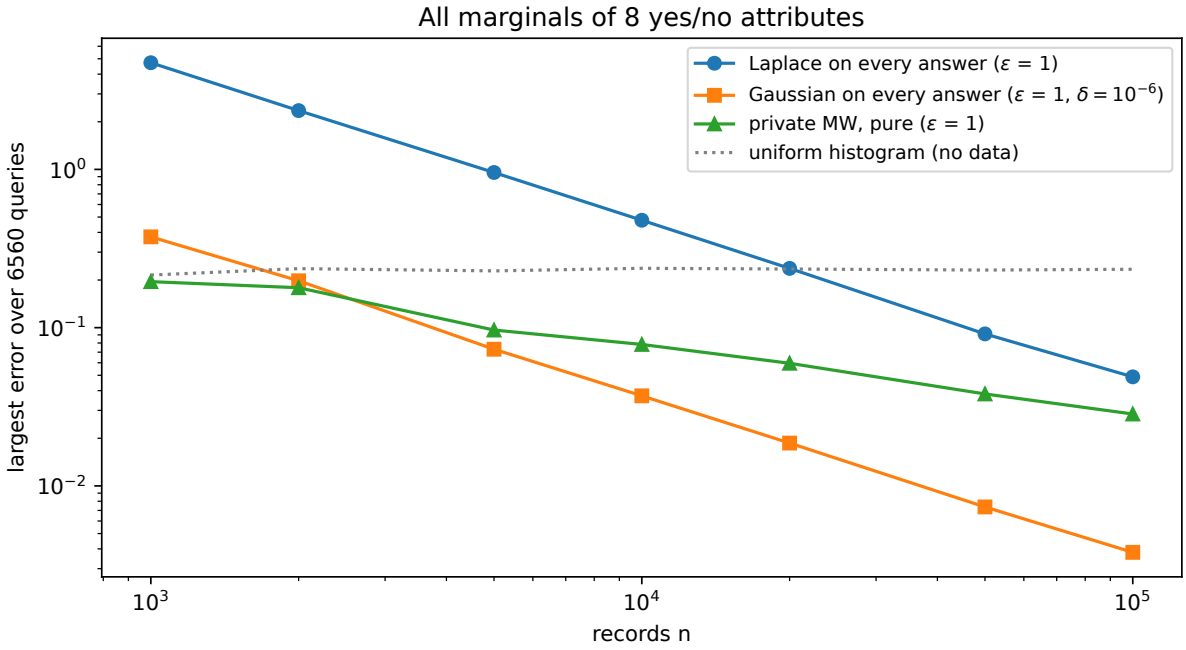
Example 23.5. With $n = 10{,}000$, $\varepsilon = 1$ and pure DP, the number of rounds that minimizes Equation 23.15 is $T = 38$, so each step gets $\varepsilon_0 = 1/76 = 0.0132$. Table 23.3 compares three choices of T, averaged over 20 runs.

Table 23.3.: Private multiplicative weights on the running example, $n = 10{,}000$, $\varepsilon = 1$.

Rounds T	Budget per step ε_0	Largest error	Bound Equation 23.15
10	0.0500	0.098	1.572
38	0.0132	0.078	1.120
100	0.0050	0.123	1.486

The bound picks a good T, although its values are useless as numbers. With 38 rounds the largest error is 0.078, against 0.497 for Laplace noise and 0.037 for Gaussian noise, so here the Gaussian mechanism wins. Figure 23.2 shows that Gaussian noise wins above a few thousand records, because 6,560 queries are not many enough.

With $\delta > 0$, advanced composition gives each step more budget once T is large. At $T = 100$ and $\delta = 10^{-6}$, pure DP gives each step $\varepsilon_0 = 0.00500$. The closed form Equation 23.14 gives 0.00673, although in total that budget spends only 0.505ε, while solving the advanced composition bound exactly for ε_0 gives 0.01322. At $T = 1000$ the same three budgets are 0.00050, 0.00213 and 0.00418.



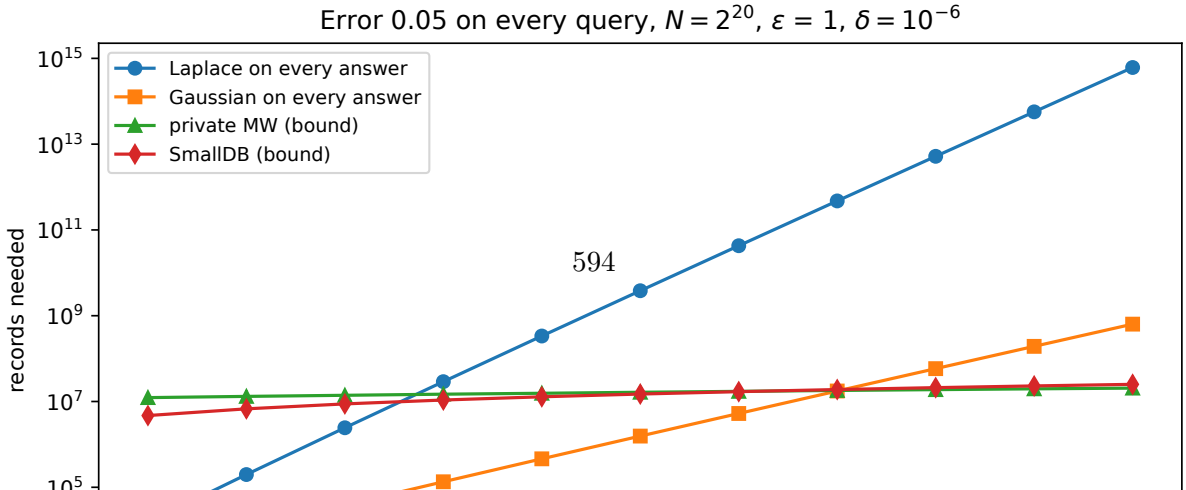


Figure 23.2.: Largest error over the 6,560 marginal queries of the running example as the number of records grows, averaged over 10 runs: Laplace and Gaussian noise on every answer, and private multiplicative weights with pure DP and its best number of rounds. The dotted line is the uniform histogram.

The guarantees separate only at a much larger scale. Table 23.4 gives the records needed for error 0.05 on every query with probability 0.95, over a universe of $N = 2^{20}$ and a workload with no structure. The Laplace and SmallDB columns are pure DP, and the other two are (ε, δ)-DP. For private multiplicative weights the table solves Equation 23.15 for n after a search over T. At 10^6 queries the search finds $T = 81{,}552$ and $L = 43.81$, and needs 1.56×10^7 records, while the closed form Equation 23.20 gives 1.55×10^7. That bound hardly moves as the queries grow a millionfold, and it crosses the Gaussian column near 10^9 queries (Figure 23.3).

Table 23.4.: Records needed for error 0.05 on every query with probability 0.95, $\varepsilon = 1$, $\delta = 10^{-6}$, $N = 2^{20}$.

Queries $\lvert\mathcal{Q}\rvert$	Laplace	Gaussian	Private multiplicative weights (bound)	SmallDB (bound)
10^3	1.98×10^5	1.08×10^4	1.31×10^7	6.74×10^6
10^6	3.36×10^8	4.61×10^5	1.56×10^7	1.29×10^7
10^9	4.74×10^{11}	1.76×10^7	1.81×10^7	1.90×10^7

pay only for the queries the guess gets wrong without searching for them. The sparse vector technique of Selection waits for a bad query to arrive instead, which is the original form of private multiplicative weights (Hardt & Rothblum 2010).

Its basic form, AboveThreshold, compares each query's noisy value with a noisy threshold, answers $\perp$ ("below") or $\top$ ("above"), and halts at the first $\top$, while the $\perp$ answers cost nothing. With probability $1-\beta$, every $\perp$ lies below the threshold plus a **margin** and every $\top$ above it minus the margin, which for K queries of sensitivity Δ at budget ε is $8\Delta(\ln K+\ln(2/\beta))/\varepsilon$ (Equation 22.15). The variant Sparse restarts it after each $\top$. Here the question asked is whether the guess's error is large, so only the few queries it gets wrong cost privacy.

Definition 23.4 (Online private multiplicative weights)**.** Input: the dataset, a target error α, privacy parameters (ε,δ), and a stream of at most K queries, with K fixed in advance. Set the budget of updates to $c=\lceil 16\ln N/\alpha^2\rceil$, the learning rate to $\eta=\alpha/4$, and the guess $\hat{p}$ to the uniform histogram. Give each of the at most c runs of AboveThreshold inside Sparse, and each of the at most c measurements, the budget ε_0 of Equation 23.14 with $k=2c$ steps. For each incoming query f_i (the letter f marks queries of the stream), the score is the current guess's error on it, $g_i=|\langle f_i,\hat{p}\rangle - f_i(D)|$. Run Sparse on these scores with threshold $3\alpha/4$, allowing up to c answers $\top$, and act on its answer:

- If Sparse answers $\perp$, answer $\langle f_i,\hat{p}\rangle$ from the guess.
- If it answers $\top$, measure $m_i=f_i(D)+\mathrm{Lap}(1/(n\varepsilon_0))$, answer m_i, and update $\hat{p}$ by Equation 23.5 with the loss $s_i f_i$, where s_i is the sign of $\langle f_i,\hat{p}\rangle - m_i$.
- After the c-th $\top$, halt.

The threshold sits at $3\alpha/4$ because a $\top$ must certify an error of at least $\alpha/2$, twice the learning rate, so that each update gains regret faster than Theorem 23.1 allows, while a $\perp$ must certify an error below α. A margin of $\alpha/4$ gives both, so accuracy needs enough records to keep every margin and every measurement's noise at most $\alpha/4$.

Theorem 23.4 (Privacy and accuracy of the online algorithm)**.** *The algorithm of Definition 23.4 is (ε,δ)-DP when $\varepsilon\le 8\ln(1/\delta)$. If*

$$n\ge\frac{32(\ln K+\ln(4c/\beta))}{\alpha\varepsilon_0},\qquad \varepsilon_0=\frac{\varepsilon}{2\sqrt{4c\ln(1/\delta)}},\tag{23.22}$$

then with probability at least $1-\beta$ every answer is within α of the truth, and the algorithm answers the whole stream without using up its c answers $\top$.

Proof. The plan is to check the scores' sensitivity, compose the steps, and, on the event where every margin and noise is at most $\alpha/4$, show that every answer is accurate and every update is a real correction, so that the mistake bound limits their number.

1. *Sensitivity.* Between two updates the guess $\hat{p}$ is fixed, because it changes only after a measurement, which is a released output. Given the history, each score g_i is the distance between a fixed number and an answer of sensitivity $1/n$, so it has sensitivity $1/n$.

2. *Privacy.* The runs of AboveThreshold and the measurements alternate: a run ends with its $\top$, that query is measured, then the next run starts with the updated guess. So the algorithm is a sequence of at most $2c$ steps, each ε_0-DP and each chosen as a function of the earlier outputs, and by Lemma 23.2 with $k = 2c$ it is (ε, δ)-DP.
3. *The good event.* Half of the failure probability goes to the c runs, $\beta/(2c)$ each, and half to the c measurements. With budget ε_0, sensitivity $1/n$ and failure probability $\beta/(2c)$, the margin of one run is $8(\ln K + \ln(4c/\beta))/(n\varepsilon_0)$ by Equation 22.15, and Equation 23.22 says exactly that this is at most $\alpha/4$. A measurement's noise exceeds $\ln(2c/\beta)/(n\varepsilon_0)$ with probability $\beta/(2c)$ by the Laplace tail, and that level is below the margin of a run, so it is at most $\alpha/4$ too. The union bound over the c runs and the c measurements gives total failure probability β.
4. *Answers.* On the good event, a $\perp$ means $g_i < 3\alpha/4 + \alpha/4 = \alpha$, so the guess's answer is within α. A $\top$ is answered by the measurement, which is within $\alpha/4$.
5. *Updates are real corrections.* A $\top$ means $g_i \geq 3\alpha/4 - \alpha/4 = \alpha/2$. The measurement's noise is at most $\alpha/4$, less than the error, so the measured answer lies on the same side of the guess's answer as the true one, and the sign s_i is right. As in step 1 of Theorem 23.2, the update's regret against the true histogram is $g_i \geq \alpha/2$.
6. *Few updates.* After U updates the regret is at least $\alpha U/2$, and by Equation 23.8 with $\eta = \alpha/4$ it is at most $\alpha U/4 + 4\ln N/\alpha$. So $\alpha U/4 \leq 4\ln N/\alpha$, which is $U \leq 16\ln N/\alpha^2 \leq c$, and the budget of c answers $\top$ is never used up.

□

Because $\sqrt{c}$ is about $4\sqrt{\ln N}/\alpha$, the records needed grow like $\sqrt{\ln N \ln(1/\delta)}/(\alpha^2\varepsilon)$ times a logarithm, as offline, but the logarithm is of the stream length K instead of $|\mathcal{Q}|$. A $\top$ query must be measured, because the guess is off by at least $\alpha/2$ there and the measurement gives the sign.

The guarantee holds even when the analyst chooses each query after the earlier answers, because every step of the proof conditions on the history, which is the setting of Adaptive data analysis. The budget c is set by the worst case, so it is far larger than a real stream needs.

Example 23.6. On the running example, with $\alpha = 0.05$, the budget is $c = 35{,}490$ corrections, against the 148 of Example 23.4. For a query server over a universe of $N = 2^{20}$ records, the budget is $c = 88{,}723$. A stream of $K = 10^6$ queries at $\varepsilon = 1$ and $\delta = 10^{-6}$, with probability 0.95, needs 8.39×10^7 records by Equation 23.22. That is about five times the offline bound in Table 23.4, the price of the worst-case budget and the wider margin.

23.7. SmallDB: the exponential mechanism over small datasets

Blum, Ligett & Roth (2008) were the first to answer many linear queries with error that grows only with $\ln|\mathcal{Q}|$, and their algorithm answers a different question: what can the exponential mechanism achieve in a single choice, when running time is ignored? **SmallDB** makes that choice among whole small datasets, like the classifier selection of Selection with datasets in place of classifiers.

The proof first needs some small dataset that answers every query well, so that the exponential mechanism has a good candidate. The next lemma shows that a random sample of the data is one with positive probability, and Exercise 5 in the exercise book checks it on the running example.

Lemma 23.3 (A small dataset with small error exists)**.** *Let $m > 2\ln(2|\mathcal{Q}|)/\alpha^2$. Then some dataset of m records from the universe has error at most $\alpha/2$ on every query of $\mathcal{Q}$.*

Proof.

1. Draw m records independently from the true histogram p and call the result $\hat{D}$. For one query q, the answer $q(\hat{D})$ is an average of m independent values in $[0,1]$ with mean $q(D)$.
2. Hoeffding's inequality (Concentration inequalities) says that such an average is more than s away from its mean with probability at most $2e^{-2ms^2}$, which at $s = \alpha/2$ is $2e^{-m\alpha^2/2}$.
3. By the union bound, some query is more than $\alpha/2$ off with probability at most $2|\mathcal{Q}|e^{-m\alpha^2/2}$, and with $m > 2\ln(2|\mathcal{Q}|)/\alpha^2$ this is below 1. So with positive probability no query is off by more than $\alpha/2$, and a dataset with that property exists.

□

Theorem 23.5 (SmallDB)**.** *Let $m = \lceil 2\ln(2|\mathcal{Q}|)/\alpha^2 \rceil$ (or $2\ln(2|\mathcal{Q}|)/\alpha^2 + 1$ if that ratio is an integer), and run the exponential mechanism with budget ε over every dataset $\hat{D}$ of m records from the universe, with the score $-\max_{q\in\mathcal{Q}} |q(\hat{D}) - q(D)|$, minus the candidate's largest error. The mechanism is ε-DP, and the chosen dataset has error at most α on every query with probability at least $1-\beta$ once*

$$n \geq \frac{4(m\ln N + \ln(1/\beta))}{\alpha\varepsilon} \approx \frac{8\ln(2|\mathcal{Q}|)\ln N}{\alpha^3\varepsilon}. \tag{23.23}$$

Proof. The plan is to show that the best candidate scores at least $-\alpha/2$, to count the candidates, and to apply the utility bound of the exponential mechanism.

1. *Privacy.* Each $q(D)$ has sensitivity $1/n$ by Proposition 23.1, so a candidate's largest error moves by at most $1/n$ between neighbours, the score has sensitivity $1/n$, and the exponential mechanism is ε-DP.
2. *A good candidate exists.* By Lemma 23.3, some candidate has error at most $\alpha/2$ on every query, so the best score is at least $-\alpha/2$.
3. *Count the candidates.* A dataset of m records is a list of m elements of the universe, so there are at most N^m candidates, and $\ln N^m = m\ln N$.
4. *The selection is nearly the best.* The utility bound of the exponential mechanism, with N^m candidates, sensitivity $1/n$ and failure probability β, says that the chosen dataset's score is within $\frac{2}{n\varepsilon}(m\ln N + \ln(1/\beta))$ of the best, except with probability β. Its error is therefore at most $\alpha/2$ plus that amount.
5. *Records.* Asking that the amount be at most $\alpha/2$ gives the first form of Equation 23.23. Substituting $m \approx 2\ln(2|\mathcal{Q}|)/\alpha^2$ and dropping the smaller term $\ln(1/\beta)$ gives the approximate form.

□

SmallDB has the same logarithm of $|\mathcal{Q}|$ as private multiplicative weights, and under pure DP the same α^{-3}, which comes from m, growing like $1/\alpha^2$, times the $1/(\alpha\varepsilon)$ of the exponential mechanism's error. It is simpler to analyse, because it makes one choice instead of T, but hopeless to run, because the exponential mechanism must weigh N^m candidates.

Example 23.7. For the 6,560 marginal queries at $\alpha = 0.1$, a dataset of $m = 1897$ records suffices, and there are $256^{1897} \approx 10^{4568}$ candidates. Equation 23.23 asks for 4.21×10^5 records at $\varepsilon = 1$. For a universe of 2^{20} and $\alpha = 0.05$, the last column of Table 23.4 shows that SmallDB's bound is close to that of private multiplicative weights.

23.8. Code

The script code/query_release.py computes every number in this chapter and draws every figure: it runs the baselines and every algorithm on the running example and evaluates every bound. From the repository root:

```
uv run python code/part03-dp-foundations/query_release.py
```

Table 23.5.: The script's output with the default seed.

Experiment	Result
Running example	$N = 256$, $\lvert\mathcal{Q}\rvert = 6560$ cells in 255 tables; uniform histogram error 0.232
Baselines, $n = 10{,}000$	Laplace scale 0.0510, largest error 0.497; Gaussian $\mu = 0.2367$, standard deviation 0.0095, largest error 0.037
Halving, 1,024 experts	At most 6 mistakes in 20 runs; bound 10
Non-private multiplicative weights, $\alpha = 0.05$	148 corrections against the bound 8,872; regret 16.70 against 225.5
Private multiplicative weights, $\varepsilon = 1$	Table 23.3; best $T = 38$
Budget per step at $\delta = 10^{-6}$	$T = 100$: 0.00500, 0.00673, 0.01322; $T = 1000$: 0.00050, 0.00213, 0.00418
Records needed	Table 23.4; closed form 1.55×10^7 at 10^6 queries
SmallDB, $\alpha = 0.1$	$m = 1897$; 10^{4568} candidates; 4.21×10^5 records
Online private multiplicative weights, $\alpha = 0.05$	$c = 88{,}723$ for $N = 2^{20}$, 8.39×10^7 records for $K = 10^6$; $c = 35{,}490$ for $N = 256$

tests/test_query_release.py checks that the output still matches.

23.9. Summary

Table 23.6.: The results of this chapter, and where each is used.

Result	Statement	Use
Proposition 23.1	$q(D) = \langle q, p \rangle$, with sensitivity $1/n$	A histogram is a synthetic dataset
Proposition 23.2	Laplace: $n \geq \lvert\mathcal{Q}\rvert \ln(\lvert\mathcal{Q}\rvert/\beta)/(\alpha\varepsilon)$; Gaussian: $n \geq \sqrt{\lvert\mathcal{Q}\rvert}\, z/(\mu\alpha)$	For up to thousands of queries, Gaussian noise scaled to the workload's structure
Lemma 23.1	$-x - x^2 \leq \ln(1-x) \leq -x$ for $\lvert x\rvert \leq \frac{1}{2}$	Keep $\eta \leq \frac{1}{2}$ and losses in $[-1, 1]$
Theorem 23.1	Regret $\leq \eta T + \ln N/\eta$, and $\leq 2\sqrt{T \ln N}$ at $\eta = \sqrt{\ln N/T}$	Learning with exponentially many experts; DP-FTRL
Theorem 23.2	$U < 4 \ln N/\alpha^2$ corrections at $\eta = \alpha/2$	Spend the budget on corrections, not on queries
Lemma 23.2	$\varepsilon_0 = \varepsilon/(2\sqrt{2k \ln(1/\delta)})$ gives (ε, δ)-DP for $\varepsilon \leq 8 \ln(1/\delta)$	A closed-form per-step budget; the exact one is up to twice as large
Theorem 23.3	Error $\leq 2\sqrt{\ln N/T} + \frac{2}{n\varepsilon_0}(\ln\lvert\mathcal{Q}\rvert + 2 \ln \frac{2T}{\beta})$	Synthetic data for a fixed workload; release the average and choose T by the bound
Corollary 23.1	$n \geq 64\sqrt{\ln N \ln(1/\delta)}\, L/(\alpha^2\varepsilon)$; $108 L \ln N/(\alpha^3\varepsilon)$ under pure DP	When the queries far outnumber the records; time proportional to N
Theorem 23.4	$c = \lceil 16 \ln N/\alpha^2 \rceil$ corrections; $n \geq 32(\ln K + \ln(4c/\beta))/(\alpha\varepsilon_0)$	Interactive query servers with adaptive queries
Theorem 23.5	$n \geq 4(m \ln N + \ln(1/\beta))/(\alpha\varepsilon)$ with $m = \lceil 2 \ln(2\lvert\mathcal{Q}\rvert)/\alpha^2 \rceil$; time N^m	What the exponential mechanism can do when running time is ignored

24. Beyond global sensitivity

The Laplace and Gaussian mechanisms add noise scaled to the **global sensitivity** of a query f, the most that changing one record can move f over every pair of neighbouring datasets that could exist (Definition 20.1). For counts that is the right scale, but the median of ages in $[0, 100]$ has global sensitivity 100. On a dataset with half its people at 0 and half at 100, one person moves the median from one end to the other. Yet on the dataset you actually hold, the median of 1,001 ages moves by about a tenth of a year when one person changes. This chapter asks whether you can add noise on the scale of the data you have and still satisfy differential privacy (DP).

The answer is yes, and one idea organizes every method: the noise scale is itself a function of the data, so it must be private too. Smooth sensitivity, propose-test-release and inverse sensitivity repair the leak for a statistic like the median. Stability-based release handles discrete answers, subsample-and-aggregate handles black-box estimators, and clipping handles unbounded data, at the price of a bias.

The running example is the median of $n = 1{,}001$ synthetic ages, drawn from a normal distribution with mean 38 and standard deviation 14 and clipped to $[0, 100]$, released with $\varepsilon = 1$ and, where needed, $\delta = 10^{-6}$. Its median is 36.96, and one changed age moves it by at most 0.1386 years. Values lie in a range $[0, \Lambda]$, with $\Lambda = 100$ for the ages, and are sorted as $x_1 \le ... \le x_n$. Datasets have a fixed size n, and their neighbours $D \sim D'$ differ by one replaced record (The definition of differential privacy), so the **Hamming distance** $d(D, D'')$ to any third dataset counts the records in which they differ. Every proof bounds the privacy loss of an output y, how much more likely y is under D than under D',

$$L_{D,D'}(y) = \ln \frac{p_{M(D)}(y)}{p_{M(D')}(y)}, \tag{24.1}$$

and pure ε-DP holds exactly when it never exceeds ε for any neighbours in either order.

24.1. Local sensitivity, and why it leaks

Global sensitivity takes a maximum over all pairs of neighbours, including pathological ones. The natural fix is to take the maximum only over the neighbours of the dataset you hold. This section computes that quantity for the median and shows why noise proportional to it is not private.

Definition 24.1 (Local sensitivity)**.** The **local sensitivity** of a real-valued query f at a dataset D is the most that one record can move f starting from D itself,

$$\mathrm{LS}_f(D) = \max_{D' \sim D} |f(D) - f(D')|. \tag{24.2}$$

The global sensitivity is its worst case over all datasets, $\Delta f = \max_D \mathrm{LS}_f(D)$, so $\mathrm{LS}_f(D) \le \Delta f$ always.

For the median, and for its smooth sensitivity in Section 24.2, you need to know how far an order statistic can travel when k records change.

Lemma 24.1 (Changing k records moves each order statistic by at most k places)**.** *Sort the values of D as $x_1 \le \ldots \le x_n$, all in $[0, \Lambda]$, and pad with $x_i = 0$ for $i \le 0$ and $x_i = \Lambda$ for $i > n$. If D'' differs from D in at most k records and has sorted values $x''_1 \le \ldots \le x''_n$, then for every rank j,*

$$x_{j-k} \le x''_j \le x_{j+k}. \tag{24.3}$$

Proof.

1. *Upper bound.* At least $j + k$ values of D are at most x_{j+k}, and the padding makes this true when $j + k > n$. Changing k records removes at most k of them, so at least j values of D'' are still at most x_{j+k}, which says that $x''_j \le x_{j+k}$.
2. *Lower bound.* At least $n - j + k + 1$ values of D are at least x_{j-k}, and at least $n - j + 1$ of them survive k changes, so $x''_j \ge x_{j-k}$.

□

Proposition 24.1 (Local and global sensitivity of the median)**.** *Let n be odd and $m = (n + 1)/2$, so that the median of D is x_m. Then*

$$\mathrm{LS}_{\mathrm{med}}(D) = \max\left(x_m - x_{m-1},\ x_{m+1} - x_m\right), \qquad \Delta\,\mathrm{med} = \Lambda. \tag{24.4}$$

Proof.

1. *The median of a neighbour lies between x_{m-1} and x_{m+1}.* This is Lemma 24.1 with $k = 1$ and $j = m$.
2. *Both ends are reached.* Replacing x_m by Λ makes x_{m+1} the m-th smallest value. Replacing it by 0 puts the new 0 first, and x_{m-1} becomes the m-th smallest.
3. *The global sensitivity.* With m values at 0 and $m - 1$ at Λ, the gap above the median is Λ, and no gap can exceed Λ.

□

Now add Laplace noise scaled to the local sensitivity, $M_{\mathrm{LS}}(D) = f(D) + \mathrm{Lap}(\mathrm{LS}_f(D)/\varepsilon)$. The proof of Theorem 20.1 needs the same scale on both sides of the pair, but by Equation 24.4 one record can change this scale from 0 to Λ, and then no (ε, δ) guarantee survives.

Proposition 24.2 (Noise scaled to the local sensitivity is not private)**.** *For the median with $n = 5$ and $\Lambda = 100$, there is a neighbouring pair on which M_{LS} is not (ε, δ)-DP for any finite ε and any $\delta < 1$ (Nissim, Raskhodnikova & Smith 2007, Example 1).*

Proof.

1. *A dataset that gets no noise.* $D = (0, 0, 0, 0, 100)$ has median 0 and both gaps next to it are 0, so $\mathrm{LS}_{\mathrm{med}}(D) = 0$, the noise has scale 0, and $M_{\mathrm{LS}}(D) = 0$ exactly.
2. *Its neighbour gets wide noise.* $D' = (0, 0, 0, 100, 100)$ also has median 0, but the gap above it is 100. So $M_{\mathrm{LS}}(D')$ has a continuous distribution, which equals 0 with probability 0.

3. *The inequality fails.* The output 0 has probability 1 under D and 0 under D', so DP would need $1 \le e^{\varepsilon} \cdot 0 + \delta$, which no $\delta < 1$ satisfies.

□

Example 24.1. The leak needs neither a degenerate dataset nor different answers. Take $\Lambda = 100$, $\varepsilon = 1$ and the neighbours of Table 24.1, which have the same median but local sensitivities six times apart.

Table 24.1.: Two neighbouring datasets with the same median and very different local sensitivities.

Dataset	Values	Median	LS
D	10, 20, 30, 31, 90	30	$\max(30-20, 31-30) = 10$
D' (31 replaced by 90)	10, 20, 30, 90, 90	30	$\max(30-20, 90-30) = 60$

The releases are $30 + \mathrm{Lap}(10)$ and $30 + \mathrm{Lap}(60)$. The narrow density decays six times faster, so the log-ratio of the two Laplace densities grows with the distance from the centre:

$$L_{D',D}(y) = \ln \frac{20}{120} + |y-30|\Big(\frac{1}{10} - \frac{1}{60}\Big) = -1.792 + \frac{|y-30|}{12}. \tag{24.5}$$

No pure ε holds (Figure 24.1). The loss exceeds 1 once $|y-30| > 33.50$, which happens with probability 0.572 under D' and 0.0351 under D. The smallest δ for which the pair is $(1,\delta)$-DP, its privacy profile of Divergences, is $0.572 - e \times 0.0351 = 0.477$ with D' in the numerator, and the script finds 0.215 with the roles swapped. An adversary tells the two apart by the width of the noise, not its centre.

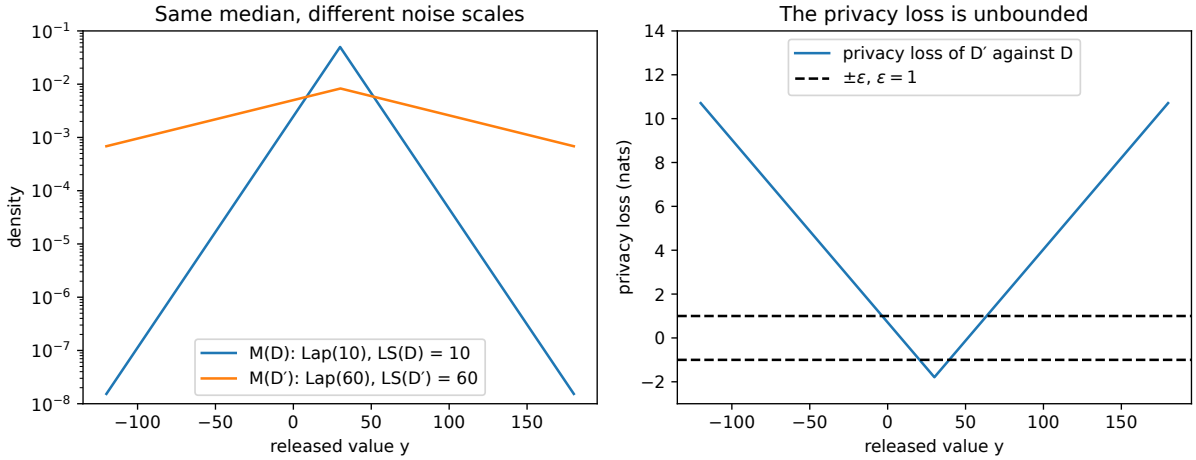

Figure 24.1.: Left: the two releases of Example 24.1, with Laplace noise of scales 10 and 60. Right: their privacy loss, which crosses $\varepsilon = 1$ at distance 33.5.

24.2. Smooth sensitivity

The leak came from a noise scale that jumps between neighbours. So use a scale that cannot jump: an upper bound on the local sensitivity that changes by at most a factor e^{β} between neighbours, since stretching noise by e^{β} moves its log-density by about β. This section finds the smallest such bound (Nissim, Raskhodnikova & Smith 2007) and computes it for the median; Section 24.3 says which noise it can be used with.

Definition 24.2 (Smooth upper bound and smooth sensitivity)**.** Let $\beta > 0$. A function S of the dataset is a **β-smooth upper bound** on LS_f if

$$S(D) \geq \mathrm{LS}_f(D) \quad \text{and} \quad S(D) \leq e^{\beta} S(D') \quad \text{for all } D \sim D'. \tag{24.6}$$

A dataset D'' at distance k with a large local sensitivity forces such a bound up at D too, discounted by a factor $e^{-\beta}$ per step. So the **β-smooth sensitivity** of f takes the maximum over every dataset D'' of size n,

$$S^*_{f,\beta}(D) = \max_{D''} \ \mathrm{LS}_f(D'')\, e^{-\beta\, d(D, D'')}. \tag{24.7}$$

Proposition 24.3 (The smooth sensitivity is the smallest smooth upper bound)**.** *$S^*_{f,\beta}$ is a β-smooth upper bound on LS_f, and every β-smooth upper bound S satisfies $S(D) \geq S^*_{f,\beta}(D)$ for every D.*

Proof.

1. *Upper bound.* The term $D'' = D$ of Equation 24.7, at distance 0, contributes $\mathrm{LS}_f(D)$, and a maximum is at least each of its terms.
2. *Smooth.* A path from D' to D'' can go through D first, so $d(D', D'') \leq 1 + d(D, D'')$. Each term of $S^*_{f,\beta}(D')$ is then at least $e^{-\beta}$ times the term for the same D'' in $S^*_{f,\beta}(D)$. Maximizing over D'' gives $S^*_{f,\beta}(D') \geq e^{-\beta} S^*_{f,\beta}(D)$, and exchanging the two neighbours gives the other direction.
3. *Smallest.* Let S be any β-smooth upper bound and D'' a dataset at distance k from D. Walking from D'' to D in k steps, S falls by at most a factor $e^{-\beta}$ per step, so $S(D) \geq e^{-\beta k} S(D'') \geq e^{-\beta k} \mathrm{LS}_f(D'')$. Maximizing over D'' gives $S(D) \geq S^*_{f,\beta}(D)$.

□

The smooth sensitivity is positive even where the local sensitivity is 0. On the degenerate pair of Proposition 24.2 it is already $100e^{-\beta}$ at D, the discounted local sensitivity of its neighbour D' (Exercise 7 in the exercise book).

You cannot enumerate all datasets, but all those at distance k get the same discount, so you need only the largest local sensitivity within each distance (a closer dataset counted again gets a smaller weight, which changes nothing):

$$S^*_{f,\beta}(D) = \max_{k=0,\ldots,n} e^{-k\beta} A^{(k)}(D), \qquad A^{(k)}(D) = \max_{D'':\ d(D,D'') \leq k} \mathrm{LS}_f(D''). \tag{24.8}$$

For the median, $A^{(k)}$ is the widest gap that k changes can open next to the median. You open one by moving the k values between two order statistics $k+1$ ranks apart out to 0 or Λ, so that the emptied window ends up next to the median.

Proposition 24.4 (The smooth sensitivity of the median)**.** *For the median, with the sorting and padding of Lemma 24.1, the largest local sensitivity within k changes is the widest of $k+2$ windows of the sorted data,*

$$A^{(k)}(D) = \max_{0 \le t \le k+1} (x_{m+t} - x_{m+t-k-1}), \qquad k = 0, \dots, n, \tag{24.9}$$

where the window with index t runs from rank $m+t-k-1$ to rank $m+t$ (Nissim, Raskhodnikova & Smith 2007, Proposition 3.4). Since $A^{(n)} = \Lambda$ and each $A^{(k)}$ costs one subtraction per window, $S^*_{\mathrm{med},\beta}$ takes $O(n^2)$ operations.

Proof. Steps 1 to 4 show that no dataset within distance k has a gap next to its median wider than the widest window, and step 5 shows that every window is reached.

1. *What the gap looks like.* Let D'' be within distance k of D, with sorted values $x''_1 \le \dots \le x''_n$. By Equation 24.4 its local sensitivity is one of its two gaps next to the median. Take the upper one, (x''_m, x''_{m+1}), since the reflection $x \mapsto \Lambda - x$ turns lower gaps into upper ones and maps the windows of Equation 24.9 to themselves.
2. *The gap contains at most k original values.* Assume the gap is positive, and let x_ℓ be the largest value of D at or below x''_m. No value of D'' lies strictly inside the gap, so the values of D inside it, say $x_{\ell+1}, \dots, x_{\ell+j}$, were all changed, and $j \le k$. The next value $x_{\ell+j+1}$ is then at or above x''_{m+1}, so the gap is at most $x_{\ell+j+1} - x_\ell$.
3. *The gap sits near rank m.* Exactly m values of D'' are at or below x''_m. Each is an unchanged value among $x_1, \dots, x_\ell$ or one of at most k new values, so $m \le \ell + k$. And at least $\ell - (k-j)$ of $x_1, \dots, x_\ell$ are unchanged, because j of the k changes were used inside the gap, and these unchanged values are among the m, so $\ell - (k-j) \le m$.
4. *Fit it in a window.* If $\ell \le m$, the window from rank ℓ to rank $\ell + k + 1$ has $t = \ell + k + 1 - m$ in $[0, k+1]$ by step 3, and it contains the span of step 2 because $j \le k$. If $\ell > m$, the window with $t = k+1$ runs from rank m to rank $m+k+1$, which is at least $\ell + j + 1$ by the second inequality of step 3, and contains it.
5. *Every window is reached.* The window with index t has k values strictly between its ends, at ranks $\ell = m + t - k - 1$ and $u = m + t$. Moving $k + 1 - t$ of them to 0 and the rest to Λ gives x_ℓ rank m (or $m - 1$ when $t = 0$), so the median sits at one end of an empty interval of length $x_u - x_\ell$. With $k = n$ and $t = m$ the window runs from the padded $x_0 = 0$ to $x_{n+1} = \Lambda$, so $A^{(n)} = \Lambda$ and no larger k is needed.

□

Example 24.2. Take $D = (1, 3, 4, 6, 9)$ on $[0, 10]$, with median 4. Table 24.2 evaluates Equation 24.9 with $\beta = 0.5$ and checks it against brute force over all $11^5 = 161{,}051$ datasets with values in $\{0, \dots, 10\}$.

Table 24.2.: The smooth sensitivity of the median of $D = (1, 3, 4, 6, 9)$ on $[0, 10]$ with $\beta = 0.5$: the formula for $A^{(k)}$ against brute force over all datasets, and the discounted values whose maximum is $S^*_{0.5}$.

k	Windows $x_{m+t} - x_{m+t-k-1}$, $t = 0, \dots, k+1$	$A^{(k)}$	Brute force	$e^{-0.5k} A^{(k)}$
0	$4-3,\ 6-4$	2	2	2.00
1	$4-1,\ 6-3,\ 9-4$	5	5	**3.03**
2	$4-0,\ 6-1,\ 9-3,\ 10-4$	6	6	2.21
3	$4-0,\ 6-0,\ 9-1,\ 10-3,\ 10-4$	8	8	1.79
4	$\dots,\ 9-0,\ 10-1,\ \dots$	9	9	1.22
5	$\dots,\ 10-0,\ \dots$	10	10	0.82

The local sensitivity is 2, the gap from 4 up to 6. But moving the 6 up to 10 opens a gap of $9 - 4 = 5$, and even after the discount $e^{-0.5} = 0.6065$ that beats 2, so $S^*_{0.5}(D) = 3.03$ at $k = 1$ (Figure 24.2, left). For the 1,001 ages the formula gives $S^*_{\text{med},1/6} = 0.1632$ at $k = 7$ and $S^*_{\text{med},0.0322} = 0.5144$ at $k = 21$, since a smaller β discounts distant datasets less. Section 24.3 says where these two values of β come from.

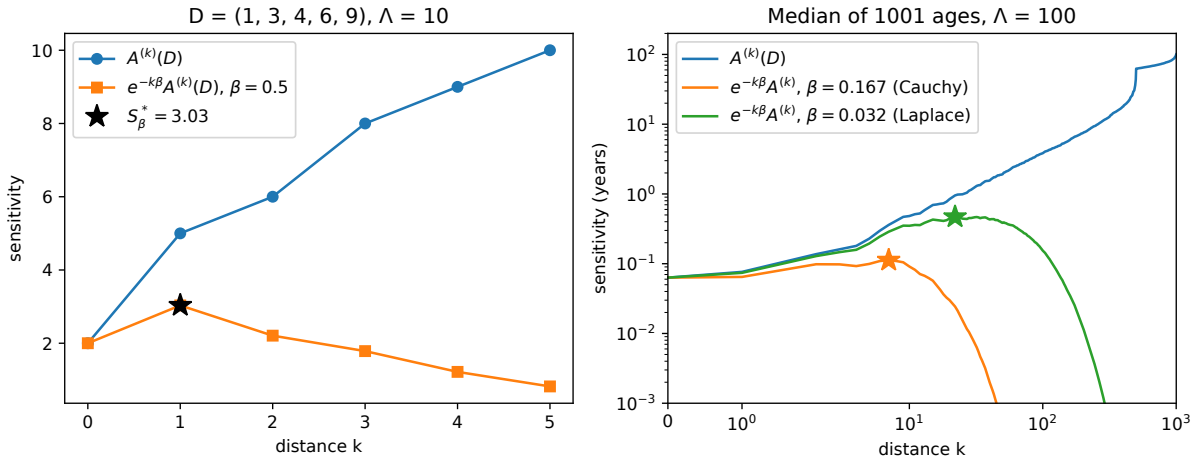

Figure 24.2.: Left: $A^{(k)}$ and $e^{-k\beta} A^{(k)}$ for the walkthrough dataset, with the star at $S^*_{0.5} = 3.03$. Right: the same for 1,001 synthetic ages (a fresh draw) with $\beta = 1/6$ and $\beta = 0.032$.

24.3. Admissible noise for smooth sensitivity

A smooth bound still changes by up to a factor e^{β}. This section asks which noise tolerates that, in the mechanism

$$M(D) = f(D) + \frac{S(D)}{\alpha} Z, \tag{24.10}$$

where Z has a fixed density h and the constant $\alpha > 0$ sets how many noise scales one record's shift of f is worth. The answer depends on the tail of h, because a light-tailed density and a stretched copy of it have a log-ratio that grows without bound, as in Example 24.1.

Theorem 24.1 (Pure DP with Cauchy-like noise)**.** *Let $h_\gamma(z) \propto 1/(1+|z|^\gamma)$ with $\gamma > 1$, a density whose tails decay like $|z|^{-\gamma}$; $\gamma = 2$ is the standard Cauchy. Let S be a β-smooth upper bound on LS_f, and let*

$$\gamma\alpha + (\gamma+1)\beta \le \varepsilon. \tag{24.11}$$

Then Equation 24.10 with $Z \sim h_\gamma$ is ε-DP.

Proof. The plan is to split the privacy loss at an output y into three pieces, for the scales, the centres and the stretch of the noise draw, and to bound each.

1. *Write out the privacy loss.* The density of $M(D)$ at y is $\frac{\alpha}{S(D)}h(z)$, where $z = \alpha\frac{y-f(D)}{S(D)}$ is the draw that produces y from D, and likewise for D' with z'. Substituting y in terms of z shows that z' is z shifted, then stretched:

$$z' = e^\kappa(z+v), \qquad e^\kappa = \frac{S(D)}{S(D')}, \quad v = \alpha\,\frac{f(D)-f(D')}{S(D)}. \tag{24.12}$$

   Inserting $h(z+v)$ in the middle of the ratio splits the log-ratio of the densities into three terms:

$$L_{D,D'}(y) = \underbrace{\ln\frac{S(D')}{S(D)}}_{\text{scale}} + \underbrace{\ln\frac{h(z)}{h(z+v)}}_{\text{sliding}} + \underbrace{\ln\frac{h(z+v)}{h(e^\kappa(z+v))}}_{\text{dilation}}. \tag{24.13}$$

2. *Size of the shift and the stretch.* Smoothness gives $|\kappa| \le \beta$. One record moves f by at most $\mathrm{LS}_f(D) \le S(D)$, so $|v| \le \alpha$, the only use of the upper-bound property.
3. *Scale term.* It is at most β, by smoothness.
4. *Sliding term.* Write $\psi(u) = \ln(1+u^\gamma)$, so that $-\ln h_\gamma(z) = \psi(|z|)$ plus a constant. Its slope $\gamma u^{\gamma-1}/(1+u^\gamma)$ is at most γ, because $u^{\gamma-1} \le 1+u^\gamma$ both for $u \le 1$ and for $u > 1$. The arguments $|z|$ and $|z+v|$ differ by at most $|v|$, so by the mean value theorem the term is at most $\gamma|v| \le \gamma\alpha$.
5. *Dilation term.* With $w = |z+v|$ and $\kappa \ge 0$, the inequality $(1+ca)/(1+a) \le c$ for $c \ge 1$ gives

$$\frac{h(w)}{h(e^\kappa w)} = \frac{1+e^{\kappa\gamma}w^\gamma}{1+w^\gamma} \le e^{\kappa\gamma} \tag{24.14}$$

   for every w, however far in the tail; that is what the power-law tail buys. For $\kappa < 0$ the argument moves towards 0, where h is larger, and the ratio is at most 1. So the term is at most $\gamma\beta$.
6. *Add up.* The loss is at most $\beta + \gamma\alpha + \gamma\beta \le \varepsilon$ at every y, which is pure ε-DP.

□

Nissim, Raskhodnikova & Smith (2007, Lemma 2.7) take $\alpha = \beta = \varepsilon/(2(\gamma+1))$, which for the Cauchy gives the release $f(D) + \frac{6}{\varepsilon}S^*_{f,\varepsilon/6}(D)\,Z$ with loss bound $0.8333\,\varepsilon$; Exercise 2 in the exercise book sharpens the sliding constant and divides the noise scale by three. For Laplace noise the dilation term grows with the draw, so the condition gains a term that charges for draws above $\ln(1/\delta)$.

Theorem 24.2 (Approximate DP with Laplace noise)**.** *Let $Z \sim \mathrm{Lap}(1)$, with density $\frac{1}{2}e^{-|z|}$, let S be a β-smooth upper bound on LS_f, let $\delta \in (0,1)$, and let*

$$\beta + e^{\beta}\alpha + (e^{\beta}-1)\ln(1/\delta) \le \varepsilon. \tag{24.15}$$

Then Equation 24.10 is (ε,δ)-DP.

Proof.

1. *Reuse the split.* Steps 1 to 3 of the proof of Theorem 24.1 did not use the shape of h. So the loss is the scale term, at most β, plus $\ln(h(z)/h(z'))$ with $z' = e^{\kappa}(z+v)$, $|\kappa| \le \beta$ and $|v| \le \alpha$.
2. *Bound the shape term by the draw.* For the Laplace density that log-ratio is $|z'| - |z|$. The triangle inequality and the bounds on κ and v give

$$\ln \frac{h(z)}{h(z')} \le e^{\beta}(|z|+\alpha) - |z| = (e^{\beta}-1)|z| + e^{\beta}\alpha. \tag{24.16}$$

3. *The rare draws pay δ.* A $\mathrm{Lap}(1)$ variable exceeds $\ln(1/\delta)$ in absolute value with probability exactly δ. Outside that event the loss is at most the left side of Equation 24.15, hence at most ε. By Lemma 20.2 the smallest δ that works for a pair is at most the probability that the loss exceeds ε, so the mechanism is (ε,δ)-DP.

□

Nissim, Raskhodnikova & Smith (2007, Lemma 2.9) split the budget as $\alpha = \varepsilon/2$ and $\beta = \varepsilon/(2\ln(2/\delta))$. With either split β must shrink like $1/\ln(1/\delta)$, because Laplace noise cannot give pure DP. Pure DP needs h at a point and at a stretched point to stay within a bounded ratio however far out the point is, and applying that repeatedly shows that h can decay at most like a power. A density that tolerates the shift and the rescaling is called **admissible**.

Heavy tails have a price. A standard Cauchy variable has $\Pr[|Z| \le t] = \frac{2}{\pi}\arctan t$, so $|Z|$ has median 1, but about one release in 16 is off by more than ten times that ($\Pr[|Z| > 10] = 0.0635$, against $e^{-10} \approx 4.5 \times 10^{-5}$ for Laplace noise).

Example 24.3. Release the median of the 1,001 ages with $\varepsilon = 1$, and compare the options by their median absolute error, which for noise bZ is b for the Cauchy and $b\ln 2$ for the Laplace. With global sensitivity it is $100\ln 2 = 69.31$ years. Cauchy noise with $\alpha = \beta = 1/6$ uses $S^*_{\mathrm{med},1/6} = 0.1632$, barely above the local sensitivity, so its error is $6 \times 0.1632 = 0.979$ (simulated: 0.980). Laplace noise with $\delta = 10^{-6}$ and $\alpha = 1/2$ allows $\beta = 0.0322$ by Equation 24.15, close to the 0.0345 of Nissim, Raskhodnikova & Smith. Then $S^*_{\mathrm{med},0.0322} = 0.5144$, the noise scale is 1.029 and the error is 0.713.

Both smooth releases are 70 to 100 times more accurate than the global one, and the gain grows with n (Figure 24.3). Below about 20 points the smooth noise is worse, because a handful of changes can then open a gap of nearly the whole range.

24.4. Propose-test-release

Smooth sensitivity needs a formula like Equation 24.9, and those are known for only a few functions. Dwork & Lei (2009) take a cruder route. Propose a bound b on the local sensitivity, check privately that the data are far from any dataset where it fails, and only then release with noise of scale b/ε. The check counts how many changes it takes before something bad happens, and the proof needs such a count to have sensitivity 1.

Lemma 24.2 (Distances to a set have sensitivity 1)**.** *For any set $\mathcal{B}$ of datasets, let* $\operatorname{dist}(D, \mathcal{B}) = \min_{D'' \in \mathcal{B}} d(D, D'')$ *be the number of changes needed to reach the nearest of them. Then* $|\operatorname{dist}(D, \mathcal{B}) - \operatorname{dist}(D', \mathcal{B})| \le 1$ *for all $D \sim D'$.*

Proof.

1. *One direction.* A path from D' into $\mathcal{B}$ can go through D first, so $d(D', D'') \le 1 + d(D, D'')$ for every D''. Minimizing over $D'' \in \mathcal{B}$ gives $\operatorname{dist}(D', \mathcal{B}) \le 1 + \operatorname{dist}(D, \mathcal{B})$.
2. *The other.* Exchange D and D'.

□

So a distance to a set can be released with $\mathrm{Lap}(1/\varepsilon)$ noise, and propose-test-release compares it with a threshold that noise alone lifts a distance of 0 above only with probability $\delta/2$.

Theorem 24.3 (Propose-test-release)**.** *Fix a proposed bound $b > 0$, $\varepsilon > 0$ and $\delta \in (0, 1)$. Let* $\operatorname{dist}_b(D) = \min\{d(D, D'') : \mathrm{LS}_f(D'') > b\}$ *be the number of records that must change before the local sensitivity can exceed b.* ***Propose-test-release*** *outputs*

- $\perp$ *if* $\operatorname{dist}_b(D) + \mathrm{Lap}(1/\varepsilon) \le \ln(1/\delta)/\varepsilon$*;*
- $f(D) + \mathrm{Lap}(b/\varepsilon)$ *otherwise.*

It is $(2\varepsilon, \delta/2)$-DP. For the median, $\operatorname{dist}_b(D) = \min\{k : A^{(k)}(D) > b\}$ *with $A^{(k)}$ from Equation 24.9.*

Proof. The plan is to split neighbouring pairs into two cases. If the proposal is right for the pair, the release is an ordinary Laplace mechanism. If it is wrong, both datasets sit at an unstable point and the test almost always refuses.

1. *The test is ε-DP.* dist_b is a distance to a set, so it has sensitivity 1 by Lemma 24.2, and adding $\mathrm{Lap}(1/\varepsilon)$ is the Laplace mechanism. Whether the test passes is post-processing of that noisy value.
2. *Case 1: $|f(D) - f(D')| \le b$.* The release $f(D) + \mathrm{Lap}(b/\varepsilon)$ has privacy loss at most ε by Theorem 20.1. The output is a function of two independent draws, each with loss at most ε, so by basic composition the mechanism is 2ε-DP on this pair.
3. *Case 2: $|f(D) - f(D')| > b$.* Then both local sensitivities exceed b, because each neighbour is in the other's maximum, so $\operatorname{dist}_b(D) = 0$. The test passes only if $\mathrm{Lap}(1/\varepsilon)$ exceeds $\ln(1/\delta)/\varepsilon$, which has probability $\frac{1}{2}e^{-\ln(1/\delta)} = \delta/2$.

4. *Bound case 2.* For any set S of outputs, $M(D)$ lands in S by refusing, if $\perp \in S$, or by releasing, with probability at most $\delta/2$. The refusal is post-processing of the ε-DP test, so its probability is at most $e^{\varepsilon} \le e^{2\varepsilon}$ times that under D', and

$$\Pr[M(D) \in S] \le e^{2\varepsilon} \Pr[M(D') \in S] + \delta/2. \tag{24.17}$$

5. *Combine.* Case 1 satisfies the same inequality, so every pair does.

□

When the data are stable the noise scale is set by the proposal, so it reveals nothing, and otherwise $\perp$ says only that the data were probably near an unstable dataset. The threshold is large, $\ln(10^6) = 13.82$ at $\varepsilon = 1$ and $\delta = 10^{-6}$, so the data must be stable against more than a dozen changes. The method needs only the distance to instability, which is often easier to bound than $S^*_{f,\beta}$, but it pays 2ε and can refuse.

The proposal must not depend on the data. Setting b to twice the observed local sensitivity makes the noise scale a function of the data again, and the leak of Section 24.1 returns.

Example 24.4. On the 1,001 ages, propose $b = 1$ year. The first k with $A^{(k)} > 1$ is 21, so $\mathrm{dist}_1(D) = 21$, and the test passes with probability $1 - \frac{1}{2}e^{-(21-13.82)} = 0.999621$. The release then has median absolute error $\ln 2 = 0.693$ years, at a total budget of 2. On 101 ages $\mathrm{dist}_1 = 1$, and the pass probability is $\frac{1}{2}e^{-(13.82-1)} = 1.36 \times 10^{-6}$. Figure 24.3 (right) shows it switching from 0 to 1 between $n = 500$ and $n = 1000$; Exercise 4 in the exercise book sizes the proposal for a given pass probability.

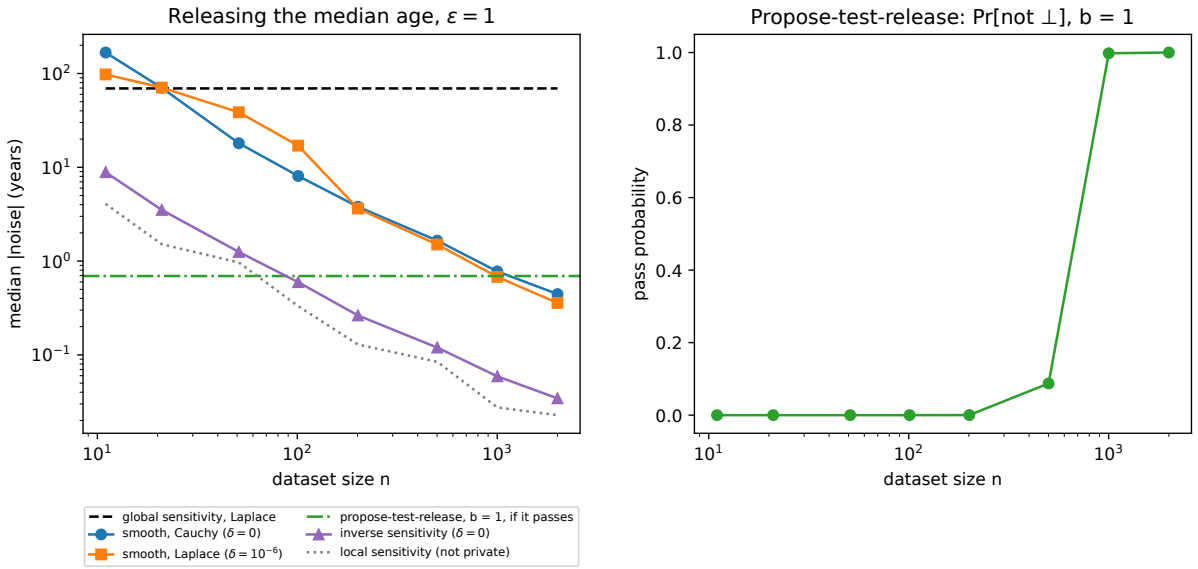

Figure 24.3.: Left: median absolute noise of each release of the median age with $\varepsilon = 1$, averaged over 10 synthetic datasets per n; the dotted line is the local sensitivity. Right: the probability that propose-test-release with $b = 1$ answers.

24.5. Inverse sensitivity

Smooth sensitivity and propose-test-release spend their effort on choosing a noise scale safely. Inverse sensitivity (Asi & Duchi 2020) has no noise scale. It samples each candidate output with a probability that falls exponentially in the number of records you would have to change to make it the true answer. That count is a distance to a set, so by Lemma 24.2 no smooth bound, test or refusal is needed.

Definition 24.3 (Inverse sensitivity and its mechanism)**.** The **inverse sensitivity** of f at D toward an output y is the number of records you must change to make f equal to y,

$$\operatorname{len}_f(D, y) = \min\{d(D, D'') : f(D'') = y\}. \tag{24.18}$$

The **inverse-sensitivity mechanism** samples y from $[0, \Lambda]$ with the density

$$p_D(y) = \frac{e^{-\varepsilon \operatorname{len}_f(D,y)/2}}{\int_0^\Lambda e^{-\varepsilon \operatorname{len}_f(D,y')/2}\,\mathrm{d}y'}. \tag{24.19}$$

This is the exponential mechanism with the score $-\operatorname{len}_f(D, y)$, and its proof is the exponential mechanism's.

Theorem 24.4 (The inverse-sensitivity mechanism is pure DP)**.** *If every output in* $[0, \Lambda]$ *is the value of* f *on some dataset of size* n*, so that every count* $\operatorname{len}_f(D, y)$ *is finite, then the mechanism of Equation 24.19 is* ε*-DP.*

Proof.

1. *The penalty has sensitivity 1.* For each y, $\operatorname{len}_f(D, y)$ is the distance from D to the non-empty set of datasets on which f equals y, so by Lemma 24.2 it changes by at most 1 between neighbours.
2. *Each weight moves by at most* $e^{\varepsilon/2}$*.* So the weight of each output changes by a factor between $e^{-\varepsilon/2}$ and $e^{\varepsilon/2}$, and so does the normalizer, an integral of such weights.
3. *Pointwise, hence pure DP.* The density is a weight over the normalizer, so $p_D(y)/p_{D'}(y) \le e^{\varepsilon/2} \cdot e^{\varepsilon/2} = e^{\varepsilon}$ at every y.

□

The factor 2 is needed because a weight and the normalizer can move in opposite directions. For the median the count has a closed form, and the density is a staircase, flat on each gap between sorted values.

Proposition 24.5 (The count for the median)**.** *Let* n *be odd, so that the median has rank* $m = (n + 1)/2$*, with the sorting and padding of Lemma 24.1. For a candidate* y *in the open gap* (x_i, x_{i+1})*,*

$$\operatorname{len}_{\text{med}}(D, y) = \begin{cases} m - i & \text{if } i < m, \\ i - m + 1 & \text{if } i \ge m. \end{cases} \tag{24.20}$$

Proof.

1. *Above the median.* Take $i \geq m$, so i values of D lie below y. A dataset with median y has at most $m-1$ values below y, and each change removes at most one, so at least $i-m+1$ changes are needed. That many suffice: move one value from below y to y and $i-m$ others to Λ.
2. *Below the median.* The reflection $x \mapsto \Lambda - x$ turns the gap with index $i < m$ into the gap with index $n - i \geq m$, and step 1 gives $(n-i) - m + 1 = m - i$, since $n + 1 = 2m$.

□

There is no noise scale to leak. Where the data are dense, the outputs a few steps from the median are also a short distance from it, so the error is a few gaps times a factor that grows with $1/\varepsilon$. Asi & Duchi (2020) show that, up to logarithmic factors, no ε-DP mechanism does much better on a dataset and its close neighbours, so the method is near-optimal dataset by dataset.

It has two limits. The outer gaps $(0, x_1)$ and (x_n, Λ) can be long and are m steps away, which is negligible for a thousand points but not for eleven. And the count must be computed: closed forms like Equation 24.20 are known for medians, quantiles and a few other statistics, and Exercise 8 in the exercise book extends it to any quantile.

Example 24.5. Take the walkthrough dataset $D = (1, 3, 4, 6, 9)$ on $[0, 10]$ with $\varepsilon = 1$. Table 24.3 lists its six gaps, their counts from Equation 24.20, and their probabilities, each its length times $e^{-\text{len}/2}$ over the total. The two gaps next to the median are one change away and together get probability $0.1477 + 0.2955 = 0.4432$.

Table 24.3.: The inverse-sensitivity release of the median of $D = (1, 3, 4, 6, 9)$ on $[0, 10]$ with $\varepsilon = 1$: each gap between sorted values, the number of changes that make a point of it the median, and its probability.

Gap	$(0, 1)$	$(1, 3)$	$(3, 4)$	$(4, 6)$	$(6, 9)$	$(9, 10)$
Length	1	2	1	2	3	1
$\text{len}_{\text{med}}(D, y)$	3	2	1	1	2	3
Probability	0.0544	0.1792	0.1477	0.2955	0.2688	0.0544

On the 1,001 ages the median absolute error, computed exactly from the density, is 0.0783 years (simulated: 0.0784). That is pure DP with no refusals, twelve times more accurate than smooth sensitivity with Cauchy noise (0.979), and even below the local sensitivity 0.1386, because a typical release lands only a few short gaps from the median. On 101 ages the error grows to 0.696 years, because the gaps are ten times wider.

24.6. Stability-based release

Some statistics take discrete values, such as the most common diagnosis or the model a selection procedure picks. On most datasets one record cannot change them, so their local sensitivity is 0. Propose-test-release with $b = 0$ then gives the **stability-based release**: test privately that

the data are far from any dataset where one change flips the answer, and if so release the answer exactly (Dwork & Roth 2014, ch. 7; Thakurta & Smith 2013).

Theorem 24.5 (Stability-based release)**.** *Let f be a discrete statistic, and let s be a* ***stability score****: a function of the data with sensitivity 1 that equals 0 on every dataset that has a neighbour where f gives a different answer. The stability-based release outputs*

$$M(D) = \begin{cases} \perp & \text{if } s(D) + \mathrm{Lap}(1/\varepsilon) \le \ln(1/\delta)/\varepsilon, \\ f(D) & \text{otherwise,} \end{cases} \tag{24.21}$$

and it is $(\varepsilon, \delta/2)$-DP. By Lemma 24.2, the distance to the set of datasets that have a neighbour with a different answer is one such score.

Proof. The proof is that of Theorem 24.3, except that nothing but the test depends on the data when the answers agree.

1. *The test is ε-DP*, as in step 1 of the proof of Theorem 24.3.
2. *Neighbours with the same answer.* The release is the same function of the test's outcome on both, so it is post-processing of an ε-DP output. The second ε that propose-test-release paid for its noisy answer is not needed.
3. *Neighbours with different answers.* Then $s(D) = s(D') = 0$, and the test passes with probability $\delta/2$. Step 4 of the proof of Theorem 24.3, with e^{ε} in place of $e^{2\varepsilon}$, gives $\Pr[M(D) \in S] \le e^{\varepsilon} \Pr[M(D') \in S] + \delta/2$ for every set S.

□

For the **mode** of a categorical dataset, the most frequent value with ties broken by a fixed order, a score can be read off the lead of the winner.

Proposition 24.6 (A stability score for the mode)**.** *Let the lead g be the top count minus the second-highest count. Under replacement,*

$$s(D) = \max\left(0,\ \lceil g/2 \rceil - 1\right) \tag{24.22}$$

is a stability score for the mode.

Proof.

1. *Sensitivity 1.* One replacement lowers one count by at most 1 and raises another by at most 1, so the lead moves by at most 2. Halving and rounding up turns that into a move of at most 1, since $\lceil (g+2)/2 \rceil = \lceil g/2 \rceil + 1$.
2. *Zero where the answer can flip.* If $g \ge 3$, after one change the mode keeps at least $c_1 - 1$ records, where c_1 is its count, and every other value has at most $c_2 + 1 \le c_1 - 2$, where c_2 is the second-highest count. So a dataset whose neighbour has a different mode has $g \le 2$, and then $s = 0$.

□

The release is exact, and the cost of privacy is the chance of a refusal, which depends on the lead and not on the number of possible values. The mode must lead by about $2\ln(1/\delta)/\varepsilon$ records, whether there are ten categories or a billion. Under pure DP, the packing lower bound of Lower bounds needs a lead of about $\ln N/\varepsilon$ to choose among N values, so this is how approximate DP gets around it. An exact release next to a flip happens with probability $\delta/2$, and that is what δ pays for.

Example 24.6. The median is not discrete, so take a mode, with $\varepsilon = 1$ and $\delta = 10^{-6}$ (threshold 13.82). Leads of 10, 30 and 40 records give scores 4, 14 and 19, and the release answers with probability 2.73×10^{-5}, 0.5842 and 0.9972. So a lead of 35 is needed for probability 0.95, whatever the number of categories. When a neighbour adds or removes a record instead, the lead needed halves (Exercise 9 in the exercise book).

24.7. Subsample-and-aggregate

Sometimes you cannot analyse f at all, because it is a trained model or a pipeline you did not write. Subsample-and-aggregate (Nissim, Raskhodnikova & Smith 2007; Smith 2011) runs f as a black box on disjoint pieces of the data and privately combines the answers. One record can change only one answer, so the aggregator needs to be private only with respect to one input.

Theorem 24.6 (Subsample-and-aggregate)**.** *Split the n records into B disjoint blocks of n/B records by a partition fixed in advance. Compute the block answers $a_j = f(\text{block } j)$, clamp each to $[0, R]$, and release*

$$M(D) = \frac{1}{B}\sum_{j=1}^{B} \operatorname{clip}_{[0,R]}(a_j) + \operatorname{Lap}\Big(\frac{R}{B\varepsilon}\Big). \tag{24.23}$$

This is ε-DP for any f. When the clipping is inactive and the blocks are independent samples, its mean squared error as an estimate of a target θ is, with a the output of f on one block,

$$\underbrace{\big(\mathbb{E}[a]-\theta\big)^2}_{\text{bias of } f \text{ on } n/B \text{ records}} + \underbrace{\frac{\operatorname{Var}(a)}{B}}_{\text{sampling}} + \underbrace{2\Big(\frac{R}{B\varepsilon}\Big)^2}_{\text{noise}}. \tag{24.24}$$

Proof. The privacy part bounds the sensitivity of the average; the error comes from squaring a sum of three independent pieces.

1. *One record touches one block.* The partition does not depend on the values, so replacing a record changes at most one block answer.
2. *The aggregate has sensitivity R/B.* After clamping, that answer moves by at most R, and the average divides by B.
3. *Privacy.* Laplace noise of scale $R/(B\varepsilon)$ on a quantity of sensitivity R/B is ε-DP by Theorem 20.1.
4. *Error.* The released value minus θ is the bias $\mathbb{E}[a]-\theta$, plus the mean-zero average of the $a_j - \mathbb{E}[a]$, with variance $\operatorname{Var}(a)/B$, plus the Laplace noise, with variance $2(R/(B\varepsilon))^2$. The cross terms of the square each contain an independent mean-zero factor and average to zero, which leaves Equation 24.24.

□

The noise falls like $1/B$, while the sampling term hardly moves, because a block estimate has about B times the variance of f on all records and averaging divides by B again. The bias of f on small blocks grows with B, so the best B balances bias and noise (Exercise 5 in the exercise book finds it in closed form). The partition must not depend on the values, or one record could reshuffle many records between blocks.

The proof never looks inside f, so the method suits trained models, as in private aggregation of teacher ensembles (Papernot et al. 2017). But the range R is still a global bound, and a loose R means large noise. Smith (2011) shows that for asymptotically normal estimators a version of the method loses nothing in the leading-order error.

Example 24.7. The running example has no black-box statistic, so take one: estimate the rate $\lambda = 1$ of $n = 10{,}000$ independent exponential inter-arrival times with $\varepsilon = 1$. The estimate $1/\bar{x}$, one over the sample mean, has infinite global sensitivity, because tiny times make it huge.

On a block of $n_b = n/B$ records the block sum G is gamma with shape n_b and rate λ, and the block estimate is $a = n_b/G$. Integrating $1/g$ and $1/g^2$ against the gamma density leaves gamma densities with shapes $n_b - 1$ and $n_b - 2$, which gives

$$\mathbb{E}[a] = \frac{n_b \lambda}{n_b - 1}, \qquad \text{bias } \frac{\lambda}{n_b - 1}, \qquad \operatorname{Var}(a) = \frac{n_b^2 \lambda^2}{(n_b - 1)^2 (n_b - 2)}. \tag{24.25}$$

With $R = 5$, Table 24.4 and Figure 24.4 show the trade-off; at $B = 10$ the noise standard deviation is $\sqrt{2} \times 0.5 = 0.7071$.

Table 24.4.: Error of subsample-and-aggregate for the rate of an exponential distribution, $n = 10{,}000$, $\lambda = 1$, $R = 5$, $\varepsilon = 1$: the three terms of Equation 24.24, their combination, and a simulation with 1,000 repetitions.

Blocks B	Block size	Bias	Sampling sd	Noise sd	Root-mean-square error	Simulated
10	1,000	0.0010	0.0100	0.7071	0.7072	0.7205
100	100	0.0101	0.0102	0.0707	0.0722	0.0733
250	40	0.0256	0.0105	0.0283	0.0396	0.0401
1,000	10	0.1111	0.0124	0.0071	0.1120	0.1114

Among the divisors of n shown, the best B is 250, with error 0.0396, where bias and noise are of similar size. A non-private estimate has standard deviation about $\lambda/\sqrt{n} = 0.0100$, so privacy at $\varepsilon = 1$ costs a factor of four, for an estimator whose sensitivity you never had to bound.

24.8. Clipping

The mean is the most common statistic of all, and on unbounded data its global sensitivity is infinite. **Clipping** replaces each value x by $\min(x, C)$ before averaging, so the sensitivity becomes C/n. But clipping changes the quantity you estimate, and the choice of C trades that bias against the noise. Applied to per-example gradients, the same move drives private model training in later parts.

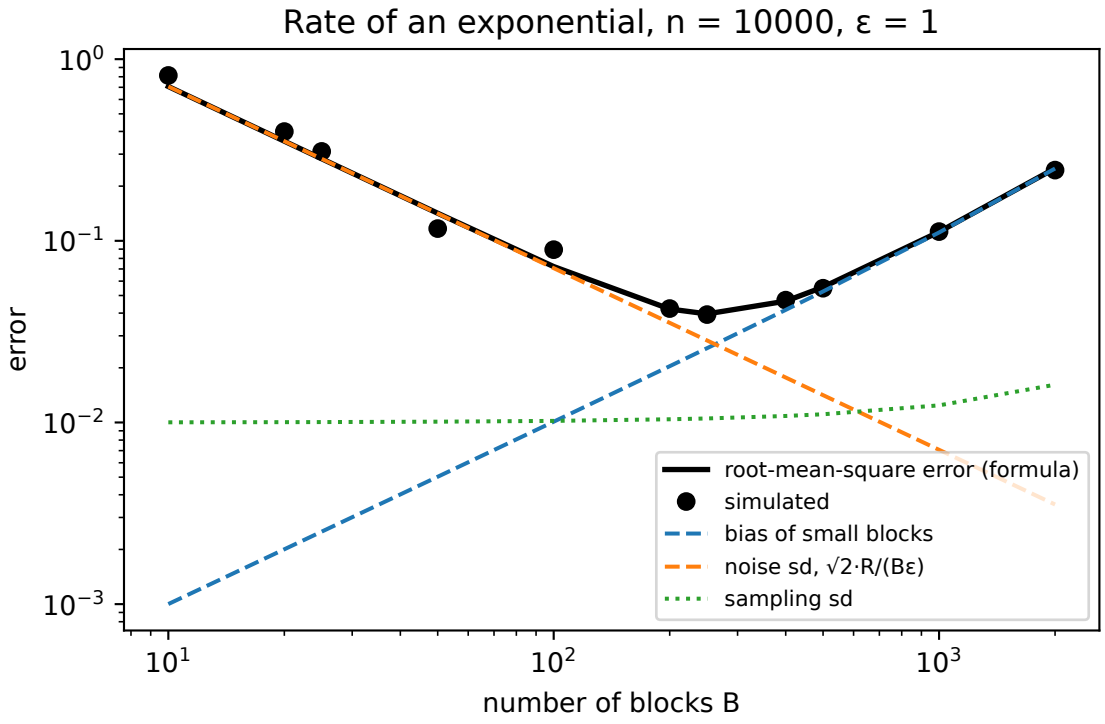

Figure 24.4.: Root-mean-square error of subsample-and-aggregate for the exponential rate against the number of blocks B, with its bias, noise and sampling components.

Theorem 24.7 (The clipped mean and its best clipping norm)**.** *Take non-negative data $X_1, \dots, X_n$ drawn independently from a distribution with mean μ, and write $(x - C)_+ = \max(x - C, 0)$ for the part of a value above C. The clipped mean*

$$M(D) = \frac{1}{n}\sum_{i=1}^{n} \min(X_i, C) + \mathrm{Lap}\Big(\frac{C}{n\varepsilon}\Big) \tag{24.26}$$

is ε-DP, and its mean squared error as an estimate of μ is

$$\mathrm{err}(C)^2 = \underbrace{\mathbb{E}[(X - C)_+]^2}_{\text{bias}^2} + \underbrace{\frac{\mathrm{Var}(\min(X, C))}{n}}_{\text{sampling}} + \underbrace{\frac{2C^2}{n^2\varepsilon^2}}_{\text{noise}}. \tag{24.27}$$

The clipping norm that minimizes it solves

$$\Pr[X > C]\Big(\mathbb{E}[(X - C)_+] - \frac{C - \mathbb{E}[\min(X, C)]}{n}\Big) = \frac{2C}{n^2\varepsilon^2}. \tag{24.28}$$

Proof. The privacy part is one line, the error splits as in Equation 24.24, and the best C is where the derivative of the error vanishes.

1. *Sensitivity.* Each clipped value lies in $[0, C]$, so one replacement moves the mean by at most C/n, and the noise makes it ε-DP by Theorem 20.1.
2. *The bias.* Clipping removes exactly the excess, $x - \min(x, C) = (x - C)_+$, so $\mu - \mathbb{E}[\min(X, C)] = \mathbb{E}[(X - C)_+]$.
3. *Error decomposition.* As in step 4 of the proof of Theorem 24.6, the error is the bias, a mean-zero sampling term with variance $\mathrm{Var}(\min(X, C))/n$ and independent noise with variance $2(C/(n\varepsilon))^2$, which gives Equation 24.27.
4. *Derivatives in C.* Raising C slightly raises $\min(X, C)$ by that amount exactly when $X > C$, so $\mathbb{E}[\min(X, C)]$ has derivative $\Pr[X > C]$ and $\mathbb{E}[\min(X, C)^2]$ has derivative $2C\Pr[X > C]$. By the chain rule the three terms have derivatives $-2\,\mathbb{E}[(X - C)_+]\Pr[X > C]$, then $\frac{2}{n}\Pr[X > C](C - \mathbb{E}[\min(X, C)])$, then $4C/(n^2\varepsilon^2)$.
5. *Set the sum to zero* and divide by 2, which is Equation 24.28.

□

The bias does not shrink with n, but the noise does, so the best C grows with n and moves into the tail (Exercise 6 in the exercise book solves Equation 24.28 for an exponential tail). Clipping from above always underestimates. Clipping to an interval around a centre cuts both sides, and the two cuts cancel for a symmetric distribution, which is why Private mean estimation first estimates the centre privately.

Choosing C is itself a data-dependent decision. Setting it to the observed maximum or the empirical 99th percentile brings back the leak of Section 24.1. Choose C from domain knowledge, or spend part of the budget on a private quantile by inverse sensitivity (Section 24.5).

Example 24.8. The ages are already bounded, so take incomes, in thousands, with $\ln X \sim \mathcal{N}(\ln 40, 0.8^2)$. The median is 40 and the mean is $e^{\ln 40 + 0.64/2} = 55.085$, pulled up by the heavy right tail. The averages of X and X^2 below C that Equation 24.27 needs have a closed form in the normal distribution function (Probability distributions), and Table 24.5 uses it with $n = 1000$ and $\varepsilon = 1$.

Table 24.5.: Error of the clipped private mean of log-normal incomes, $n = 1000$, $\varepsilon = 1$, for four clipping norms: the three terms of Equation 24.27, their combination, and a simulation with 5,000 repetitions.

Clipping norm C	$\Pr[X > C]$	Bias	Sampling sd	Noise sd	Root-mean-square error	Simulated
40 (the median)	0.5000	23.415	0.335	0.057	23.417	23.411
257.23 (99th percentile)	0.0100	0.924	1.462	0.364	1.767	1.747
331.34 (optimal)	0.0041	0.438	1.538	0.469	1.666	1.649
1000	0.0000	0.006	1.645	1.414	2.169	2.134

Clipping at the median cuts back half the incomes, and the bias of 23 dwarfs everything. The optimum, $C^* = 331.34$, cuts off 0.4% of the population and has error 1.666, only 1% above the standard deviation 1.649 of the unclipped, non-private mean. That the simulated error also prints as 1.649 is a coincidence of 5,000 repetitions, whose own standard error is about 1%. Above the optimum the noise takes over (Figure 24.5, left). The optimum grows with n: 177.5 at $n = 100$, 557.3 at $n = 10{,}000$ and 876.3 at $n = 100{,}000$ (Figure 24.5, right).

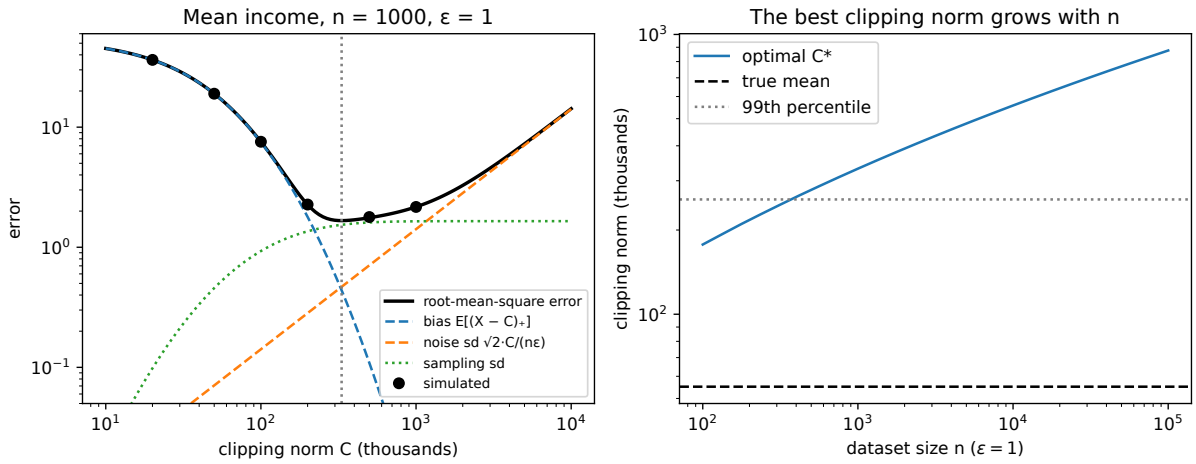

Figure 24.5.: Left: root-mean-square error of the clipped mean of incomes against C, with its components; the dotted line marks $C^* = 331$. Right: the optimal clipping norm against the dataset size.

24.9. Code

The script code/sensitivity.py computes every number in this chapter and draws its figures. From the repository root:

```
uv run python code/part03-dp-foundations/sensitivity.py
```

Table 24.6.: The script's output with seed 0.

Experiment	Result
Local-sensitivity noise, Table 24.1	smallest δ at $\varepsilon = 1$: 0.477 and 0.215
$A^{(k)}$, Table 24.2	Formula equals brute force; $S^*_{0.5} = 3.03$
Noise parameters	Cauchy loss bound 0.8333; Laplace $\beta = 0.0322$
Median of the ages, median error	Cauchy 0.979 (simulated 0.980); Laplace 0.713; global 69.31
Propose-test-release, $b = 1$, pass probability	0.999621 at $n = 1001$; 1.36×10^{-6} at $n = 101$
Subsample-and-aggregate	Best $B = 250$, error 0.0396
Inverse sensitivity, median error	0.0783 (simulated 0.0784); 0.696 on 101 ages
Stable mode, pass probability	0.5842 at a lead of 30; lead 35 for 0.95
Clipped mean of incomes	$C^* = 331.34$, error 1.666 (simulated 1.649)

tests/test_sensitivity.py checks that the output still matches this table.

24.10. Summary

Table 24.7.: The results of this chapter, and where each is used.

Result	Statement	Use
Definition 24.1	The most one record can move f from D	Never a noise scale on its own
Proposition 24.1	The larger gap next to the median; globally Λ	Medians and quantiles
Proposition 24.2	Noise scaled to LS_f is not private	Ask what a data-dependent scale reveals
Proposition 24.3	$S^*_{f,\beta}$ is the smallest β-smooth upper bound	Data-dependent noise with a proof
Proposition 24.4	$A^{(k)}$ is the widest of $k + 2$ windows	Pays off once n is in the hundreds
Theorem 24.1	Cauchy-like noise is ε-DP under Equation 24.11	Pure DP needs polynomial tails
Theorem 24.2	Laplace noise is (ε, δ)-DP under Equation 24.15	Light tails need δ and $\beta \approx \varepsilon/(2\ln(1/\delta))$
Lemma 24.2	A distance to a set of datasets has sensitivity 1	Any "how many changes until something bad" count

Result	Statement	Use
Theorem 24.3	Test the distance to instability, then add $\mathrm{Lap}(b/\varepsilon)$	Statistics with no formula for S^*; fix b before looking
Theorem 24.4	Exponential mechanism on the number of changes	Medians, quantiles, clipping norms
Theorem 24.5	Test a stability score, then release $f(D)$ exactly	The mode once its lead exceeds about $2\ln(1/\delta)/\varepsilon$
Theorem 24.6	Clamped average of block answers plus Laplace noise	Black-box estimators; teacher ensembles in Part 5
Theorem 24.7	Clipped mean plus Laplace noise; best C from Equation 24.28	Means and gradient clipping; never choose C from the raw data

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

25. Discrete and floating-point-safe mechanisms

Every privacy proof so far was a statement about real numbers, such as the proof in the Laplace and Gaussian mechanisms that compares two densities on the real line. A computer has only floating-point numbers, a finite set with uneven gaps, and random bits, so the program that "samples Lap(b)" produces a distribution that the proof says nothing about. Mironov (2012) showed that the gap matters: the textbook Laplace sampler has outputs that only one of two neighbouring datasets can produce, and an observer who sees one knows which dataset was used.

The one idea of this chapter is that **differential privacy (DP) is a property of the output distribution the code actually produces**, so the code must produce exactly the distribution the proof is about. One way there keeps floating point and rounds the output to a coarse grid, so that every output is reachable from every input. The other way samples integer noise for integer-valued queries exactly, from uniform random integers, which gives the discrete Laplace and the discrete Gaussian mechanisms.

The running example is a hospital's count of patients with a rare diagnosis, with sensitivity $\Delta_1 f = 1$ under add/remove neighbours, released at $\varepsilon = 1$. In a toy floating-point model of the Laplace mechanism, almost half of the outputs name the true count with certainty. The discrete Laplace releases the exact count with probability 0.4621, yet no output identifies the count, and the discrete Gaussian at $\sigma = 1$ has $\delta = 0.1414$ at $\varepsilon = 1$, close to the continuous Gaussian's 0.1269.

25.1. Floating-point Laplace breaks differential privacy

The textbook way to sample Lap(b) is inverse cumulative distribution function (CDF) sampling. Draw U uniform on $(0, 1)$ and a fair sign $\xi \in \{-1, +1\}$, and output $\xi \cdot b \ln(1/U)$. The magnitude exceeds a level z exactly when $U < e^{-z/b}$, so it is exponential with mean b (Probability distributions), and the sign mirrors it into Lap(b). In floating point, U, the logarithm and the sum with $f(D)$ are each rounded. This section asks whether the rounded mechanism is still DP, and the answer is no, for every ε.

The tool that shows it also audits any implementation. If some outputs can only come from D, seeing one of them reveals D with certainty, and since no factor e^{ε} can pay for that, δ has to.

Proposition 25.1 (The support argument)**.** *Let M be (ε, δ)-DP, let $D \sim D'$ be neighbouring datasets, and write $\mathcal{Y}_D$ for the set of outputs that $M(D)$ can produce. Let $S = \mathcal{Y}_D \setminus \mathcal{Y}_{D'}$ be the outputs reachable from D but not from D'. Then, whatever ε is,*

$$\delta \geq \Pr[M(D) \in S]. \tag{25.1}$$

In particular, if $\Pr[M(D) \in S] > 0$, then M is not ε-DP for any finite ε.

Proof.

1. *Apply the definition to the event S.* The definition of (ε, δ)-DP in the definition of differential privacy, applied to the set S, says that

$$\Pr[M(D) \in S] \leq e^{\varepsilon} \Pr[M(D') \in S] + \delta. \tag{25.2}$$

   By the choice of S the multiplicative term is 0 however large e^{ε} is, which leaves Equation 25.1.
2. *Pure DP.* Pure ε-DP is the case $\delta = 0$, where Equation 25.1 forces $\Pr[M(D) \in S] = 0$. So a positive probability rules out every finite ε.

□

Exercise 7 in the exercise book reads the argument as an attack, the test "say D when the output is in S", and reaches the same bound through the hypothesis-testing form of DP.

The floating-point sampler has such outputs because of how floats are spaced. A float with a p-bit significand (IEEE 754 doubles have $p = 53$) is $m \cdot 2^e$ for an integer $m < 2^p$, so floats are dense near 0 and sparse far from it. With $f(D) = 0$, the outputs near 0 are the fine-grained noise values themselves. With $f(D') = 1$, an output near 0 needs a noise value near -1, where floats are about 2^{-p} apart, and adding 1 keeps that coarse spacing. So many outputs of $M(D)$ near 0 are impossible under $M(D')$, and the mismatch of grids elsewhere works in both directions. In the narrow window of Figure 25.1 (left), 3 of the 9 outputs of $M(D)$ cannot come from $M(D')$, and 4 of the 10 outputs of $M(D')$ cannot come from $M(D)$.

Doubles have too many values to enumerate, so the chapter's script (Section 25.7) uses p-bit floats with p from 6 to 14. Its U is a real uniform rounded down to a p-bit float, the logarithm and the sum are each rounded to p bits, and every output's probability is computed exactly (Table 25.1).

Table 25.1.: The toy floating-point Laplace sampler with $b = 1$, $f(D) = 0$ and $f(D') = 1$. S is the set of outputs of $M(D)$ that $M(D')$ cannot produce, and S' the reverse.

Significand bits p	Outputs of $M(D)$	Outputs of $M(D')$	$\Pr[M(D) \in S]$	$\Pr[M(D') \in S']$
8	1,604	1,409	0.4795	0.2070
12	25,646	22,477	0.4791	0.2033
14	102,586	89,859	0.4826	0.2053

More precision does not help. The right panel of Figure 25.1 stays at about 48% from 6 to 14 bits, because adding bits refines both grids together. Mironov (2012) found the same effect at $p = 53$ in several DP libraries of the time. The leak is not in where the output lands on the real line but in which float it is, so printing the output to a few decimals would hide it. That is the idea behind snapping.

A second, smaller leak comes from the tails, which are cut off. A uniform made of 53 random bits, a positive multiple of 2^{-53}, is never below 2^{-53}, so the noise magnitude never exceeds $b \ln(2^{53}) \approx 36.74\, b$, and outputs between $f(D) + 36.74b$ and $f(D') + 36.74b$ are reachable from one input only. By Equation 25.1, their probability of about 2^{-53} is a floor on δ that rules out pure DP. Jin et al. (2022) found such leaks in libraries released after Mironov's paper.

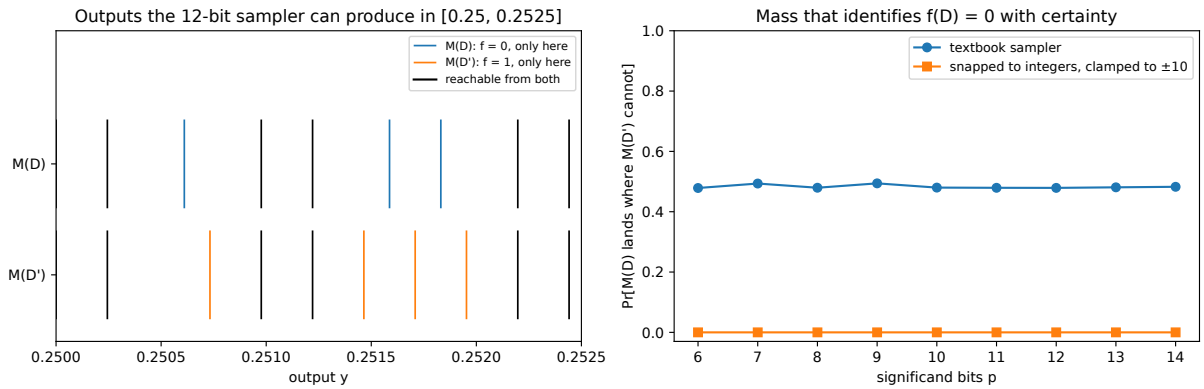

Figure 25.1.: The toy floating-point Laplace sampler with $b = 1$. Left: at 12 bits, the outputs of $f(D) = 0$ (top) and $f(D') = 1$ (bottom) in a narrow window, coloured by whether the other input can produce them. Right: $\Pr[M(D) \in S]$ against p, textbook and snapped (Section 25.2).

Example 25.1. The hospital releases its count with the textbook sampler and $b = 1$, so the exact mechanism would be ε-DP with $\varepsilon = \Delta_1 f/b = 1$. An analyst who knows that the count is 0 or 1, say whether one particular patient is in the data, checks whether the released float can be produced from 1. In the 12-bit toy the check identifies the count 0 with certainty 47.91% of the time, since $\Pr[M(D) \in S] = 0.4791$ in Table 25.1. By Proposition 25.1, no ε with a δ below 0.4791 describes the release, although the proof promised that one output moves the analyst's odds by at most a factor e.

25.2. The snapping mechanism

If the output must be a float, its low-order bits have to go. This section states the snapping mechanism of Mironov (2012), which removes them, gives its guarantee, whose proof is Mironov's, and checks it on the toy of Section 25.1.

In words, the mechanism clamps the true answer into a range $[-B, B]$, adds Laplace noise computed in floating point, rounds to the nearest multiple of a power of 2 at least as large as the noise scale, and clamps again. The clamps keep rounding errors small next to the grid.

Definition 25.1 (The snapping mechanism)**.** Let f have sensitivity 1 and let b be the noise scale. Let Λ be the smallest power of 2 with $\Lambda \geq b$, and let $[-B, B]$ be the clamping range. Write $\oplus$, $\otimes$ and LN for floating-point addition, multiplication and logarithm. Write $\lfloor \cdot \rceil_\Lambda$ for rounding to the nearest multiple of Λ, and clamp_B for the map onto $[-B, B]$. With a fair sign ξ and an ideal uniform double U^*, the **snapping mechanism** outputs

$$M(D) = \mathrm{clamp}_B\Big(\big\lfloor \mathrm{clamp}_B(f(D)) \oplus \xi \otimes b \otimes \mathrm{LN}(U^*) \big\rceil_\Lambda\Big). \tag{25.3}$$

The guarantee is the exact Laplace mechanism's $\varepsilon = 1/b$ plus two small terms that pay for floating-point error. One floating-point operation errs by at most a fixed fraction of the number it produces, the **unit roundoff** of doubles, written $\omega = 2^{-53}$. Clamping keeps every number below B in size, so the terms grow with $B\omega$.

Theorem 25.1 (Privacy of the snapping mechanism)**.** *If $b < B < 2^{46}b$, the snapping mechanism is ε-DP with*

$$\varepsilon = \frac{1 + 12B\omega}{b} + \frac{2^{-49}B}{b}, \qquad \omega = 2^{-53}. \tag{25.4}$$

The proof is Mironov's (2012, Theorem 1 and §5). Clamping the input keeps every sum where floats are at most about $B\omega$ apart. Rounding makes the output one of the multiples of Λ in $[-B, B]$, the same set for every input, so Proposition 25.1 has nothing to bite on. In exact arithmetic, each grid point collects an interval of noise values. The two inputs give it the probabilities of two intervals shifted by at most 1, whose ratio is at most $e^{1/b}$, as post-processing of the Laplace mechanism (Post-processing, group privacy and composition). Floating-point error moves each interval's endpoints by a relative amount of order ω, which gives the extra terms.

The price is accuracy. Rounding to Λ, which is below $2b$, adds up to $\Lambda/2 \le b$ of error, and clamping biases answers near $\pm B$. The extra terms in ε are tiny, about 3.1×10^{-14} with $b = 1$ and $B = 10$. The guarantee assumes a correctly behaved logarithm and an ideal uniform U^*, which a library has to supply.

The snapped toy is measured by the **privacy loss** of the definition of differential privacy, the log of the ratio of an output's probabilities under the two inputs:

$$L_{D,D'}(y) = \ln \frac{\Pr[M(D) = y]}{\Pr[M(D') = y]}. \tag{25.5}$$

That chapter showed that for discrete outputs, pure ε-DP is the same as $|L_{D,D'}(y)| \le \varepsilon$ at every output y.

Example 25.2. Snap the toy sampler of the running example to integers, $\Lambda = 1$ for $b = 1$, and clamp to $[-10, 10]$. Both inputs now reach the same 21 outputs, the integers from -10 to 10, as Exercise 7 in the exercise book checks, so $\Pr[M(D) \in S] = 0$ at every precision (Figure 25.1, right). The largest privacy loss over those outputs is 1.0010 at $p = 12$ and 1.0002 at $p = 14$, against $\varepsilon = 1$ for the exact mechanism, and the excess shrinks with precision as the ω terms predict, with $\omega = 2^{-p}$ in the toy.

25.3. An exact coin with an exponential bias

Both exact samplers below need a coin that comes up 1 with probability $e^{-\lambda}$ for a rational $\lambda \ge 0$. The obvious code, `random() < exp(-lam)`, is inexact twice over, because `exp` rounds and `random()` has only 53 bits. The exact samplers use one primitive instead, a uniform integer in $\{0, 1, \dots, d-1\}$, which Python's `random.Random.randrange(d)` and `secrets.SystemRandom().randrange(d)` provide exactly, by drawing random bits and redrawing when the result is d or more. Algorithm 1 of Canonne, Kamath and Steinke (2020), after von Neumann (1951), builds the $e^{-\lambda}$ coin from these integers.

Its first step flips coins whose bias is a fraction, and the lemma says that such coins are exact.

Lemma 25.1 (An exact coin with rational bias)**.** *For integers $0 \le m \le d$, let W be uniform on $\{0, \dots, d-1\}$. Then $\Pr[W < m] = m/d$, so the indicator $\mathbf{1}[W < m]$, which is 1 when $W < m$ and 0 otherwise, is an exact $\mathrm{Bern}(m/d)$ draw.*

Proof.

1. There are m favourable values, 0 to $m-1$, among d equally likely ones, so $\Pr[W < m] = m/d$. No step rounds, because comparing two integers is exact.

□

No fraction equals e^{-1}, so the lemma alone cannot make the coin. The way around is the power series $e^{-\lambda} = 1 - \lambda + \frac{\lambda^2}{2!} - \frac{\lambda^3}{3!} + \cdots$. Flip coins with success probabilities $\lambda, \lambda/2, \lambda/3, \ldots$ until one fails, so that the chance of surviving k flips is $\lambda^k/k!$, the k-th term of the series. The parity of the stopping index then supplies the alternating signs.

Theorem 25.2 (Algorithm 1: an exact coin with an exponential bias)**.** *Let λ be rational with $0 \le \lambda \le 1$. Draw independent coins $I_k \sim \mathrm{Bern}(\lambda/k)$ for $k = 1, 2, \ldots$ and stop at the first $I_K = 0$, so that K is the index of the first failure. Output 1 if K is odd and 0 if K is even. Then the survival probabilities, the output probability and the mean number of flips are*

$$\Pr[K > k] = \frac{\lambda^k}{k!}, \qquad \Pr[K \text{ odd}] = e^{-\lambda}, \qquad \mathbb{E}[K] = e^{\lambda}. \tag{25.6}$$

For rational $\lambda > 1$, draw $\lfloor \lambda \rfloor$ coins with probability e^{-1} this way, stopping at the first 0, then one coin with probability $e^{-(\lambda - \lfloor \lambda \rfloor)}$. The output, which is 1 only if every coin is 1, is an exact $\mathrm{Bern}(e^{-\lambda})$ *draw.*

Proof. The plan is to compute the survival probabilities, turn them into point probabilities, add the odd ones, read the mean off the survival probabilities, and reduce a large exponent to several small ones.

1. *The survival probabilities.* The event $K > k$ means that the first k coins all came up 1. They are independent with probabilities $\lambda/1, \lambda/2, \ldots, \lambda/k$, so $\Pr[K > k]$ is their product, $\lambda^k/k!$. For $\lambda = m/d$, each $\lambda/j = m/(dj)$ is a ratio of integers, at most 1 since $\lambda \le 1$, so each coin is exact by Lemma 25.1.
2. *The point probabilities.* The event $K = k$ means that the coins survived $k-1$ flips but not k, so
$$\Pr[K = k] = \Pr[K > k-1] - \Pr[K > k] = \frac{\lambda^{k-1}}{(k-1)!} - \frac{\lambda^k}{k!}. \tag{25.7}$$
3. *Add over odd k.* Over $k = 1, 3, 5, \ldots$, every power λ^j appears exactly once, with a plus sign when $j = k-1$ is even and a minus sign when $j = k$ is odd. So the sum is the series
$$\sum_{k \text{ odd}} \Pr[K = k] = \sum_{j \ge 0} \frac{(-\lambda)^j}{j!} = e^{-\lambda}. \tag{25.8}$$
4. *The mean.* A variable K on $\{1, 2, \ldots\}$ is a count of survivals, $K = \sum_{k \ge 0} \mathbf{1}[K > k]$, since exactly K of the indicators $\mathbf{1}[K > 0], \mathbf{1}[K > 1], \ldots$ are 1. Taking expectations and using step 1,
$$\mathbb{E}[K] = \sum_{k \ge 0} \Pr[K > k] = \sum_{k \ge 0} \frac{\lambda^k}{k!} = e^{\lambda}. \tag{25.9}$$
Each flip uses one uniform integer, so a coin costs $e^{\lambda} \le e$ uniform draws on average.

5. *Large* λ. A product of probabilities is the probability that independent coins all come up 1, and $e^{-\lambda} = (e^{-1})^{\lfloor\lambda\rfloor}\, e^{-(\lambda-\lfloor\lambda\rfloor)}$, so the output is Bern$(e^{-\lambda})$. Each coin has an exponent of at most 1, so steps 1 to 3 cover it. Stopping at the first 0 does not change the output, which is 0 as soon as one coin is 0.

□

The coin is exact, because no step rounds and the only randomness is uniform integers. It costs at most e draws for $\lambda \le 1$ and below $\frac{e}{1-e^{-1}} + 1 \approx 5.3$ for any λ (Exercise 1 in the exercise book). The cost jumps at each integer (Figure 25.2), from $e = 2.7183$ just below 1 to $e + e^{-1} = 3.0862$ at 1, because there the final coin for the fractional part 0 still costs a draw.

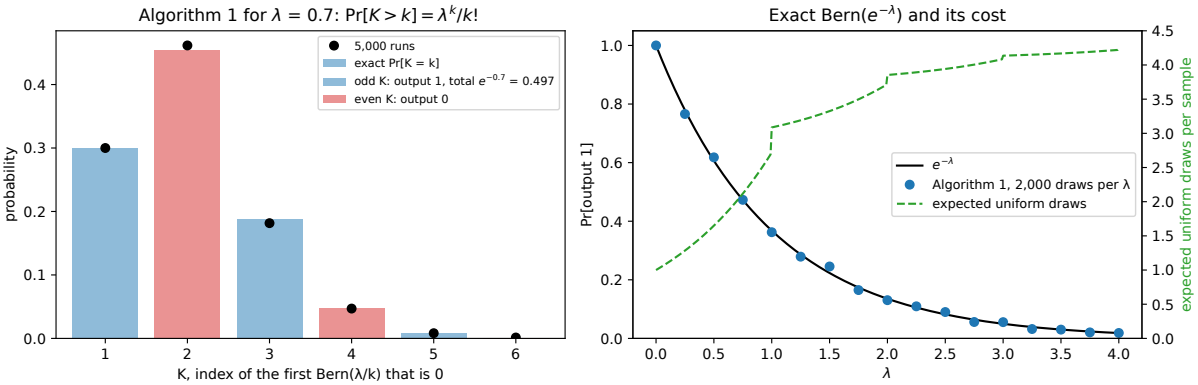

Figure 25.2.: Left: the distribution of K for $\lambda = 0.7$, exact and from 5,000 runs, odd and even K coloured. Right: the frequency of 1s against $e^{-\lambda}$, with the expected draws per coin.

Example 25.3. To see the parity trick outcome by outcome, take $\lambda = 0.7$ (Table 25.2). Each row is the chance of surviving $k-1$ flips minus the chance of surviving k, and the odd rows add up to $0.3000 + 0.1878 + 0.0086 + \cdots = 0.4966 = e^{-0.7}$. Over 10,000 runs the script sees $K = 1$ in a fraction 0.2987 of them, against 0.3000, and outputs 1 with frequency 0.4897.

Table 25.2.: Algorithm 1 for $\lambda = 0.7$, outcome by outcome. The output is the parity of the index of the first 0.

K	Coins seen	$\Pr[K = k]$	Output
1	$I_1 = 0$	$1 - 0.7 = 0.3000$	1
2	$I_1 = 1$, $I_2 = 0$	$0.7 - 0.7^2/2 = 0.4550$	0
3	$I_1 = I_2 = 1$, $I_3 = 0$	$0.245 - 0.0572 = 0.1878$	1
4	three 1s, then 0	0.0472	0
5	four 1s, then 0	0.0086	1

The running count's sampler in Section 25.4 needs only the coin with $\lambda = 1$. Over 10,000 draws it comes up 1 with frequency 0.3709, against $e^{-1} = 0.3679$, at 3.096 uniform draws each, against the expected 3.086.

25.4. The discrete Laplace mechanism

Most queries in DP are counts or histograms, like the running example. For them the natural noise is integer-valued too, so that the output has no low-order bits to leak and the noise can be sampled exactly. This section defines the discrete Laplace distribution, proves that adding it, the **geometric mechanism** of Ghosh, Roughgarden and Sundararajan (2009), has the continuous guarantee, and samples it exactly.

Keep the Laplace density $e^{-|z|/b}$ only at the integers, and divide by the sum of those values. Each step away from 0 then multiplies the probability by the same factor $r = e^{-1/b}$.

Definition 25.2 (The discrete Laplace distribution)**.** The **discrete Laplace** distribution with scale $b > 0$, written $\mathrm{Lap}_{\mathbb{Z}}(b)$, has the probability mass function (PMF)

$$\Pr[Z = z] = \frac{1-r}{1+r}\, r^{|z|}, \qquad z \in \mathbb{Z}, \qquad r = e^{-1/b}. \tag{25.10}$$

The constant in front and the variance both come from sums of geometric series.

Proposition 25.2 (Normalization and variance of the discrete Laplace)**.** *The probabilities in Equation 25.10 add up to 1, the mean of Z is 0, and*

$$\mathrm{Var}(Z) = \frac{2r}{(1-r)^2}. \tag{25.11}$$

Proof.

1. *Normalize.* The weights $r^{|z|}$ are 1 at $z = 0$ and appear twice, at $\pm z$, for each $z \geq 1$. Summing the geometric series gives
$$\sum_{z \in \mathbb{Z}} r^{|z|} = 1 + \frac{2r}{1-r} = \frac{1+r}{1-r}, \tag{25.12}$$
and dividing by it gives the constant in Equation 25.10.
2. *Mean.* The PMF gives z and $-z$ the same probability, so their contributions to the mean cancel, and the variance is $\mathbb{E}[Z^2]$.
3. *Variance.* Differentiating the geometric series $\sum_{z \geq 0} r^z = \frac{1}{1-r}$ twice in r, multiplying by r after each step, gives
$$\sum_{z \geq 1} z^2 r^z = \frac{r(1+r)}{(1-r)^3}. \tag{25.13}$$
Counting $\pm z$ twice,
$$\mathbb{E}[Z^2] = \frac{1-r}{1+r} \cdot 2 \cdot \frac{r(1+r)}{(1-r)^3} = \frac{2r}{(1-r)^2}. \tag{25.14}$$

□

Shifting the input by one unit changes each output's probability by at most the factor $e^{1/b}$, so the guarantee is the continuous one.

Theorem 25.3 (The discrete Laplace mechanism)**.** *Let f be integer-valued, with values in $\mathbb{Z}^d$ and ℓ_1 sensitivity $\Delta_1 f$, and let $b > 0$. The mechanism $M(D) = f(D) + Z$, with independent $\mathrm{Lap}_{\mathbb{Z}}(b)$ noise on each coordinate, is ε-DP with*

$$\varepsilon = \frac{\Delta_1 f}{b}, \tag{25.15}$$

and for a scalar f whose answers differ by $\Delta_1 f$, the privacy loss reaches $\pm\varepsilon$ at every output above both answers.

Proof.

1. *The privacy loss.* Take $d = 1$ first, and neighbours with true answers $f(D) = a$ and $f(D') = a'$. An output y requires noise $y - a$ under D and $y - a'$ under D'. The constant $\frac{1-r}{1+r}$ is the same for both, so it cancels in the ratio, and with $\ln r = -1/b$

$$L_{D,D'}(y) = \ln \frac{r^{|y-a|}}{r^{|y-a'|}} = \frac{|y - a'| - |y - a|}{b}. \tag{25.16}$$

2. *Bound it.* By the triangle inequality, two numbers' distances to y differ by at most their distance to each other, so in both directions

$$\big||y - a'| - |y - a|\big| \le |a - a'| \le \Delta_1 f. \tag{25.17}$$

   So $|L_{D,D'}(y)| \le \Delta_1 f/b$ at every integer y, which is pure DP with Equation 25.15 by the pointwise criterion of Section 25.2. For $y \ge \max(a, a')$ the difference of distances is exactly $|a - a'|$, so the bound is reached.
3. *Vectors.* With independent noise per coordinate, the privacy loss is a sum of per-coordinate losses. Each is at most $|a_i - a'_i|/b$ by step 2, and these add up to at most $\Delta_1 f/b$.

□

Step 1 is where integers matter, because a non-integer shift would give different inputs different supports, the floating-point failure again.

For rational $b = t/s$, Algorithm 2 of Canonne, Kamath and Steinke (2020) samples $\mathrm{Lap}_{\mathbb{Z}}(b)$ exactly. It assembles a one-sided geometric variable from a remainder W below t and a quotient V, divides it by s, and attaches a random sign. The proof needs two tools. The first, used by the remainder step and the sign step, reshapes one distribution into another by throwing some draws away.

Lemma 25.2 (Rejection sampling)**.** *Let q be a PMF you can sample from, the **proposal**, and let $h(x) \in [0, 1]$ be an acceptance probability for each value x. Repeat: draw $Y \sim q$ and accept it with probability $h(Y)$, until a draw is accepted. Then the output has PMF $q(x)h(x)/A$, where $A = \sum_x q(x)h(x)$ is the probability that one round accepts, and the number of rounds is geometric with mean $1/A$.*

Proof.

1. *One round.* A round proposes x with probability $q(x)$ and accepts it with probability $h(x)$, so it outputs x with probability $q(x)h(x)$, and something with probability A.

2. *Add up the rounds.* The rounds are independent, so the output is x when the first j rounds output nothing and round $j+1$ outputs x, for some $j \geq 0$. That is a geometric series with ratio $1 - A < 1$:
$$\sum_{j \geq 0} (1-A)^j q(x) h(x) = \frac{q(x)h(x)}{A}. \tag{25.18}$$
3. *The cost.* Each round succeeds with probability A independently, so the number of rounds is geometric with mean $1/A$.

□

So the output is exact as long as each acceptance is an exact coin, and A never has to be computed. The second tool, for the quotient step, says that counting coin flips gives a geometric variable.

Lemma 25.3 (Counting successes gives a geometric variable)**.** *Flip independent coins with success probability κ and let V be the number of successes before the first failure. Then $\Pr[V = v] = \kappa^v(1-\kappa)$ for $v = 0, 1, 2, \ldots$, and $\Pr[V \geq v] = \kappa^v$.*

Proof.

1. The event $V = v$ means exactly v successes followed by one failure, and independent flips multiply, which gives $\kappa^v(1-\kappa)$. The event $V \geq v$ says that the first v flips were successes, which has probability κ^v. This is the geometric distribution of Probability distributions, counted from 0.

□

Theorem 25.4 (Algorithm 2: exact sampling of the discrete Laplace)**.** *Input integers $s, t \geq 1$, so that $b = t/s$. Repeat until a value is returned:*

1. *Draw W uniform on $\{0, \ldots, t-1\}$ and accept it with probability $e^{-W/t}$ (Algorithm 1); on rejection, start over.*
2. *Count the successes V of independent coins with probability e^{-1} before the first failure (Algorithm 1 with $\lambda = 1$).*
3. *Set $G = W + tV$ and $Y = \lfloor G/s \rfloor$.*
4. *Draw a fair bit J. If $J = 1$ and $Y = 0$, start over. Otherwise return $(1-2J)Y$.*

The output is exactly $\mathrm{Lap}_{\mathbb{Z}}(b)$, and the mean number of passes through the loop is $1/(A_W\,(1 - \frac{1}{2}(1 - e^{-s/t})))$, where $A_W = \frac{1}{t}\sum_{w<t} e^{-w/t}$ is the acceptance probability of step 1.

Proof. The plan follows the algorithm's own order: the accepted remainder, the quotient, their combination, the division and the sign, then the cost.

1. *W given acceptance.* By Lemma 25.2 with a uniform proposal and acceptance $e^{-w/t}$, the accepted W has $\Pr[W = w] \propto e^{-w/t}$ on $\{0, \ldots, t-1\}$.
2. *V is geometric.* By Lemma 25.3 with $\kappa = e^{-1}$, $\Pr[V = v] = (1 - e^{-1})e^{-v}$.
3. *$G = W + tV$ is geometric with ratio $e^{-1/t}$.* Each $g \geq 0$ is $w + tv$ for exactly one pair, $w = g \bmod t$ and $v = \lfloor g/t \rfloor$, and the independent weights multiply to $e^{-w/t}e^{-v} = e^{-g/t}$. So $\Pr[G = g] \propto e^{-g/t}$.

4. $Y = \lfloor G/s \rfloor$ *is geometric with ratio* $e^{-s/t} = e^{-1/b}$. The event $Y = y$ collects $g = sy, \dots, sy + s - 1$, so its weight is a factor that does not depend on y times $e^{-sy/t} = r^y$:

$$\sum_{j=0}^{s-1} e^{-(sy+j)/t} = e^{-sy/t} \sum_{j=0}^{s-1} e^{-j/t}. \tag{25.19}$$

5. *The sign.* A fair sign gives $\pm y$ probability $\frac{1}{2}\Pr[Y = y]$ each, but 0 would get both halves, since $+0$ and -0 are the same output. Rejecting the case $J = 1$, $Y = 0$ leaves $\frac{1}{2}\Pr[Y = y]$ for every $z = \pm y$, including 0, and after renormalizing by Lemma 25.2, $\Pr[Z = z] \propto r^{|z|}$, which is Equation 25.10.
6. *The cost.* A pass survives step 1 with probability A_W, and step 4 unless $J = 1$ and $Y = 0$, which has probability $\frac{1}{2}(1 - e^{-s/t})$ by Lemma 25.3. By step 3 of Lemma 25.2, the mean number of passes is one over the product of the two survival probabilities.

□

To follow steps 3 and 4 by hand, take $t = 3$ and $s = 2$, so $b = 1.5$ (Table 25.3). Then $\Pr[Y = 0] = 0.4866$ and $\Pr[Y = 1] = 0.2498$, and their ratio 0.5134 is $e^{-2/3}$, as step 4 says.

Table 25.3.: Algorithm 2 with $t = 3$, $s = 2$. Each g is one pair (w, v); pairs of consecutive g merge into one y.

g	$w = g \bmod 3$	$v = \lfloor g/3 \rfloor$	$\Pr[G = g] = (1 - e^{-1/3})e^{-g/3}$	$y = \lfloor g/2 \rfloor$
0	0	0	0.2835	0
1	1	0	0.2031	0
2	2	0	0.1455	1
3	0	1	0.1043	1

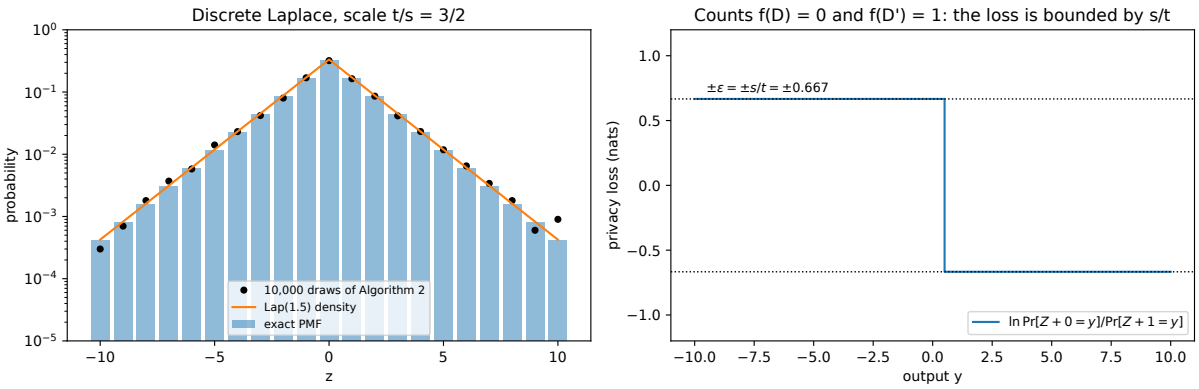

Figure 25.3.: Left: the PMF of $\mathrm{Lap}_{\mathbb{Z}}(1.5)$ on a log scale, exact and from 10,000 draws of Algorithm 2. Right: the privacy loss between counts 0 and 1, bounded by $\varepsilon = 2/3$.

The discrete Laplace gives the continuous guarantee with slightly less noise. At $b = 1$ its variance is 1.8413 against 2, and Exercise 3 in the exercise book shows that the gap tends to $\frac{1}{6}$ as b grows.

Rounding $f(D) + \mathrm{Lap}(b)$ to an integer would also be ε-DP, but it is a different distribution and needs a floating-point sampler.

For a single count, the discrete Laplace is the best possible mechanism. Ghosh, Roughgarden and Sundararajan (2009) show that every user, whatever their loss and prior, can post-process its output to do as well as with any other ε-DP mechanism.

Example 25.4. Release the running count at $\varepsilon = 1$, so $b = 1$ and $r = e^{-1} = 0.3679$. The exact count is released when the noise is 0, which happens with probability $\frac{1-r}{1+r} = \frac{0.6321}{1.3679} = 0.4621$. The noise has variance $\frac{2r}{(1-r)^2} = 1.8413$, a standard deviation of 1.357. Algorithm 2 with $s = t = 1$ always accepts in step 1, so a pass is a run of e^{-1} coins and a fair bit, and a sample takes 1.462 passes on average. The script's 10,000 draws have variance 1.8305 and cost 11.49 uniform draws each, and over the scales in Table 25.6 the cost stays between 10 and 12.

25.5. The discrete Gaussian mechanism

The Gaussian mechanism is the workhorse of private machine learning, because its noise grows with the ℓ_2 sensitivity, far smaller than the ℓ_1 sensitivity in high dimension. Its integer analogue (Canonne, Kamath & Steinke 2020) served the 2020 US Census (Abowd et al., 2022) and suits noise added before secure aggregation, which works with integers (Kairouz, Liu & Steinke, 2021). This section compares it with the continuous Gaussian of the Laplace and Gaussian mechanisms in exact $\delta(\varepsilon)$, Rényi divergence and variance.

As with the discrete Laplace, keep the bell curve at the integers and normalize.

Definition 25.3 (The discrete Gaussian distribution)**.** The **discrete Gaussian** with parameter $\sigma > 0$ and integer location μ, written $\mathcal{N}_{\mathbb{Z}}(\mu, \sigma^2)$, gives each integer x the probability

$$\Pr[X = x] = \frac{e^{-(x-\mu)^2/(2\sigma^2)}}{\mathcal{Z}_\sigma}, \qquad \mathcal{Z}_\sigma = \sum_{y \in \mathbb{Z}} e^{-y^2/(2\sigma^2)}. \tag{25.20}$$

The parameter σ^2 is the variance of the bell curve, not quite that of X (Proposition 25.3). An integer shift only relabels the terms of $\mathcal{Z}_\sigma$, so the normalizer cancels in the privacy loss of $M(D) = f(D) + X$ for integer-valued f. Then the smallest δ at each ε has the continuous Gaussian's formula, with discrete tails.

Theorem 25.5 (Privacy loss and exact δ of the discrete Gaussian mechanism)**.** *Let f be integer-valued with sensitivity Δ, an integer, and let $M(D) = f(D) + X$ with $X \sim \mathcal{N}_{\mathbb{Z}}(0, \sigma^2)$. For a neighbouring pair whose answers differ by exactly Δ, the privacy loss at an integer output y is*

$$L_{D,D'}(y) = \frac{(y - f(D'))^2 - (y - f(D))^2}{2\sigma^2}, \tag{25.21}$$

and the smallest δ for which the pair satisfies (ε, δ)-DP is

$$\delta(\varepsilon) = \Pr\Big[X > \frac{\varepsilon\sigma^2}{\Delta} - \frac{\Delta}{2}\Big] - e^{\varepsilon} \Pr\Big[X > \frac{\varepsilon\sigma^2}{\Delta} + \frac{\Delta}{2}\Big]. \tag{25.22}$$

Proof. The plan is to cancel the normalizer, write the smallest δ as a sum over the outputs where the loss exceeds ε, and evaluate that sum under each input. Take $f(D) = 0$ and $f(D') = \Delta$, since an integer shift of both changes nothing.

1. *The normalizer cancels.* Under D the output y has probability $e^{-y^2/(2\sigma^2)}/\mathcal{Z}_\sigma$, and under D' it has $e^{-(y-\Delta)^2/(2\sigma^2)}/\mathcal{Z}_\sigma$. So the ratio is the ratio of the two exponentials, and
$$L_{D,D'}(y) = \frac{(y-\Delta)^2 - y^2}{2\sigma^2} = \frac{\Delta^2 - 2\Delta y}{2\sigma^2}, \tag{25.23}$$
the formula of the continuous Gaussian, now only at integers y.
2. *The smallest δ as a sum.* The definition asks $\Pr[M(D) \in S] - e^\varepsilon \Pr[M(D') \in S] \le \delta$ for every set S. The left side is a sum over $y \in S$ of the terms $\Pr[M(D) = y] - e^\varepsilon \Pr[M(D') = y]$, so it is largest when S holds exactly the outputs with a positive term. The smallest valid δ is therefore the sum of the positive terms, the hockey-stick divergence of Divergences. A term is positive exactly when $L_{D,D'}(y) > \varepsilon$, which by step 1 means $y < \frac{\Delta}{2} - \frac{\varepsilon\sigma^2}{\Delta}$.
3. *The sum under D.* Under D the output is X, so those outputs have the probability of a lower tail of X. The PMF gives x and $-x$ the same probability, so the lower tail equals the mirrored upper tail:
$$\Pr\left[X < \frac{\Delta}{2} - \frac{\varepsilon\sigma^2}{\Delta}\right] = \Pr\left[X > \frac{\varepsilon\sigma^2}{\Delta} - \frac{\Delta}{2}\right]. \tag{25.24}$$
4. *The sum under D'.* Under D' the output is $X + \Delta$, so the same outputs need X below $-\frac{\Delta}{2} - \frac{\varepsilon\sigma^2}{\Delta}$, and by the same symmetry their probability is the second tail in Equation 25.22. Subtracting e^ε times it from step 3 gives Equation 25.22.

□

Canonne, Kamath and Steinke (2020, Theorem 7) show that a pair with a smaller shift has a smaller δ, so Equation 25.22 is the privacy profile of the mechanism, its smallest δ at each ε over all neighbouring pairs. Because the proof needs integer shifts, a real-valued query is first scaled by $1/h$ for a small step h and randomly rounded to an integer, and the accounting uses the sensitivity of the rounded query.

The curve $\delta(\varepsilon)$ is close to the continuous one but not equal to it. Moving y by one moves the privacy loss by Δ/σ^2, so the loss takes values on a lattice. As ε crosses a lattice value, a whole output enters or leaves the sum in step 2 of the proof, which puts a kink in $\delta(\varepsilon)$ (Figure 25.4). At $\varepsilon = 1$ the discrete curve is above the continuous one, 0.6032 against 0.5099 at $\sigma = 0.5$, but just past a kink it can be below, and the gap closes as σ grows.

The two remaining comparisons rest on one question: how does the sum of a Gaussian bump over the integers depend on where the bump is centred? The Rényi proof needs it largest at an integer centre, and the variance proof needs it in closed form. The tool is the Poisson summation formula (Stein & Shakarchi 2003, ch. 5), which for a smooth, fast-decaying g with Fourier transform $\hat{g}(k) = \int g(x)e^{-2\pi ikx}\,\mathrm{d}x$ says
$$\sum_{x\in\mathbb{Z}} g(x) = \sum_{k\in\mathbb{Z}} \hat{g}(k). \tag{25.25}$$

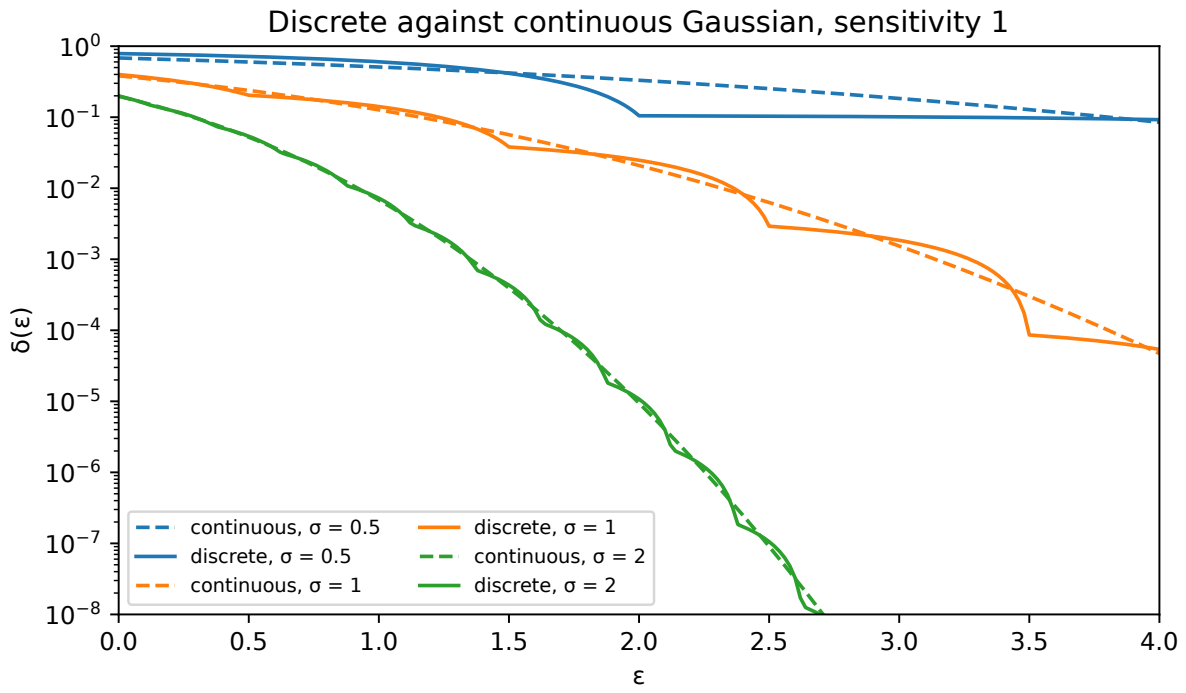

Figure 25.4.: Discrete against continuous Gaussian for sensitivity 1: $\delta(\varepsilon)$ from Equation 25.22 (solid) and for the continuous Gaussian (dashed), for $\sigma = 0.5$, 1 and 2.

Lemma 25.4 (A Gaussian bump summed over the integers)**.** *For every real centre c and every $\sigma > 0$,*

$$\sum_{x\in\mathbb{Z}} e^{-(x-c)^2/(2\sigma^2)} = \sqrt{2\pi}\,\sigma \sum_{k\in\mathbb{Z}} e^{-2\pi^2\sigma^2k^2}\cos(2\pi kc). \tag{25.26}$$

The sum is largest when c is an integer, where it equals $\mathcal{Z}_\sigma$.

Proof.

1. *Transform the bump.* The Fourier transform of $e^{-x^2/(2\sigma^2)}$ is again a Gaussian, $\sqrt{2\pi}\,\sigma e^{-2\pi^2\sigma^2k^2}$, and shifting a function by c multiplies its transform by the phase $e^{-2\pi ikc}$. So for $g(x) = e^{-(x-c)^2/(2\sigma^2)}$,
$$\hat{g}(k) = \sqrt{2\pi}\,\sigma e^{-2\pi^2\sigma^2k^2}e^{-2\pi ikc}. \tag{25.27}$$
2. *Pair k with $-k$.* Poisson summation adds $\hat{g}(k)$ over all integers k. The terms for k and $-k$ have the same real coefficient and phases that add to $2\cos(2\pi kc)$, which gives Equation 25.26.
3. *Where it is largest.* Every coefficient $e^{-2\pi^2\sigma^2k^2}$ is positive and $\cos \le 1$, with $\cos(2\pi kc) = 1$ for all k exactly when c is an integer. So the right side is largest at integer c, and there the left side is $\mathcal{Z}_\sigma$ by relabelling.

□

So moving the centre off the integers can only lower the sum. At $\sigma = 0.5$ the script finds 1.271342 at $c = 0$ and 1.235287 at $c = 0.5$, while at $\sigma = 1$ both are 2.506628, $\sqrt{2\pi}$ to six decimals.

The second comparison is in Rényi divergence. For two distributions P and Q on the integers, the **Rényi divergence** of order $\alpha > 1$ is

$$D_\alpha(P\|Q) = \frac{1}{\alpha - 1} \ln \sum_x P(x)^\alpha Q(x)^{1-\alpha}, \tag{25.28}$$

an average of the privacy loss that weights large losses more as α grows (Divergences). For continuous Gaussians with variance σ^2 and means μ and ν it is $\alpha(\mu-\nu)^2/(2\sigma^2)$ (Equation 3.15). For discrete ones, completing a square turns the sum into a bump summed over the integers, which the lemma bounds.

Theorem 25.6 (Rényi divergence of two discrete Gaussians)**.** *For integers μ and ν and every $\alpha > 1$,*

$$D_\alpha(\mathcal{N}_\mathbb{Z}(\mu,\sigma^2)\,\|\,\mathcal{N}_\mathbb{Z}(\nu,\sigma^2)) \le \frac{\alpha(\mu-\nu)^2}{2\sigma^2}, \tag{25.29}$$

with equality when α is an integer.

Proof. The plan is to write out the sum, complete the square in its exponent, and apply Lemma 25.4 to what is left. Write $p_\mu(x) = e^{-(x-\mu)^2/(2\sigma^2)}/\mathcal{Z}_\sigma$, with the same normalizer for every integer μ.

1. *Write out the summand.* In $\sum_x p_\mu(x)^\alpha p_\nu(x)^{1-\alpha}$ the powers of the normalizer combine to $1/\mathcal{Z}_\sigma$, and the exponents add up to

$$-\frac{\alpha(x-\mu)^2 + (1-\alpha)(x-\nu)^2}{2\sigma^2}. \tag{25.30}$$

2. *Complete the square.* With $c = \alpha\mu + (1-\alpha)\nu$ the x^2 and x terms match, and the constant is what is left over:

$$\alpha(x-\mu)^2 + (1-\alpha)(x-\nu)^2 = (x-c)^2 - \alpha(\alpha-1)(\mu-\nu)^2. \tag{25.31}$$

3. *Factor the sum.* Substituting step 2 into step 1 gives

$$\sum_x p_\mu(x)^\alpha p_\nu(x)^{1-\alpha} = e^{\alpha(\alpha-1)(\mu-\nu)^2/(2\sigma^2)} \cdot \frac{1}{\mathcal{Z}_\sigma} \sum_x e^{-(x-c)^2/(2\sigma^2)}. \tag{25.32}$$

4. *Apply the lemma.* The last factor is the bump sum centred at c divided by the bump sum centred at an integer, which by Lemma 25.4 is at most 1, with equality when c is an integer. For integer α the centre c is an integer, because μ and ν are. Taking $\frac{1}{\alpha-1}\ln$ of step 3 gives Equation 25.29.

□

So the discrete Gaussian is never worse than the continuous one in Rényi divergence. It satisfies the same zero-concentrated DP (Canonne, Kamath & Steinke 2020, Theorem 4), the guarantee of Part 4 that bounds every D_α by a constant times α.

The third comparison is the variance. Restricting the bell curve to integers pulls a little mass towards 0, and the proof reads the variance off the derivative of the normalizer, which the lemma gives in closed form.

Proposition 25.3 (Variance of the discrete Gaussian)**.** *For $X \sim \mathcal{N}_{\mathbb{Z}}(0, \sigma^2)$,*

$$\operatorname{Var}(X) = \sigma^2 - \frac{\sum_{k\neq 0} 4\pi^2\sigma^4 k^2 e^{-2\pi^2\sigma^2 k^2}}{1 + \sum_{k\neq 0} e^{-2\pi^2\sigma^2 k^2}} < \sigma^2. \tag{25.33}$$

Proof. The plan is to express the variance through the derivative of the normalizer, evaluate the normalizer by Lemma 25.4, and differentiate. Let $\tau = 1/(2\sigma^2)$ and $\mathcal{Z}(\tau) = \sum_x e^{-\tau x^2}$.

1. *Variance from the normalizer.* The mean is 0 because x and $-x$ have the same probability, so $\operatorname{Var}(X) = \mathbb{E}[X^2] = \sum_x x^2 e^{-\tau x^2}/\mathcal{Z}(\tau)$. Differentiating $e^{-\tau x^2}$ in τ brings down a factor $-x^2$, so
$$\mathbb{E}[X^2] = -\frac{\mathrm{d}}{\mathrm{d}\tau} \ln \mathcal{Z}(\tau). \tag{25.34}$$
2. *Poisson summation at $c = 0$.* With $\sigma = 1/\sqrt{2\tau}$, Equation 25.26 gives
$$\mathcal{Z}(\tau) = \sqrt{\pi/\tau}\,(1 + \theta(\tau)), \qquad \theta(\tau) = \sum_{k\neq 0} e^{-\pi^2 k^2/\tau}. \tag{25.35}$$
3. *Differentiate.* The log splits into $\frac{1}{2}\ln\pi - \frac{1}{2}\ln\tau + \ln(1 + \theta(\tau))$, so
$$-\frac{\mathrm{d}}{\mathrm{d}\tau}\ln\mathcal{Z} = \frac{1}{2\tau} - \frac{\theta'(\tau)}{1+\theta(\tau)}, \qquad \theta'(\tau) = \sum_{k\neq 0} \frac{\pi^2 k^2}{\tau^2} e^{-\pi^2 k^2/\tau} > 0. \tag{25.36}$$
4. *Substitute $\tau = 1/(2\sigma^2)$.* Then $1/(2\tau) = \sigma^2$ and $\pi^2 k^2/\tau = 2\pi^2\sigma^2 k^2$, which turns step 3 into Equation 25.33. The correction is positive, so $\operatorname{Var}(X) < \sigma^2$.

□

The deficit is invisible in practice. Its leading term comes from $k = \pm 1$, so the relative deficit $1 - \operatorname{Var}(X)/\sigma^2$ is about $8\pi^2\sigma^2 e^{-2\pi^2\sigma^2}$, which is 2.11×10^{-7} at $\sigma = 1$. Only below $\sigma \approx 0.6$ does it show, as $\operatorname{Var}(X) = 0.8601\,\sigma^2$ at $\sigma = 0.5$ (Figure 25.5).

One property does not carry over: the sum of two independent discrete Gaussians is not exactly a discrete Gaussian. For $\sigma \geq 1$ it is very close (Exercise 6 in the exercise book), and distributed noise addition, where each client adds a share, relies on that.

Example 25.5. Release the running count with $\mathcal{N}_{\mathbb{Z}}(0, 1)$ noise, so $\sigma = 1$ and $\Delta = 1$. The privacy loss at an integer output y is $(1 - 2y)/2$, so the kinks are at $\varepsilon = 0.5, 1.5, \ldots$ (Figure 25.4). At $\varepsilon = 1$ the outputs with loss above ε are $y \leq -1$, and Equation 25.22 gives $\delta(1) = 0.1414$, against 0.1269 for continuous $\mathcal{N}(0, 1)$ noise. In Table 25.4, integer orders match $\alpha/(2\sigma^2)$ exactly, because their centre c is an integer, while the order 2.5 has $c = (1 - \alpha)\cdot 1 = -1.5$ and at $\sigma = 0.5$ falls below the continuous value. At $\sigma \geq 1$ the lemma's slack is below the four decimals shown.

Table 25.4.: Rényi divergences between discrete Gaussians shifted by 1, by direct summation, with the continuous value $\alpha/(2\sigma^2)$ in parentheses.

σ	D_2 (continuous)	$D_{2.5}$ (continuous)	D_5 (continuous)
0.5	4.0000 (4.0000)	4.9808 (5.0000)	10.0000 (10.0000)

σ	D_2 (continuous)	$D_{2.5}$ (continuous)	D_5 (continuous)
1	1.0000 (1.0000)	1.2500 (1.2500)	2.5000 (2.5000)
2	0.2500 (0.2500)	0.3125 (0.3125)	0.6250 (0.6250)

25.6. Sampling the discrete Gaussian exactly

The privacy analysis is only as good as the sampler, and inverse-CDF sampling of $\mathcal{N}_{\mathbb{Z}}(0, \sigma^2)$ would need the irrational normalizer and a floating-point uniform. Algorithm 3 of Canonne, Kamath and Steinke (2020) instead proposes from the discrete Laplace, whose tails are heavier, and thins the proposals with exact $e^{-\lambda}$ coins. By Lemma 25.2, proposal times acceptance only has to be proportional to $e^{-y^2/(2\sigma^2)}$, so the acceptance probability is a Gaussian factor shifted to cancel the Laplace factor.

Theorem 25.7 (Algorithm 3: exact sampling of the discrete Gaussian)**.** *Input a rational $\sigma^2 > 0$ and let $t = \lfloor \sigma \rfloor + 1$. Repeat: draw $Z \sim \mathrm{Lap}_{\mathbb{Z}}(t)$ with Algorithm 2 ($s = 1$), and accept it with probability*

$$\exp\Big(- \frac{(|Z| - \sigma^2/t)^2}{2\sigma^2} \Big) \tag{25.37}$$

using Algorithm 1. Output the first accepted Z. The output is exactly $\mathcal{N}_{\mathbb{Z}}(0, \sigma^2)$, and the acceptance probability per proposal is

$$A = \frac{1 - r}{1 + r}\, e^{-\sigma^2/(2t^2)}\, \mathcal{Z}_\sigma, \qquad r = e^{-1/t}, \tag{25.38}$$

which tends to $\sqrt{\pi/2}\, e^{-1/2} = 0.7602$ as σ grows.

Proof. The plan is to check the shape of proposal times acceptance, that the acceptance is a probability and that every quantity is rational, and then to average the acceptance over proposals.

1. *Proposal times acceptance.* The proposal has $\Pr[Z = y] \propto e^{-|y|/t}$, and multiplying by the acceptance probability adds the exponents. Expanding the square gives
$$-\frac{|y|}{t} - \frac{(|y| - \sigma^2/t)^2}{2\sigma^2} = -\frac{|y|}{t} - \frac{y^2}{2\sigma^2} + \frac{|y|}{t} - \frac{\sigma^2}{2t^2} = -\frac{y^2}{2\sigma^2} - \frac{\sigma^2}{2t^2}. \tag{25.39}$$
The $|y|/t$ terms cancel, leaving $e^{-y^2/(2\sigma^2)}$ times a constant, so by Lemma 25.2 the output is $\mathcal{N}_{\mathbb{Z}}(0, \sigma^2)$.
2. *The acceptance is a probability.* Its exponent is minus a square, so it is at most 1.
3. *Everything is rational.* The integer t is computed as $\lfloor \sqrt{\lfloor \sigma^2 \rfloor} \rfloor + 1$ with an integer square root. An integer n has $n^2 \le \sigma^2$ exactly when $n^2 \le \lfloor \sigma^2 \rfloor$, so this equals $\lfloor \sigma \rfloor + 1$ without computing σ. So $\lambda = (|y| - \sigma^2/t)^2/(2\sigma^2)$ is a ratio of integers, and Algorithm 1 applies.
4. *The acceptance rate.* By Lemma 25.2, A is the average acceptance over proposals. With $\Pr[Z = y] = \frac{1-r}{1+r} r^{|y|}$, step 1 turns each term of that average into $\frac{1-r}{1+r} e^{-\sigma^2/(2t^2)} e^{-y^2/(2\sigma^2)}$, and the sum over y is Equation 25.38. Exercise 5 in the exercise book derives the limit from Equation 25.26.

□

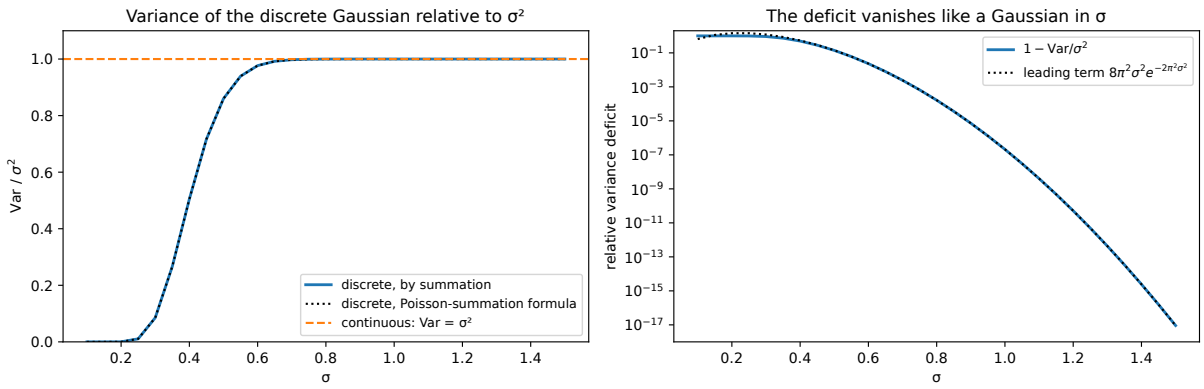

Figure 25.5.: Left: $\mathrm{Var}(X)/\sigma^2$ for $X \sim \mathcal{N}_{\mathbb{Z}}(0, \sigma^2)$, by direct summation and from Equation 25.33. Right: the relative deficit $1 - \mathrm{Var}(X)/\sigma^2$ on a log scale, with its leading term.

To follow the algorithm by hand, take $\sigma^2 = 4$, so $t = 3$ and $\frac{1-r}{1+r} = 0.1651$ (Table 25.5). Dividing each product by the first gives $e^{-y^2/8}$, for instance $0.1167/0.1322 = 0.883 = e^{-1/8}$.

Table 25.5.: Algorithm 3 for $\sigma^2 = 4$, by hand. Each acceptance is one coin of Algorithm 1, with λ kept as a fraction.

y	Proposal $0.1651\, r^{\lvert y\rvert}$	$\lambda = (\lvert y\rvert - 4/3)^2/8$	Acceptance $e^{-\lambda}$	Product
0	0.1651	2/9	0.8007	0.1322
1	0.1183	1/72	0.9862	0.1167
2	0.0848	1/18	0.9460	0.0802
4	0.0435	8/9	0.4111	0.0179
6	0.0223	49/18	0.0657	0.0015

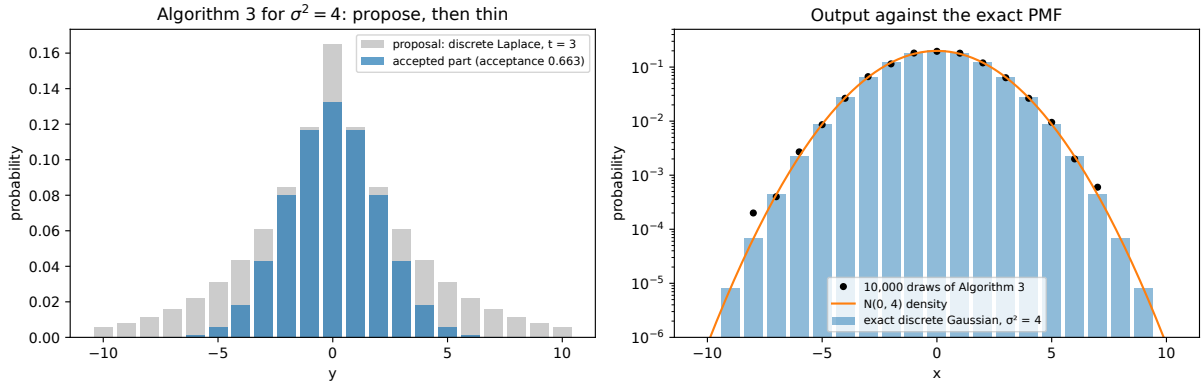

Figure 25.6.: Algorithm 3 for $\sigma^2 = 4$. Left: the discrete Laplace proposal with $t = 3$ and its accepted part, A times the discrete Gaussian PMF. Right: 10,000 draws against the exact PMF on a log scale.

The sampler is exact and cheap. The acceptance rate runs from 0.5185 at $\sigma^2 = \frac{1}{4}$ to 0.7532 at $\sigma^2 = 100$, so a draw takes fewer than two proposals and 15 to 27 uniform integers (Table 25.6). The choice of t affects only the cost, because step 1 of the proof works for every integer $t \geq 1$. For large σ, $\frac{1-r}{1+r} \approx \frac{1}{2t}$ and $\mathcal{Z}_\sigma \approx \sqrt{2\pi}\sigma$, so A is about $\frac{\sqrt{2\pi}\sigma}{2t} e^{-\sigma^2/(2t^2)}$. The derivative of its logarithm in t is $-\frac{1}{t} + \frac{\sigma^2}{t^3}$, which vanishes at $t = \sigma$, and $\lfloor \sigma \rfloor + 1$ is an integer next to it.

Exactness is not timing safety. The number of rounds depends on the output, so the running time leaks information about the noise, and Jin et al. (2022) show that such leaks are exploitable. A deployment pads the running time or runs a fixed number of rounds.

Example 25.6. Release the running count with $\mathcal{N}_{\mathbb{Z}}(0, 1)$ noise, as in Example 25.5. The proposal scale is $t = 2$ and the acceptance rate 0.5418, so a draw takes 1.85 proposals on average, and the

25.7. Code

The script code/discrete_mechanisms.py implements Algorithms 1 to 3 with `fractions.Fraction` and integers, drawing uniform integers from a seeded `random.Random`. It also enumerates the toy floating-point sampler exactly and computes the discrete Gaussian's quantities by summation. Each sampler is compared with its exact distribution by the total variation (TV) distance, half the sum of the absolute differences between exact probabilities and observed frequencies. The "noise floor" is that distance for 10,000 draws from the exact PMF drawn with NumPy. From the repository root:

```
uv run python code/part03-dp-foundations/discrete_mechanisms.py
```

Table 25.6.: The script's output with the default seed.

Experiment	Result
Float Laplace, $p = 12$	$\Pr[M(D) \in S] = 0.4791$; snapped to integers: 0, with $\max\|L\| = 1.0010$
Algorithm 1, $\lambda = \frac{1}{2}, 1, \frac{5}{2}, 4$	Frequencies 0.6024, 0.3709, 0.0869, 0.0168 against 0.6065, 0.3679, 0.0821, 0.0183; draws per coin 1.662, 3.096, 3.976, 4.218 against 1.649, 3.086, 3.941, 4.240
Algorithm 2, $b = 1$	Variance 1.8305 (exact 1.8413); TV to exact 0.0114 (noise floor 0.0074); 11.49 draws per sample
Algorithm 2, $b = 3/2$	Variance 4.3834 (exact 4.3370); TV 0.0119 (noise floor 0.0243); 12.08 draws per sample
Algorithm 2, $b = 10$	Variance 195.2985 (exact 199.8334); TV 0.0339 (noise floor 0.0331); 10.25 draws per sample
Algorithm 3, $\sigma^2 = \frac{1}{4}$	Variance 0.2189 (exact 0.2150); TV 0.0028 (noise floor 0.0045); acceptance 0.5185; 26.6 draws
Algorithm 3, $\sigma^2 = 1$	Variance 0.9977 (exact 1.0000); TV 0.0076 (noise floor 0.0042); acceptance 0.5418; 24.8 draws
Algorithm 3, $\sigma^2 = 4$	Variance 4.0826 (exact 4.0000); TV 0.0154 (noise floor 0.0142); acceptance 0.6629; 18.9 draws
Algorithm 3, $\sigma^2 = 100$	Variance 99.4386 (exact 100.0000); TV 0.0243 (noise floor 0.0325); acceptance 0.7532; 15.6 draws

Experiment	Result
Discrete Gaussian variance	$\mathrm{Var}/\sigma^2 = 0.010728, 0.860051, 1.000000$ at $\sigma = 0.25, 0.5, 1$, by summation and by Equation 25.33 alike

tests/test_discrete_mechanisms.py checks that the output still matches.

25.8. Summary

Table 25.7.: The results of this chapter, and where each is used.

Result	Statement	Use
Proposition 25.1	$\delta \geq \Pr[M(D) \in \mathcal{Y}_D \setminus \mathcal{Y}_{D'}]$ for every ε	Auditing an implementation with one event
Example 25.1	The textbook floating-point sampler leaks about 48% of its mass	Never ship `f(D) + laplace(b)` in floating point
Theorem 25.1	Rounding to $\Lambda \geq b$ and clamping gives $\varepsilon = \frac{1+12B\omega}{b} + \frac{2^{-49}B}{b}$	Laplace noise when the output must be a float
Theorem 25.2	The parity of the first 0 among $\mathrm{Bern}(\lambda/k)$ coins is $\mathrm{Bern}(e^{-\lambda})$	The coin both samplers need; `exp` or `random()` in a sampler breaks exactness
Theorem 25.3	$f(D) + \mathrm{Lap}_{\mathbb{Z}}(b)$ is ε-DP with $\varepsilon = \Delta_1 f / b$	Counts and histograms, with variance about $2b^2 - \frac{1}{6}$
Theorem 25.4	Remainder, quotient and sign give $\mathrm{Lap}_{\mathbb{Z}}(t/s)$ exactly	10 to 12 uniform draws per sample
Theorem 25.5	The continuous $\delta(\varepsilon)$ with discrete tails	Census releases and secure aggregation
Theorem 25.6	$D_\alpha \leq \frac{\alpha(\mu-\nu)^2}{2\sigma^2}$, with equality at integer α	The same zero-concentrated DP as the continuous Gaussian (Part 4)
Proposition 25.3	$\mathrm{Var}(X) < \sigma^2$, by $O(\sigma^4 e^{-2\pi^2\sigma^2})$	Invisible for $\sigma \geq 1$; sums are only nearly discrete Gaussian
Theorem 25.7	Propose $\mathrm{Lap}_{\mathbb{Z}}(\lfloor\sigma\rfloor + 1)$ and thin with exact coins	Fewer than two proposals per draw; the running time is a separate side channel

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

26. Local, shuffle and distributed trust models

Every mechanism so far in this part assumed a **trusted curator**, who holds the raw data, runs the mechanism and releases only its output. The guarantee of differential privacy (DP) is about that output. It says nothing about the curator's database, the engineer who can read it or the court order that can demand it. As Threat models put it, trust decides who the adversary is. A browser vendor collecting usage statistics is exactly the party its users do not want to see their data.

This chapter asks how much accuracy each weaker trust assumption costs, and what you trust instead. There are four answers (Figure 26.1). In the **central** model the curator is trusted, and the noise is added once, to the answer. In the **local** model nobody is trusted, and each person randomizes their own record before it leaves their device. In the **shuffle** model a shuffler is trusted only to unlink reports from senders. In the **distributed** model cryptography is trusted, and each person adds a share of the noise to a sum that a protocol reveals only in total.

What separates the models is where the noise enters. The further upstream it enters, the fewer parties you trust and the more noise reaches the answer, because n independent noises of one size add up to about $\sqrt{n}$ times that size. The running example is the telemetry of an app, starting with one yes/no question put to $n = 10{,}000$ users, of whom 3,000 hold a 1. At $\varepsilon = \ln 3$, a trusted curator answers with standard deviation 1.287 on the count, while randomized response on every device has 86.6. The chapter proves that no local protocol avoids that factor of 67.3, and shows how shuffling and distributed noise win the accuracy back.

Table 26.1.: The symbols of this chapter.

Symbol	Meaning
ε_0; (ε, δ)	the local level of one report; the central guarantee
R, $p_R(y \mid x)$	a local randomizer, and the probability that it reports y on the record x
p, q	the probabilities that a report supports a value its sender holds, or does not hold (q is not a sampling rate here)
k, f_v, C_v	the domain size, the frequency of value v, the number of reports that support v
w, m	the number of hash buckets; the bound on a numeric value
T, b_0, b_m, α	the number of rounds; the kept bits and secret offset of α-point rounding

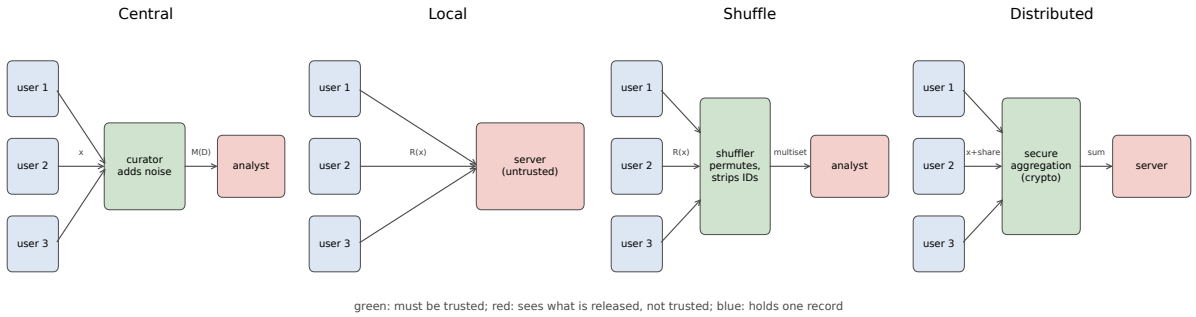

Figure 26.1.: The four trust models. Blue boxes hold one record each, green boxes must be trusted, and red boxes see the release and are not trusted.

26.1. Central and local differential privacy

In the **local model** there is no curator, and each person sends only a randomized version of their own record. This section asks what such a randomizer promises, to whom, and what it costs on the simplest task, counting one bit.

A report must look about the same whatever its owner's record is, because whoever receives it may know whose it is. So the requirement is the DP definition applied to a dataset of one record. In every model of this chapter, $D \sim D'$ means that the datasets differ by **replacing** one record. Each report arrives from a known device, so whether a person took part is visible anyway, and only their value can be hidden.

Definition 26.1 (Local randomizer)**.** Let $\mathcal{X}$ be the domain of one record and $\mathcal{Y}$ a set of reports. A randomizer $R\colon \mathcal{X} \to \mathcal{Y}$ is an **ε_0-DP local randomizer** if for every pair of records $x, x' \in \mathcal{X}$ and every event $S \subseteq \mathcal{Y}$,

$$\Pr[R(x) \in S] \le e^{\varepsilon_0} \Pr[R(x') \in S]. \tag{26.1}$$

Write $p_R(y \mid x)$ for the probability that R reports y on x. The **local protocol** releases $(R(x_1), \dots, R(x_n))$, with independent randomness for each person.

Replacing one record changes only one report, so the transcript should be exactly as private as one report.

Proposition 26.1 (What a local protocol promises)**.** *If R is an ε_0-DP local randomizer, the transcript of the local protocol is ε_0-DP under replace neighbours, and each report is ε_0-DP against anyone who sees it, including its collector.*

Proof.

1. *The transcript factorizes.* The randomness is independent, so a transcript has probability $\prod_i p_R(y_i \mid x_i)$.
2. *Neighbours differ in one factor.* If D and D' differ in record j, the other factors cancel in the ratio, which leaves $p_R(y_j \mid x_j)/p_R(y_j \mid x'_j) \le e^{\varepsilon_0}$ by Equation 26.1. Single outcomes extend to events by addition, as for randomized response.

3. *Who sees it does not matter.* Equation 26.1 is about the distribution of one report, so it holds for every observer, and any estimate computed from the reports is covered by post-processing.

□

So a breach of the collector, an insider or a subpoena reveals only reports that are already private. That is why Google's RAPPOR in Chrome, Apple's telemetry and Microsoft's telemetry in Windows used local DP. But each report must hide its owner from everyone, so each carries the noise that the central mechanism adds once in total. Table 26.2 compares the four models, and the sections below derive its last column.

Table 26.2.: The four trust models and the order of the error of a count.

Model	Who must be trusted	What the untrusted party sees	Error of a count, ε fixed
Central	The curator, with all raw records	$M(D)$	Order $1/\varepsilon$
Local	Nobody	Every report $R(x_i)$	Order $\sqrt{n}/\varepsilon$
Shuffle	The shuffler, to unlink reports	The multiset of reports	Order $\sqrt{\ln(1/\delta)}/\varepsilon$
Distributed	Cryptography, and enough honest clients	The noisy sum	Order $\sqrt{\ln(1/\delta)}/\varepsilon$

Every local estimator in this chapter is built the same way. A randomizer shrinks the signal, so the mean of a report moves less than the true value does, and the next lemma undoes the shrinking and says what that costs.

Lemma 26.1 (Debiasing a linear randomizer)**.** *Suppose a report Y has mean $\mathbb{E}[Y] = c_0 + c_1\vartheta$ for an unknown quantity ϑ, a known offset c_0 and a known slope $c_1 \neq 0$. Then*

$$\hat{\vartheta} = \frac{Y - c_0}{c_1} \tag{26.2}$$

is unbiased for ϑ, with $\mathrm{Var}(\hat{\vartheta}) = \mathrm{Var}(Y)/c_1^2$.

Proof.

1. Linearity of expectation gives $\mathbb{E}[\hat{\vartheta}] = (c_0 + c_1\vartheta - c_0)/c_1 = \vartheta$.
2. Subtracting a constant leaves a variance unchanged, and scaling by $1/c_1$ multiplies it by $1/c_1^2$.

□

A strongly private randomizer has a small slope, so the estimator multiplies the noise variance by a large $1/c_1^2$. That is where the cost of local privacy comes from. The variances below also use the fact from Distributions that variances of independent reports add. A 0/1 report has variance equal to its probability of a 1 times its probability of a 0.

The simplest local randomizer is **randomized response** from the definition of differential privacy. It reports the true bit with probability $t = e^{\varepsilon_0}/(1+e^{\varepsilon_0})$ and the flipped bit otherwise, so its two rows differ by the factor $t/(1-t) = e^{\varepsilon_0}$.

Proposition 26.2 (Randomized response on a fraction)**.** *Let a fraction π of n people hold a 1, and let each report their bit by randomized response at level ε_0. With $\bar{y}$ the mean of the reports, the estimate*

$$\hat{\pi} = \frac{\bar{y} - (1-t)}{2t-1} \tag{26.3}$$

is unbiased for π, and for every dataset

$$\operatorname{sd}(\hat{\pi}) = \frac{e^{\varepsilon_0/2}}{(e^{\varepsilon_0}-1)\sqrt{n}}. \tag{26.4}$$

Proof.

1. *The mean.* A holder of a 1 reports a 1 with probability t, and a holder of a 0 with probability $1-t$. So the reports have mean $(1-t)+\pi(2t-1)$, and Lemma 26.1 gives the estimate.
2. *The variance.* Every report has variance $t(1-t)$ whatever its bit, so the mean of n reports has variance $t(1-t)/n$, and the debiasing divides it by $(2t-1)^2$.
3. *In terms of ε_0.* Substituting t gives $t(1-t) = e^{\varepsilon_0}/(1+e^{\varepsilon_0})^2$ and $2t-1 = (e^{\varepsilon_0}-1)/(e^{\varepsilon_0}+1)$, and the factors $(1+e^{\varepsilon_0})^2$ cancel.

□

Example 26.1. Of the app's $n = 10{,}000$ users, 3,000 hold a 1, and each uses randomized response at $\varepsilon_0 = \ln 3$, so $t = 0.75$. There $e^{\varepsilon_0}/(e^{\varepsilon_0}-1)^2 = 3/4$, so Equation 26.4 gives a standard deviation of $\sqrt{0.75/10{,}000} = 0.00866$, and 20,000 simulated surveys give a mean of 0.3000 and a standard deviation of 0.00861. On the count, that is $10{,}000 \times 0.00866 = 86.6$ people.

A trusted curator would add Laplace noise to the count instead. One person moves the count by at most 1, so by Theorem 20.1 the noise at the same level $\varepsilon = \ln 3 = 1.0986$ has standard deviation $\sqrt{2}/\varepsilon = 1.287$. The local survey is $86.6/1.287 = 67.3$ times noisier.

26.2. The price of local privacy

Is the factor 67 a weakness of randomized response, or of the local model? This section shows that it is the model. No local protocol estimates a fraction with error below order $1/((e^{\varepsilon_0}-1)\sqrt{n})$, while the central Laplace mechanism reaches order $1/(n\varepsilon)$. The shuffle and distributed models exist to escape this gap.

The proof measures what the reports reveal with the **Kullback–Leibler (KL) divergence** of Divergences, $D_{\mathrm{KL}}(Q_0 \| Q_1) = \sum_y q_0(y) \ln \frac{q_0(y)}{q_1(y)}$, which adds over independent observations.

The proof compares two populations by their **total variation (TV) distance** $\mathrm{TV}(P_0, P_1) = \frac{1}{2}\sum_x |P_0(x) - P_1(x)|$. The key step is that a randomizer changes each report's probability by at most a factor e^{ε_0}, so the reports of two populations differ only a little, however different the populations are.

Lemma 26.2 (A local randomizer contracts KL divergence)**.** *Let each record be drawn from P_0 or P_1 on a finite domain, and let R be an ε_0-DP local randomizer. Write Q_0 and Q_1 for the distributions of one report, $q_j(y) = \sum_x P_j(x)\, p_R(y \mid x)$. Then*

$$D_{\mathrm{KL}}(Q_0 \| Q_1) \le (e^{\varepsilon_0} - 1)^2\, \mathrm{TV}(P_0, P_1)^2. \tag{26.5}$$

Proof. The plan is to bound $q_0(y) - q_1(y)$ by a multiple of $q_1(y)$ for each report y, then turn that into a bound on KL with $\ln u \le u - 1$.

1. *A band.* Let $\underline{p}(y) = \min_x p_R(y \mid x)$. By Equation 26.1, $g(x) = p_R(y \mid x) - \underline{p}(y)$ lies in $[0, G]$ with $G = (e^{\varepsilon_0} - 1)\underline{p}(y)$.
2. *Only the difference matters.* The differences $P_0(x) - P_1(x)$ sum to 0, so subtracting the floor $\underline{p}(y)$, which does not depend on x, changes nothing:
$$q_0(y) - q_1(y) = \sum_x \big(P_0(x) - P_1(x)\big)\, g(x). \tag{26.6}$$
3. *Bound the sum.* The differences sum to 0, so the positive ones and the negative ones each total $\mathrm{TV}(P_0, P_1)$. With g between 0 and G, the sum lies within $\pm \mathrm{TV} \cdot G$. Also $q_1(y)$ is an average of numbers that are each at least $\underline{p}(y)$, so $\underline{p}(y) \le q_1(y)$ and
$$|q_0(y) - q_1(y)| \le (e^{\varepsilon_0} - 1)\, \mathrm{TV}(P_0, P_1)\, q_1(y). \tag{26.7}$$
4. *To KL.* The concave curve $\ln u$ lies below its tangent $u - 1$ at $u = 1$. Applied to $u = q_0(y)/q_1(y)$,
$$D_{\mathrm{KL}}(Q_0 \| Q_1) \le \sum_y q_0 \Big(\frac{q_0}{q_1} - 1\Big). \tag{26.8}$$
5. *Complete the square.* Since $\sum_y q_0 = \sum_y q_1 = 1$, the right side equals $\sum_y (q_0 - q_1)^2 / q_1$. Squaring step 3 and summing bounds it by $(e^{\varepsilon_0} - 1)^2\, \mathrm{TV}^2 \sum_y q_1$, and the last sum is 1.

□

The lower bound below turns little information into large error. Its last step needs a second lemma, that a good estimator is a good test. By Hypothesis testing, every test between two distributions has error rates summing to at least $1 - \mathrm{TV}$.

Lemma 26.3 (A test built from an estimator)**.** *Suppose an estimator $\hat{\vartheta}$ is within $a/2$ of the truth with probability at least $1 - \beta$, both when the truth is ϑ_0 and when it is $\vartheta_0 + a$. Then the two distributions of the data have TV distance at least $1 - 2\beta$.*

Proof.

1. Decide $\vartheta_0 + a$ when $\hat{\vartheta} > \vartheta_0 + a/2$, the midpoint.

2. The test errs only when the estimate misses the truth by at least $a/2$, which has probability at most β under each value.
3. Every test has error rates summing to at least $1 - \mathrm{TV}$, so $1 - \mathrm{TV} \le 2\beta$.

□

The theorem compares two populations whose fractions differ by a small gap a. Their reports are too alike to tell apart, so no estimator is accurate to half the gap under both.

Theorem 26.1 (The local lower bound for a fraction)**.** *Let each of n people apply an ε_0-DP local randomizer, possibly different per person, to a bit drawn from* $\mathrm{Bern}(\frac{1}{2})$ *or from* $\mathrm{Bern}(\frac{1}{2} + a)$*. No estimator built from the reports is within $a/2$ of the true fraction with probability at least $1 - \beta$ under both unless*

$$\frac{a}{2} \ge \frac{1 - 2\beta}{(e^{\varepsilon_0} - 1)\sqrt{2n}}. \tag{26.9}$$

Proof.

1. *Add over people.* The reports are independent, so KL adds over people. The two populations have TV distance a, so by Lemma 26.2 the n reports have KL at most $n(e^{\varepsilon_0} - 1)^2 a^2$.
2. *Convert to TV.* TV does not add over people, which is why the proof went through KL. **Pinsker's inequality** (Divergences) says $\mathrm{TV} \le \sqrt{D_{\mathrm{KL}}/2}$, so for the distributions Q_0^n, Q_1^n of all n reports
$$\mathrm{TV}(Q_0^n, Q_1^n) \le a(e^{\varepsilon_0} - 1)\sqrt{n/2}. \tag{26.10}$$
3. *Turn information into error.* Lemma 26.3 forces this TV to be at least $1 - 2\beta$, so $a \ge (1 - 2\beta)\sqrt{2}/((e^{\varepsilon_0} - 1)\sqrt{n})$, and halving gives Equation 26.9.

□

Randomized response is optimal up to a constant, since dividing Equation 26.4 by Equation 26.9 leaves $\sqrt{2}\, e^{\varepsilon_0/2}/(1 - 2\beta)$. The contraction is loose by a constant. For one report at $\varepsilon_0 = 1$, comparing Bern(0.5) with Bern(0.6), the exact KL is 0.00429 and Equation 26.5 gives 0.02952. Duchi, Jordan & Wainwright (2018) apply the contraction to many local problems. Bounds of the same order hold even when each randomizer may depend on earlier reports.

Example 26.2. At $\varepsilon = 1$ and $n = 1{,}000$ (Figure 26.2), randomized response has standard deviation 3.03×10^{-2} and the lower bound at $\beta = 0.1$ is 1.04×10^{-2}. Their ratio 2.91 is the constant $\sqrt{2}\, e^{1/2}/(1 - 2\beta) = 1.4142 \times 1.6487/0.8$. The central Laplace mechanism gives $\sqrt{2}/1000 = 1.41 \times 10^{-3}$, 21 times less. That ratio is $0.678\sqrt{n}$, so it is 215 at $n = 100{,}000$ and 2146 at $n = 10^7$. For a standard deviation of 0.001, randomized response needs 920,674 people and the central mechanism 1,415 (Exercise 3 in the exercise book). So local DP suits only the frequent items of very large populations.

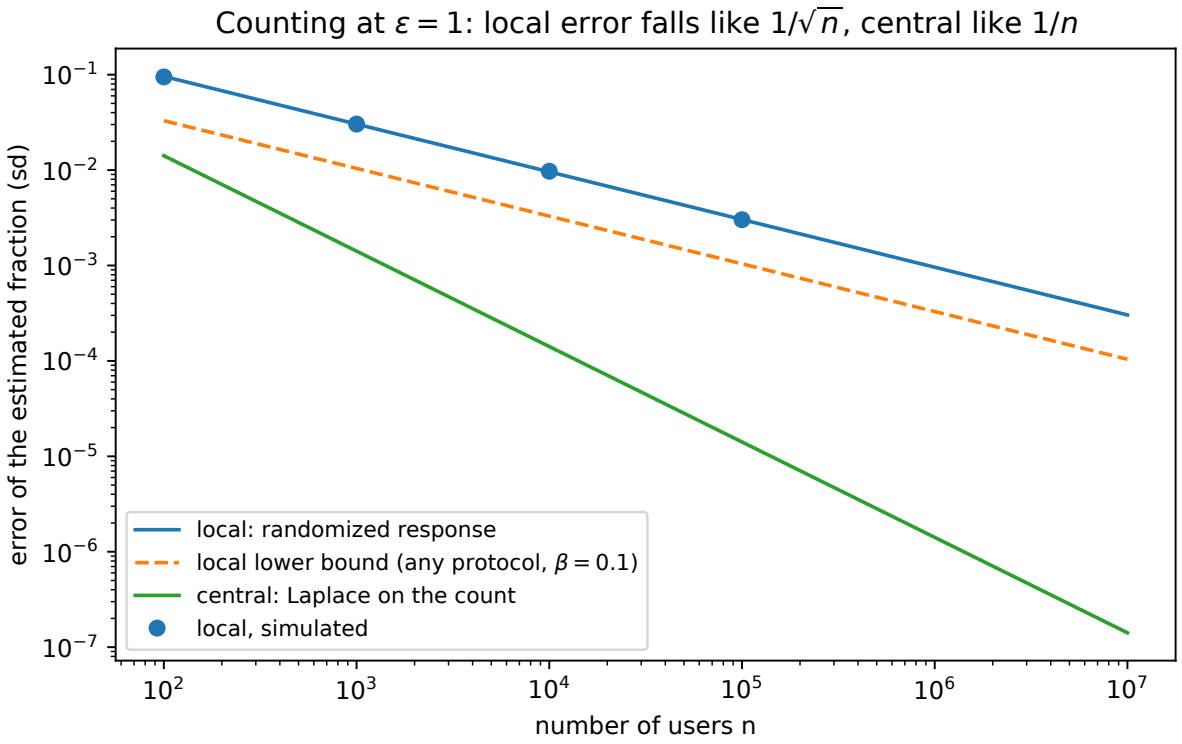

Figure 26.2.: Standard deviation of an estimated fraction at $\varepsilon = 1$. Randomized response (line, simulated dots) falls like $1/\sqrt{n}$, a constant above the local lower bound; the central Laplace mechanism falls like $1/n$.

26.3. Frequency estimation

In **frequency estimation** each person holds one of k values, such as an emoji, and the analyst wants the fraction f_v holding each value v. It is the workhorse of deployed local DP. This section compares two generalizations of randomized response, which behave very differently as k grows.

Both fit one template. For each value v, a report either **supports** v or not, and it supports v more often when its sender holds v, so Lemma 26.1 unshrinks the count of supports.

Proposition 26.3 (A pure frequency oracle)**.** *Suppose that for each value v a report supports v with probability p when its sender holds v and $q < p$ otherwise, independently across people. Let C_v count the reports that support v. Then the estimate $\hat{f}_v$ below is unbiased, with the exact variance shown:*

$$\hat{f}_v = \frac{C_v/n - q}{p - q}, \qquad \mathrm{Var}(\hat{f}_v) = \frac{f_v p(1-p) + (1-f_v)q(1-q)}{n(p-q)^2}. \tag{26.11}$$

Proof.

1. *Unbiased.* The holders support v with probability p and the others with q, so $\mathbb{E}[C_v/n] = q + f_v(p-q)$, and Lemma 26.1 applies.
2. *Variance.* The independent supports have variances $p(1-p)$ and $q(1-q)$, which add. Dividing by n^2 for the mean and by $(p-q)^2$ for the debiasing gives Equation 26.11.

□

What decides utility is the variance at $f_v = 0$. Most values of a large domain are rare, and below this noise floor a value cannot be told from an absent one.

Proposition 26.4 (k-ary randomized response and unary encoding)**.** ***k-ary randomized response*** *reports the true value with probability $p = \frac{e^{\varepsilon_0}}{e^{\varepsilon_0}+k-1}$ and each other value with probability $q = \frac{1}{e^{\varepsilon_0}+k-1}$, and a report supports the value it names. It is an ε_0-DP local randomizer, with rare-value variance*

$$\frac{e^{\varepsilon_0} + k - 2}{n(e^{\varepsilon_0} - 1)^2}. \tag{26.12}$$

Unary encoding *writes the value as k bits with only bit v set, sends each 1 as 1 with probability p and each 0 as 1 with probability q, and supports v if bit v is sent as 1. It is an ε_0-DP local randomizer with*

$$\varepsilon_0 = \ln \frac{p(1-q)}{q(1-p)}. \tag{26.13}$$

*The **symmetric** choice $q = 1 - p$, which is basic one-shot RAPPOR, has rare-value variance $e^{\varepsilon_0/2}/(n(e^{\varepsilon_0/2} - 1)^2)$. The **optimized** choice $p = \frac{1}{2}$, $q = 1/(e^{\varepsilon_0} + 1)$ (Wang et al. 2017) has $4e^{\varepsilon_0}/(n(e^{\varepsilon_0} - 1)^2)$. k-ary randomized response beats optimized unary encoding exactly when $k < 3e^{\varepsilon_0} + 2$.*

Proof. The plan is to check both privacy levels, then put each scheme's p and q into Equation 26.11 at $f_v = 0$.

1. *k-ary randomized response.* A report has probability p under the record it names and q under any other, so two records differ by at most $p/q = e^{\varepsilon_0}$.
2. *Unary encoding.* Changing x to x' changes two bits, and the others cancel. Bit x contributes p/q or $(1-p)/(1-q)$, and bit x' contributes q/p or $(1-q)/(1-p)$. Since $p > q$, the largest product is $\frac{p}{q} \cdot \frac{1-q}{1-p}$, so the two bits together cost ε_0, not $2\varepsilon_0$.
3. *Rare-value variances.* At $f_v = 0$, Equation 26.11 is $q(1-q)/(n(p-q)^2)$. For k-ary randomized response the factors $(e^{\varepsilon_0} + k - 1)^2$ cancel. For the optimized choice, $p - q = (e^{\varepsilon_0} - 1)/(2(e^{\varepsilon_0} + 1))$, and the squared 2 leaves the 4. The symmetric choice is binary randomized response at $\varepsilon_0/2$ per bit, so Proposition 26.2 gives its variance.
4. *Crossover.* The two variances share a denominator, so compare $e^{\varepsilon_0} + k - 2$ with $4e^{\varepsilon_0}$.

□

k-ary randomized response reports the truth with probability about e^{ε_0}/k, so its variance grows linearly in k (Figure 26.3). Unary encoding pays ε_0 once for two bits, so its variance does not depend on k, at the price of a k-bit report. The optimized choice rarely invents a 1, which matters because almost all bits are 0, and Exercise 2 in the exercise book shows $p = \frac{1}{2}$ is best. Every entry of Table 26.3 is still divided by n, so the gap of Theorem 26.1 remains.

Table 26.3.: n times the rare-value variance at $\varepsilon_0 = 1$. k-ary randomized response wins below $k = 3e + 2 = 10.15$.

k	k-ary randomized response	Symmetric unary	Optimized unary
2	0.921	3.918	3.683
8	2.953	3.918	3.683
32	11.082	3.918	3.683
128	43.596	3.918	3.683

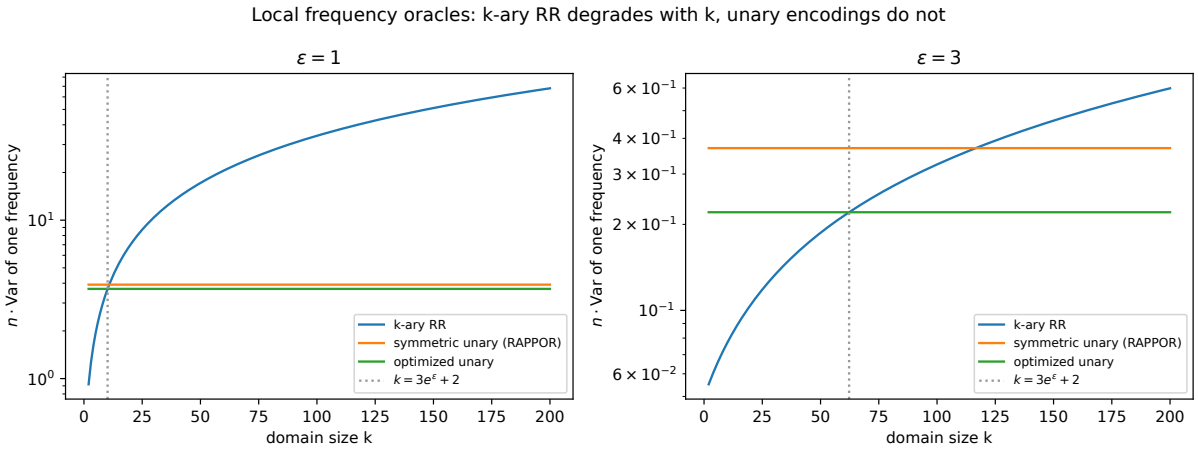

Figure 26.3.: n times the rare-value variance against k, at $\varepsilon_0 = 1$ and 3. The dotted line is the crossover $k = 3e^{\varepsilon_0} + 2$.

Example 26.3. The app's keyboard wants the frequency of each of $k = 128$ emoji at $\varepsilon_0 = 1$ from $n = 10^6$ users. k-ary randomized response gives a rare emoji a standard deviation of $\sqrt{43.596/10^6} = 0.0066$, and optimized unary encoding gives $\sqrt{3.683/10^6} = 0.0019$. An estimate must stand about three standard deviations above 0, so even with optimized unary encoding, emoji used by fewer than about 0.6% of users are lost. With $k = 8$, below the crossover, k-ary randomized response is better, at $\sqrt{2.953/10^6} = 0.0017$.

26.4. Large and unknown domains

A unary report carries one bit per possible value, which is absurd for all web addresses. And an oracle answers only for values the analyst names in advance, while a keyboard app wants words nobody listed. This section removes both limits. Hashing makes reports short, and growing prefixes finds the frequent values without a dictionary, the **heavy hitters** problem.

In **local hashing** each person draws a hash function h from a public family that maps the domain to w buckets, so that two values collide with probability $1/w$. They send the index of h and a w-ary randomized response of $h(x)$, with the p and q of Proposition 26.4 at w in place of k. A report supports v if its bucket equals $h(v)$.

Proposition 26.5 (Local hashing)**.** *Let $\hat{g}_v$ be the estimate of Equation 26.11 applied to the supports of v, which estimates the share of people whose own bucket is $h(v)$. Then the estimate below is unbiased for f_v, with the stated variance at $f_v = 0$:*

$$\hat{f}_v = \frac{w\,\hat{g}_v - 1}{w - 1}, \qquad \operatorname{Var}(\hat{f}_v)\big|_{f_v=0} = \frac{(e^{\varepsilon_0} + w - 1)^2}{n\,(w-1)\,(e^{\varepsilon_0} - 1)^2}. \tag{26.14}$$

It is smallest at $w = e^{\varepsilon_0} + 1$, where it equals optimized unary encoding's $4e^{\varepsilon_0}/(n(e^{\varepsilon_0} - 1)^2)$.

Proof. The plan is to undo two shrinkings with Lemma 26.1, the randomized response and then the collisions, and then to minimize the rare-value variance.

1. *The own bucket.* A holder of v lands in $h(v)$, and anyone else does with probability $1/w$. So a person's bucket is $h(v)$ with probability $g_v = \frac{1}{w} + f_v \frac{w-1}{w}$.
2. *The randomized response.* A report equals $h(v)$ with probability p if the bucket is $h(v)$ and q otherwise, so Lemma 26.1 makes $\hat{g}_v$ unbiased for g_v.
3. *The collisions.* Step 1 has offset $1/w$ and slope $(w-1)/w$, so Lemma 26.1 gives $\hat{f}_v$, with $(w/(w-1))^2$ times the variance of $\hat{g}_v$.
4. *A rare value.* At $f_v = 0$ a report supports v with probability exactly $1/w$, so each support has variance $(w-1)/w^2$. Dividing by n and $(p-q)^2$ and multiplying by $w^2/(w-1)^2$ leaves $1/(n(w-1)(p-q)^2)$, and $p - q = (e^{\varepsilon_0} - 1)/(e^{\varepsilon_0} + w - 1)$.
5. *The best width.* With $u = w - 1$, the part that depends on w is $e^{2\varepsilon_0}/u + 2e^{\varepsilon_0} + u$. Two positive terms with a fixed product have the smallest sum when equal, at $u = e^{\varepsilon_0}$.

□

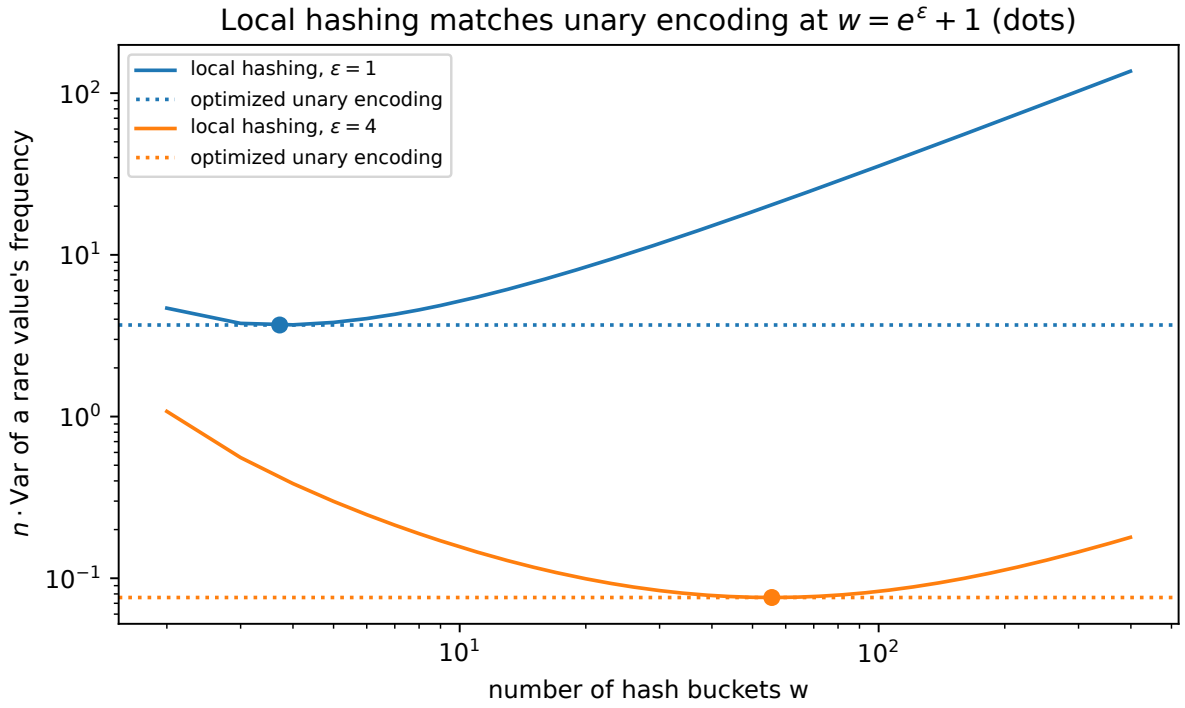

Figure 26.4.: n times the rare-value variance of local hashing against w, at $\varepsilon_0 = 1$ and 4. Dots mark $w = e^{\varepsilon_0} + 1$; dotted lines are optimized unary encoding.

Too few buckets waste the signal on collisions, and too many spread it thin (Figure 26.4). At $\varepsilon_0 = 4$, with $w = 56$, a report needs about 6 bits. The price is the server's work, which Hadamard response (Acharya, Sun & Zhang 2019) makes fast at a constant factor in variance.

To find unlisted values, write each as a string of L symbols from an alphabet of A symbols, and split the people at random into L groups. Group ℓ reports its first ℓ symbols, its **prefix**, by local hashing. The analyst keeps the prefixes whose estimate passes a threshold, extends each by every symbol, and moves to the next group. Write s for the standard deviation of an absent value's estimate, and Φ for the standard normal distribution function.

Proposition 26.6 (Heavy hitters by growing prefixes)**.** *If c_ℓ candidates are tested at level ℓ, then under the normal approximation the threshold*

$$\tau_\ell = z_\ell \, s, \qquad \text{where} \quad c_\ell \, (1 - \Phi(z_\ell)) = \beta, \tag{26.15}$$

admits on average β false candidates. Every prefix of a string is at least as frequent as the string, and each level tests only A extensions of each kept prefix.

Proof.

1. *The threshold.* An absent value's estimate averages many independent reports, so it is close to normal with mean 0, and exceeds $z\,s$ with probability about $1 - \Phi(z)$. Linearity of expectation sums this over the c_ℓ candidates.

2. *Prefixes.* Each holder of a string holds all its prefixes, so a prefix is at least as frequent as every string that starts with it.

□

The search is the TreeHist protocol of Bassily et al. (2017), and Bassily & Smith (2015) show that no local protocol finds values rarer than order $\sqrt{\ln k/n}/\varepsilon_0$.

Example 26.4. A million users each type one of 200 six-letter words with Zipf frequencies, at $\varepsilon_0 = 4$. The domain has $26^6 = 308{,}915{,}776$ strings. Local hashing uses $w = 56$, the integer nearest $e^4 + 1 = 55.60$, from 16,384 hash functions, so that collisions average out. Each of the six levels sees about 166,666 people, giving $s = 6.75 \times 10^{-4}$, and no level tests more than 2,054 candidates. At the last level, $\beta = 0.1$ puts the threshold at 3.80 standard deviations, a frequency of 0.0026.

The search returns 50 strings, all real words (Figure 26.5). The rarest word found has frequency 0.0033, and the most frequent word missed has 0.0035, lost to noise at one level. Testing all 26^6 strings would need 6.18 standard deviations, and at 3.80 it would raise about 22,418 false alarms.

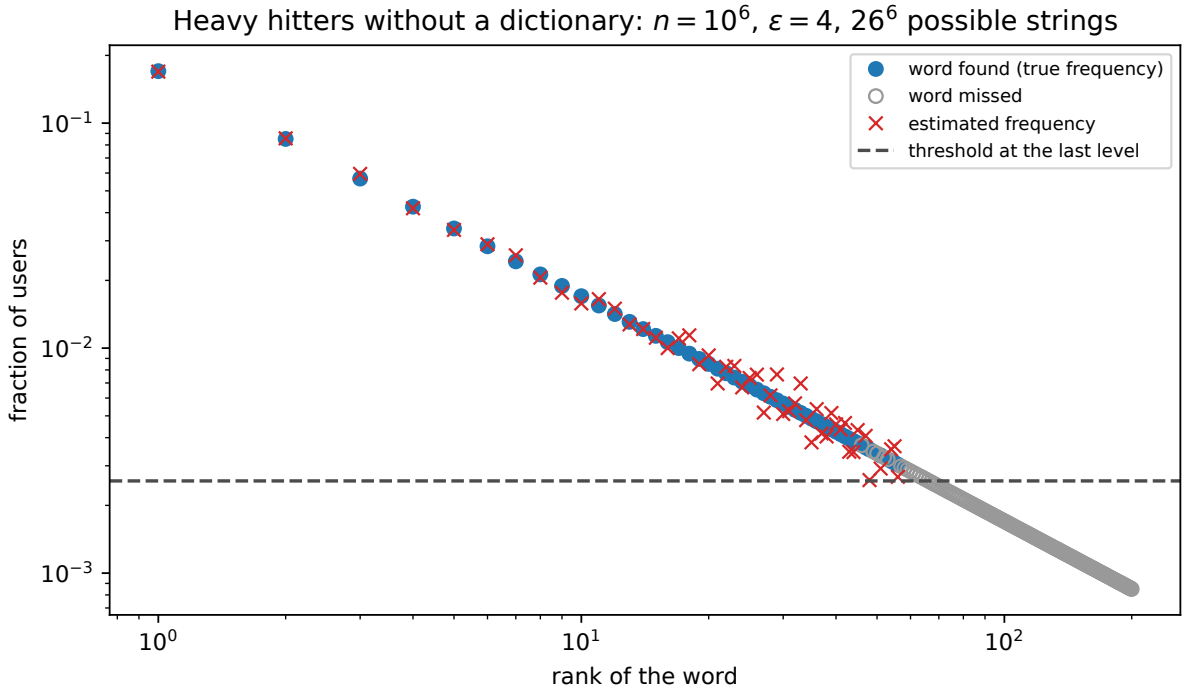

Figure 26.5.: The 200 words by rank: true frequency (circles, filled when found) and the estimate for each word found (crosses). The dashed line is the last level's threshold.

26.5. Estimating a mean

Telemetry also collects numbers, such as minutes in the app. Each person holds x_i between 0 and a known bound m, and the analyst wants the mean $\mu = \frac{1}{n}\sum_i x_i$. The questions are how accurate a local mean can be, and how few bits each phone must send.

Adding Laplace noise to each value is the obvious randomizer. Ding, Kulkarni & Yekhanin (2017) send one bit instead, whose probability of a 1 rises linearly from randomized response's lie probability at $x = 0$ to its truth probability at $x = m$.

Proposition 26.7 (Local means)**.** *Reports $x_i + \mathrm{Lap}(m/\varepsilon_0)$ are ε_0-DP, and their average is unbiased with standard deviation $\sqrt{2}\,m/(\varepsilon_0\sqrt{n})$. A bit Y_i with*

$$\Pr[Y_i = 1] = \frac{1}{e^{\varepsilon_0}+1} + \frac{x_i}{m}\cdot\frac{e^{\varepsilon_0}-1}{e^{\varepsilon_0}+1} \tag{26.16}$$

is also ε_0-DP, and the estimate below is unbiased with the stated bound for all data:

$$\hat{\mu} = \frac{m}{n}\sum_{i=1}^{n}\frac{(e^{\varepsilon_0}+1)Y_i - 1}{e^{\varepsilon_0}-1}, \qquad \mathrm{sd}(\hat{\mu}) \le \frac{m}{2\sqrt{n}}\cdot\frac{e^{\varepsilon_0}+1}{e^{\varepsilon_0}-1}. \tag{26.17}$$

Proof. The plan is to handle the Laplace reports in one step, then show that the bit is private, unbiased and of bounded variance.

1. *Laplace reports.* One value moves by at most m, so Theorem 20.1 applies, and the average of n variances $2m^2/\varepsilon_0^2$ has variance $2m^2/(n\varepsilon_0^2)$.
2. *Private.* For every value, both outcome probabilities of the bit lie between $1/(e^{\varepsilon_0}+1)$ and $e^{\varepsilon_0}/(e^{\varepsilon_0}+1)$, whose ratio is e^{ε_0}.
3. *Unbiased.* The mean of Y_i is linear in x_i, so Lemma 26.1 makes each summand of $\hat{\mu}$ unbiased for x_i.
4. *Variance.* A 0/1 variable has variance at most $1/4$, the summand scales it by $(m(e^{\varepsilon_0}+1)/(e^{\varepsilon_0}-1))^2$, and the average divides by n.

□

Both errors are of order $m/(\varepsilon_0\sqrt{n})$, against $m/(\varepsilon_0 n)$ centrally, and Duchi, Jordan & Wainwright (2018) show that no local protocol beats this order. The bit wins on communication, since a Laplace report needs about $\log_2 m$ bits. Its bound is 0.765 times the Laplace standard deviation at $\varepsilon_0 = 1$, and the two are equal at $\varepsilon_0 = 2.324$.

The bound m must be fixed before collection, because every randomizer uses it. A device whose value exceeds m clips it, which biases the mean down, so a bound set too low trades noise for bias.

Example 26.5. A million users spend between 0 and $m = 1{,}440$ minutes a day in the app, with a mean of 82.74. At $\varepsilon_0 = 1$ the one-bit estimate has standard deviation 1.420 minutes, within the bound 1.558 of Equation 26.17. In 200 simulated collections the estimates average 82.61, with standard deviation 1.415. Laplace reports would give 2.036 minutes, at about 11 bits each.

26.6. Collecting every day

Telemetry asks the same question every day, and basic composition (Post-processing, group privacy and composition) prices T reports of one record at $T\varepsilon_0$. This section shows that the price is real, then gives the two fixes deployments use, **memoization** and **α-point rounding**.

Proposition 26.8 (Fresh reports leak)**.** *Suppose a person reports the same bit every day by randomized response at level ε_0, with fresh randomness. After T days with k ones, the likelihood ratio between bit 1 and bit 0 is $e^{\varepsilon_0(2k-T)}$, and the majority of the reports is wrong with a probability that falls exponentially in T.*

Proof.

1. *The ratio.* A sequence with k ones has probability $t^k(1-t)^{T-k}$ under bit 1 and $(1-t)^k t^{T-k}$ under bit 0, and $t/(1-t) = e^{\varepsilon_0}$.
2. *The majority.* It errs when more than half the reports flip, a binomial tail with flip probability below $\frac{1}{2}$, which falls exponentially by the Chernoff bound of Concentration inequalities.

□

The fix is to randomize once. In memoization the person draws one permanent randomized response per value and reuses it. RAPPOR encodes the value as a **Bloom filter**, a bit vector in which H hash functions each set one bit, and the permanent response replaces each bit by a fair coin with probability ϕ.

Proposition 26.9 (Memoization)**.** *All reports of an unchanged value, however many, are together as private as its permanent response. For RAPPOR that level, written ε_∞ because it covers unboundedly many reports, is*

$$\varepsilon_\infty = 2H \ln \frac{1-\phi/2}{\phi/2}. \tag{26.18}$$

Proof.

1. *Post-processing.* The reports are a function of the permanent response and of randomness independent of the data.
2. *RAPPOR.* A 1 is reported as 1 with probability $1-\phi/2$ and a 0 with probability $\phi/2$. Two values' filters differ in at most $2H$ bits, and the others cancel.

□

Each new value costs another ε_∞. RAPPOR's homepage collection used $H = 2$ and $\phi = 0.75$, giving $\varepsilon_\infty = 4\ln(5/3) = 2.043$. A fixed response would let the collector link a sender's reports across days, like a cookie, so RAPPOR re-randomizes it before each report, and one report is then ε_1-DP with $\varepsilon_1 = 0.5343$ (Exercise 9 in the exercise book).

A value that drifts, such as minutes, would need a new response every day. Ding, Kulkarni & Yekhanin (2017) instead draw, once, a bit b_0 by Equation 26.16 at $x = 0$, a bit b_m at $x = m$ and an offset α uniform on $[0, m)$. In round t the person sends b_m if $x_t + \alpha \geq m$ and b_0 otherwise, so

that the random offset picks b_m with probability x_t/m. **Output perturbation** then flips each sent bit with a small probability κ, to blur the days on which the sent bit switches.

Proposition 26.10 (α-point rounding)**.** *With values in* $[0, m]$*, and* b_0*,* b_m *and* α *drawn once, independently of the data:*

1. *Each report has the distribution of Equation 26.16, so each round's* $\hat{\mu}$ *satisfies Equation 26.17.*
2. *The reports depend on the data only through the days with* $x_t + \alpha \geq m$*, and with probability* $2e^{\varepsilon_0}/(e^{\varepsilon_0}+1)^2$ *the kept bits agree, so every report is the same.*
3. *Values that stay in a band of width* d *change the report only if* $m - \alpha$ *falls in the band, which has probability* d/m*.*
4. *With output perturbation one round is* ε_0'*-DP, with*

$$\varepsilon_0' = \ln \frac{(1-2\kappa)\frac{e^{\varepsilon_0}}{e^{\varepsilon_0}+1} + \kappa}{(1-2\kappa)\frac{1}{e^{\varepsilon_0}+1} + \kappa}, \tag{26.19}$$

and if, for every offset, two sequences of values select different kept bits on at most r *days, their transcripts have likelihood ratio at most* $((1-\kappa)/\kappa)^r$*.*

Proof. The plan is to average over the offset for item 1, read items 2 and 3 off the construction, and multiply daily ratios for item 4.

1. *Unbiased.* For a value x, b_m is sent with probability $\Pr[\alpha \geq m - x] = x/m$, so the report is 1 with probability $(1 - x/m)/(e^{\varepsilon_0}+1) + (x/m)\, e^{\varepsilon_0}/(e^{\varepsilon_0}+1)$.
2. *Dependence.* Each report is b_0 or b_m, chosen by $x_t + \alpha \geq m$. Both kept bits are 1 with probability $e^{\varepsilon_0}/(e^{\varepsilon_0}+1)^2$, and both 0 with the same probability. The choice switches only if $m - \alpha$, uniform on $(0, m]$, lies in the band.
3. *One round.* The flip maps a probability π of a 1 to $\kappa + (1-2\kappa)\pi$, still linear, so the worst ratio is between the ends of Equation 26.16.
4. *Transcripts.* Fix the kept bits and offset. A day sending the same kept bit under both sequences cancels, and a differing day has ratio at most $(1-\kappa)/\kappa$. The flips are independent, so the ratios multiply, for every offset.

□

So the collector learns nothing about people whose kept bits agree, and about the others only when their value crosses a secret threshold. So the guarantee protects steady behaviour, while a person whose behaviour changes reveals roughly when. Microsoft deployed the protocol in Windows 10 at $\varepsilon_0 = 1$ every six hours with $\kappa = 0.2$, where Equation 26.19 gives 0.569 per round, while the paper reports a more conservative 0.686.

Example 26.6. Fresh reports at $\varepsilon_0 = \ln 3$ leak fast. After 100 days with 75 ones the likelihood ratio is 3^{50}, about 7.18×10^{23}, while a memoized report leaves the majority wrong with probability $1 - t = 0.25$ (Figure 26.6).

For the app's minutes, with $m = 1{,}440$ and $\varepsilon_0 = 1$, the kept bits agree with probability $2e/(e+1)^2 = 0.3932$. Let each person's minutes wobble by up to 15 either side of their level for 30 days. By item 3, the fraction whose report ever changes is $(1 - 0.3932)$ times the expected range of their values over m, which is 0.0118. A simulation of 100,000 people gives 0.0119, against 1.0000

with fresh one-bit reports. On one freshly simulated day the α-point estimate is 82.17 minutes against that day's true mean of 82.68, within the standard deviation of 1.42. With $\kappa = 0.2$, each change costs $\ln(0.8/0.2) = 1.386$.

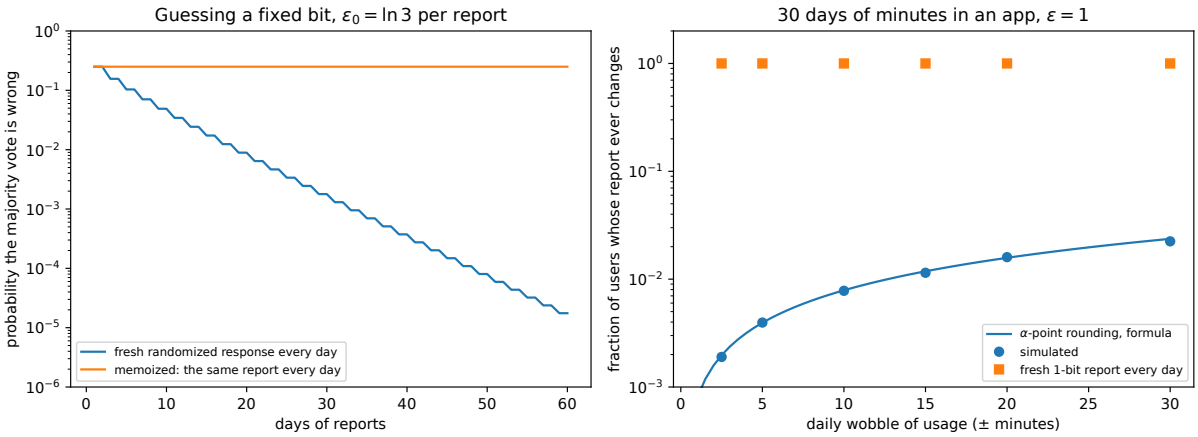

Figure 26.6.: Left: how often the majority of T daily reports is wrong, fresh or memoized. Right: the fraction of reports that ever change in 30 days, α-point or fresh.

26.7. The shuffle model

The local model loses $\sqrt{n}$ because the analyst knows whose report is whose. In the **shuffle model** (Bittau et al. 2017; Cheu et al. 2019) each person sends a randomized report to a **shuffler**, which strips identifiers and forwards a random permutation. The shuffler is trusted only to unlink, since the reports it sees are ε_0-DP. This section asks how far the central ε then falls.

Call the person whose privacy is at stake the target. The more reports the target's report is mixed with, the less the multiset reveals. The bound to compute with is Theorem 3.1 of Feldman, McMillan & Talwar (2021), in this book's notation and for replace neighbours. Its randomizers may depend on earlier outputs, which covers adaptive protocols.

Theorem 26.2 (Amplification by shuffling)**.** *Let $R_i(z_{1:i-1}, \cdot)$, for $i = 1, \dots, n$, be an ε_0-DP local randomizer for every value of the earlier outputs $z_{1:i-1}$. Let M_{sh} draw a uniform random permutation Π, compute $z_i = R_i(z_{1:i-1}, x_{\Pi(i)})$ in turn and output $z_{1:n}$. For any $\delta \in [0,1]$ with $\varepsilon_0 \le \ln\left(\frac{n}{16\ln(2/\delta)}\right)$, M_{sh} is (ε, δ)-DP with*

$$\varepsilon \le \ln\left(1 + \frac{e^{\varepsilon_0} - 1}{e^{\varepsilon_0} + 1}\left(\frac{8\sqrt{e^{\varepsilon_0}\ln(4/\delta)}}{\sqrt{n}} + \frac{8e^{\varepsilon_0}}{n}\right)\right). \tag{26.20}$$

The proof is in Amplification by shuffling and by iteration, which bounds the hockey-stick divergence of two binomial counts. Its first step, the lemma below, carries the intuition that other people's reports can look exactly like the target's.

Lemma 26.4 (Clones)**.** *Let R be an ε_0-DP local randomizer and x^0, x^1 the two values the target might hold. Then for every other value x there is a distribution $\mathrm{LO}(x)$, the leftover, with*

$$R(x) = \frac{e^{-\varepsilon_0}}{2} R(x^0) + \frac{e^{-\varepsilon_0}}{2} R(x^1) + (1 - e^{-\varepsilon_0})\,\mathrm{LO}(x). \tag{26.21}$$

Proof.

1. *A floor.* By Equation 26.1, $p_R(y \mid x)$ is at least $e^{-\varepsilon_0} p_R(y \mid x^0)$ and at least $e^{-\varepsilon_0} p_R(y \mid x^1)$, so it is at least half their sum.
2. *The leftover.* Subtracting the two pieces leaves a non-negative mass of total $1 - e^{-\varepsilon_0}$, which rescales to $\mathrm{LO}(x)$.

□

So with probability $e^{-\varepsilon_0}$ each other person sends a **clone**, a report distributed like one of x^0 or x^1. About $(n-1)e^{-\varepsilon_0}$ clones, split at random between the two values, hide the target after shuffling. The theorem's condition, $ne^{-\varepsilon_0} \geq 16 \ln(2/\delta)$, asks for enough expected clones.

Example 26.7. For 4-ary randomized response at $\varepsilon_0 = \ln 3$ (Figure 26.7), $p = \frac{1}{2}$ and $q = \frac{1}{6}$. Take a target with $x^0 = 1$ or $x^1 = 2$. Another person with value 3 reports $(\frac{1}{6}, \frac{1}{6}, \frac{1}{2}, \frac{1}{6})$, the clone part is $\frac{1}{6}(R(1) + R(2)) = (0.1111, 0.1111, 0.0556, 0.0556)$, and the leftover has mass $0.6667 = 1 - e^{-\varepsilon_0}$.

For central $(1, 10^{-6})$, bisection on Equation 26.20 allows each user $\varepsilon_0 = 3.504$ at $n = 10^4$, 5.701 at 10^5 and 7.992 at 10^6. At 7.992, 8-ary randomized response keeps the truth with probability 0.998. For adding up bits as in Cheu et al. (2019), only about 676 of a million people then send a random bit, and the count has standard deviation 18.4, against 960 for local randomized response at $\varepsilon_0 = 1$.

The factor before the bracket of Equation 26.20 is $\tanh(\varepsilon_0/2)$. For large n the $1/n$ term is negligible and $\ln(1+u) \approx u$, so the bound is about $8 \tanh(\varepsilon_0/2) \sqrt{e^{\varepsilon_0} \ln(4/\delta)/n}$ (Figure 26.8). So a target ε allows e^{ε_0} of order $\varepsilon^2 n / \ln(1/\delta)$, and binary randomized response at that level has error about $1/\sqrt{ne^{\varepsilon_0}} = \sqrt{\ln(1/\delta)}/(\varepsilon n)$ on a fraction. Times n, that is the shuffle row of Table 26.2. The constants are loose (Table 26.4). The numeric column computes the paper's clone-count comparison exactly, and the exact column is shuffled binary randomized response, below which no general bound can go. Reason with the closed form, but deploy with a numerical accountant.

Table 26.4.: Central ε after shuffling $n = 10^4$ reports at $\delta = 10^{-6}$; the condition requires $\varepsilon_0 \leq 3.763$.

ε_0	Closed form, Equation 26.20	Numeric (Theorem 3.2)	Exact, shuffled binary randomized response
0.5	0.0939	0.0204	0.0162
1	0.2140	0.0530	0.0357
2	0.5009	0.1550	0.0870
3	0.8241	0.3207	0.1692

The amplification lasts only while the shuffler does its job, because a shuffler that colludes with the analyst leaves only ε_0. Fake senders hide nobody, so only honest senders count in n (Exercise 5 in the exercise book).

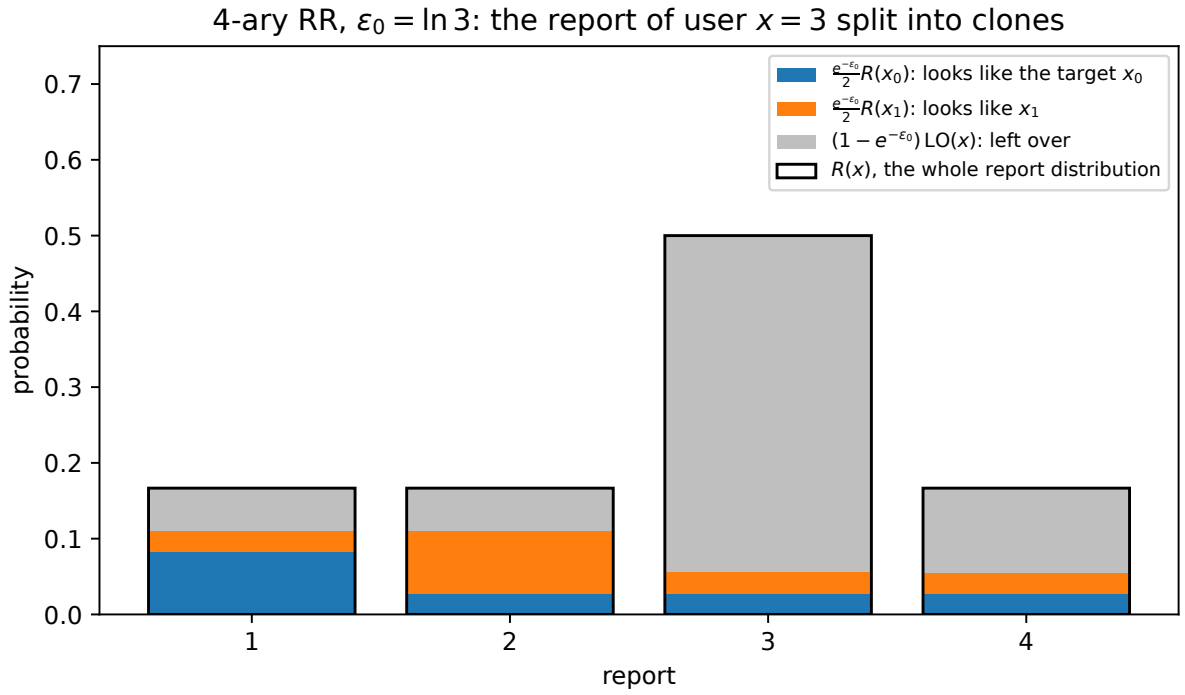

Figure 26.7.: The report distribution of value 3 under 4-ary randomized response at $\varepsilon_0 = \ln 3$, split into clones of value 1 (blue) and value 2 (orange) and a leftover (grey).

26.8. Distributed noise

The shuffle model still adds noise to every report. In the **distributed model** each client adds a small share of the central noise, and a **secure aggregation** protocol reveals only the sum. The question is what that costs, and what dishonest clients do to it.

Secure aggregation is built from the additive secret sharing of Cryptography basics, with a practical version by Bonawitz et al. (2017). The one property used is **simulation**: everything the server sees could be generated from the sum alone. The noise works because independent Gaussian shares add to a Gaussian whose variance is the sum of theirs.

Proposition 26.11 (Distributed Gaussian noise)**.** *Let n clients hold vectors x_i whose sum $f(D)$ has ℓ_2 sensitivity $\Delta_2 f$, and let each send $x_i + Z_i$ through secure aggregation, with independent $Z_i \sim \mathcal{N}(0, \frac{\sigma^2}{n} I)$. The server's view is (ε, δ)-DP whenever the Gaussian mechanism with noise σ on f is. If an adversary knows the noise of t clients, the guarantee is that of noise $\sigma\sqrt{(n-t)/n}$.*

Proof.

1. *The shares add up.* Independent normals add their variances, so $\sum_i Z_i \sim \mathcal{N}(0, \sigma^2 I)$.
2. *Only the sum is revealed.* By simulation the view is a function of the sum and independent randomness, so post-processing applies.
3. *Colluders.* Removing what they know leaves $n - t$ shares of variance σ^2/n, whose privacy is the exact curve of Theorem 20.3.

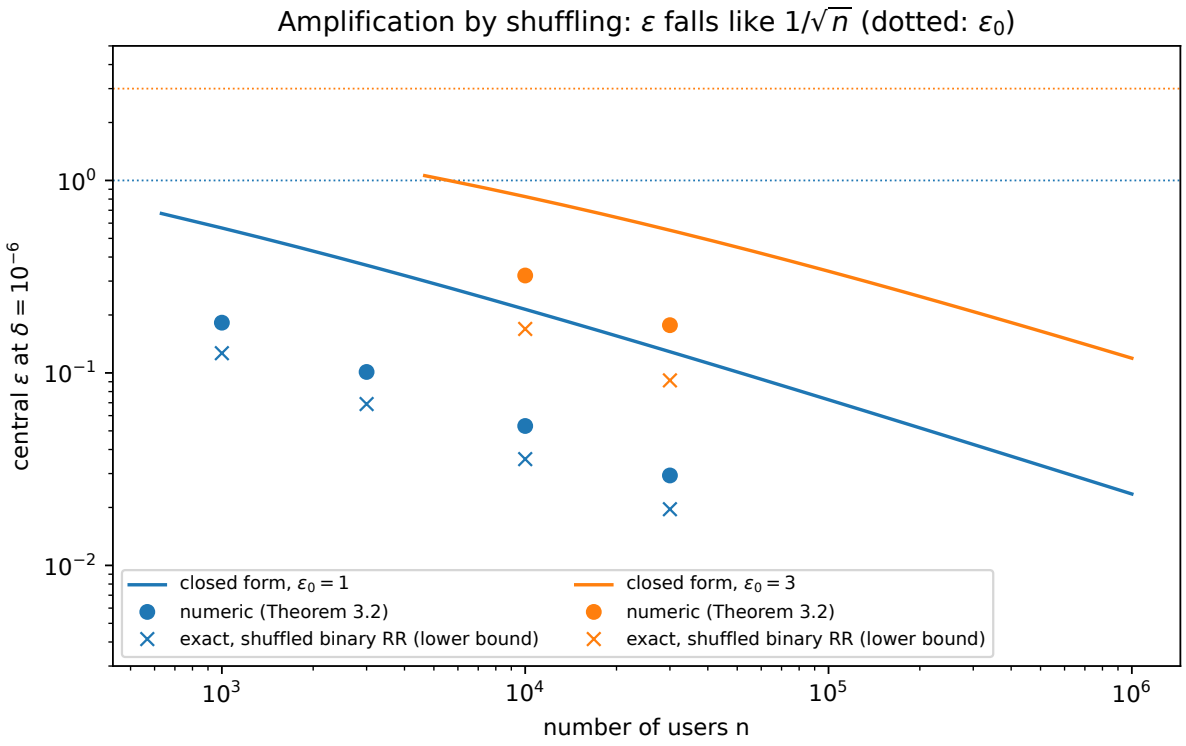

Figure 26.8.: Central ε at $\delta = 10^{-6}$ after shuffling, against n: closed form (lines), numeric bound (dots), exact binary randomized response (crosses). Dotted lines mark ε_0.

□

Secure aggregation adds integers modulo a large number, because only on a finite set can shares be uniformly random. **Skellam noise** (Agarwal, Kairouz & Liu 2021) fits. $\mathrm{Sk}(\mu)$ is the difference of two independent Poisson(μ) variables, with variance 2μ. Sums of independent Poisson variables are Poisson, because their moment generating functions multiply (Distributions), so n shares $\mathrm{Sk}(\mu/n)$ add to exactly $\mathrm{Sk}(\mu)$. Its privacy is close to a Gaussian's of the same variance, which this chapter uses as the approximation. The distributed discrete Gaussian (Kairouz, Liu & Steinke 2021) is the alternative.

Distributed noise gives central Gaussian accuracy without a curator, as long as enough clients are honest (Figure 26.9). If at most a fraction ρ may collude or drop out, each client adds variance $\sigma^2/(n(1-\rho))$, so the honest ones alone supply σ^2 (Exercise 7 in the exercise book). Malicious inputs are another problem, since secure aggregation does not check them.

Example 26.8. A server aggregates the app's histogram through 100 clients at $(\varepsilon, \delta) = (1, 10^{-6})$. A user who changes value moves one count down and another up, so $\Delta_2 f = \sqrt{2}$. The analytic calibration of Corollary 20.1 gives total noise $\sigma = 5.975$, so each client adds standard deviation $5.975/\sqrt{100} = 0.597$. With 80%, 50% or 10% of the clients honest, ε rises to 1.128, 1.455 or 3.525. The script also checks that 100 Skellam shares of total variance 25 sum to mean 0.004 and variance 25.15, and that sharing $(3, -2)$, $(5, 7)$ and $(0, 1)$ modulo 2^{20} reveals $(8, 6)$.

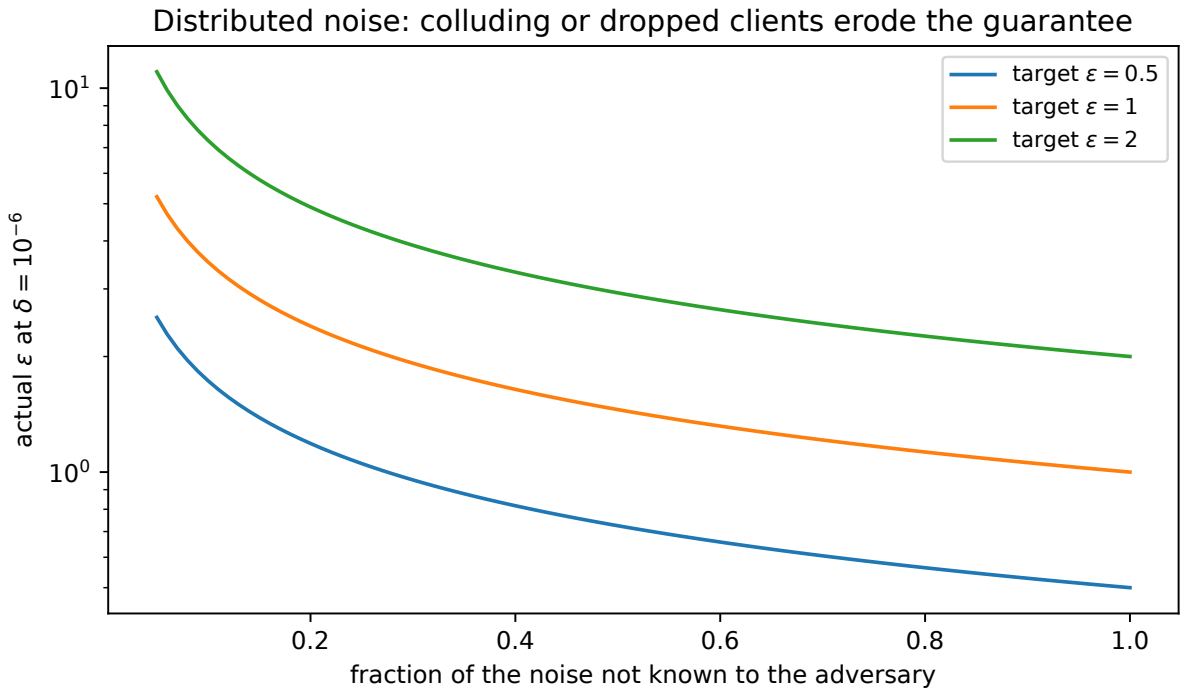

Figure 26.9.: The actual ε at $\delta = 10^{-6}$ against the fraction of the noise the adversary does not know.

26.9. Code

The script code/trust_models.py computes every number in this chapter and draws its figures. Its central comparison estimates an 8-value histogram at $(1, 10^{-6})$ in all four models, exactly and in 200 simulated runs (Figure 26.10). From the repository root:

```
uv run python code/part03-dp-foundations/trust_models.py
```

Table 26.5.: Output of the chapter's script (seed 0). The matched rows are the exact expected squared ℓ_2 errors; the simulated ones agree within Monte Carlo error.

Experiment	Result
Randomized response, $\varepsilon = \ln 3$, $n = 10^4$	sd 0.00866 (simulated mean 0.3000, sd 0.00861); count sd local 86.6, central 1.287, ratio 67.3
Fraction sd at $\varepsilon = 1$	$n = 10^3$: local 3.03×10^{-2}, central 1.41×10^{-3}, ratio 21, lower bound 1.04×10^{-2}; ratio 215 at 10^5, 2146 at 10^7
One report, Bern(0.5) against Bern(0.6)	KL 0.00429; bound 0.02952
Frequency oracles, $\varepsilon_0 = 1$	Table 26.3; both unary encodings have $\varepsilon_0 = 1.0000$
Local hashing, best w	$n \cdot$ Var 3.6917 ($w = 4$) and 0.0760 ($w = 56$); optimized unary 3.6827 and 0.0760
Heavy hitters, $\varepsilon_0 = 4$	50 found, all real; rarest 0.0033; threshold 0.0026; 22,418 false alarms if every string were tested
One-bit mean, $\varepsilon_0 = 1$	sd 1.420 (bound 1.558, simulated 1.415); Laplace 2.036; equal at $\varepsilon_0 = 2.324$
Repeated collection	Ratio 7.18×10^{23}; $\varepsilon_\infty = 2.043$, $\varepsilon_1 = 0.5343$; α-point changes 0.0119 (formula 0.0118)
Clones and shuffling	Leftover 0.6667; Table 26.4; largest ε_0 for $\varepsilon = 1$: 1.460 (10^3, the cap), 3.504, 5.701, 7.992
Distributed, 100 clients	$\sigma = 5.975$, 0.597 per client; ε at 80%, 50%, 10% honest: 1.128, 1.455, 3.525
Matched, $n = 10^3$	Central 6.40×10^{-5}; distributed 2.86×10^{-4}; shuffle 9.35×10^{-3}; local 2.71×10^{-2}
Matched, $n = 10^4$	Central 6.40×10^{-7}; distributed 2.86×10^{-6}; shuffle 4.88×10^{-5}; local 2.71×10^{-3}
Matched, $n = 10^5$	Central 6.40×10^{-9}; distributed 2.86×10^{-8}; shuffle 4.76×10^{-7}; local 2.71×10^{-4}

tests/test_trust_models.py checks that the output still matches.

26.10. Summary

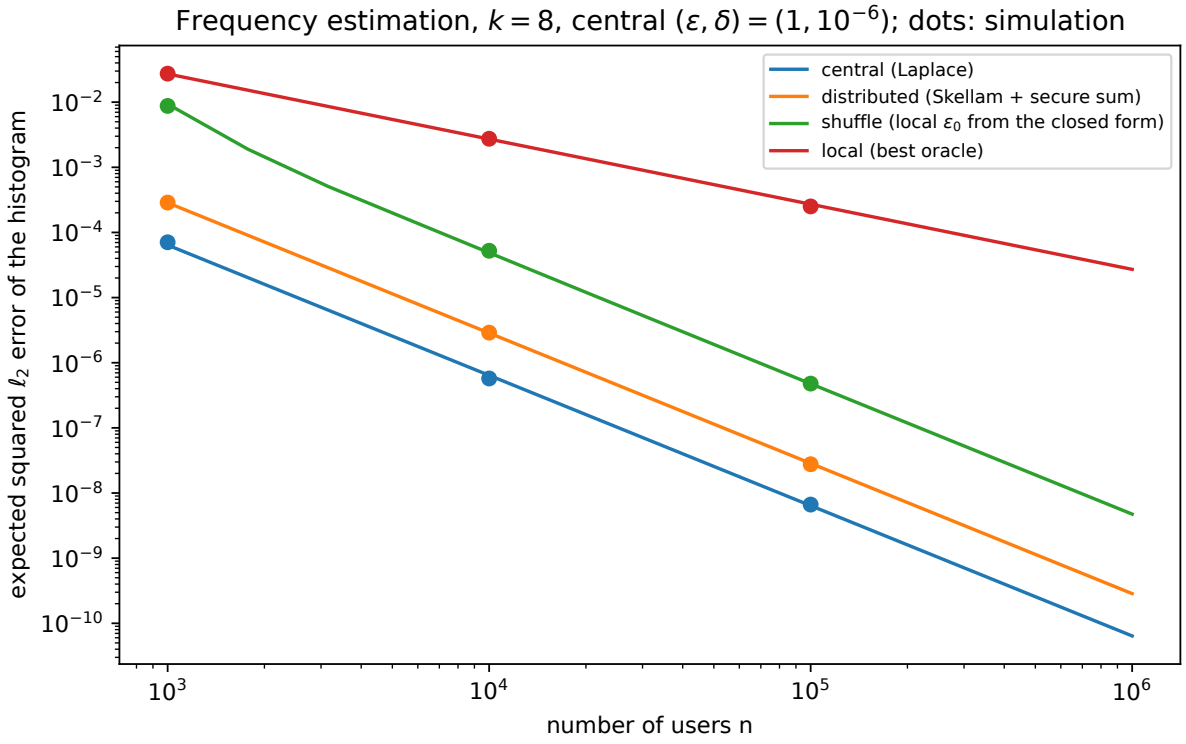

Figure 26.10.: Expected squared ℓ_2 error of the 8-value histogram at $(1, 10^{-6})$ in the four models: exact (lines) and simulated (dots).

Table 26.6.: The results of this chapter, and where each is used.

Result	Statement	Use
Proposition 26.1	Local randomizers make the transcript ε_0-DP against everyone	State the trust model next to (ε, δ)
Lemma 26.1	$(Y - c_0)/c_1$ is unbiased, variance $\mathrm{Var}(Y)/c_1^2$	Every local estimator
Proposition 26.2	$\mathrm{sd} = e^{\varepsilon_0/2}/((e^{\varepsilon_0} - 1)\sqrt{n})$	Counting one bit
Theorem 26.1	Error $\geq (1 - 2\beta)/((e^{\varepsilon_0} - 1)\sqrt{2n})$	Local DP costs about $\sqrt{n}$; use it for frequent items of large populations
Proposition 26.4	Rare variance grows with k for k-ary, is flat for unary	k-ary when $k < 3e^{\varepsilon_0} + 2$, else optimized unary
Proposition 26.5, Proposition 26.6	Best at $w = e^{\varepsilon_0} + 1$; prefixes grown level by level	Huge or unknown domains
Proposition 26.7	One bit per person, sd at most Equation 26.17	Numeric telemetry; fix m in advance
Proposition 26.9, Proposition 26.10	One permanent response per value; α-point rounding for drifting values	Memoize daily collection; fresh noise is averaged away (Proposition 26.8)
Theorem 26.2	Equation 26.20, about $8 \tanh(\varepsilon_0/2)\sqrt{e^{\varepsilon_0} \ln(4/\delta)/n}$	ε_0 up to about $\ln(\varepsilon^2 n / \ln(1/\delta))$; deploy with a numerical bound
Proposition 26.11	Shares $\mathcal{N}(0, \sigma^2/n)$ sum to $\mathcal{N}(0, \sigma^2)$	Over-provision for collusion and dropouts

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

27. Lower bounds: what privacy costs

The earlier chapters of this part built mechanisms and measured their error. The Laplace mechanism releases a histogram over N bins with error about $\ln N/\varepsilon$ per bin, and the Gaussian mechanism releases d attribute means with error about $\sqrt{d\ln(1/\delta)}/(n\varepsilon)$ each. These **upper bounds** leave a question open: is that error the price of privacy, or of a clumsy mechanism? A **lower bound** answers it, because it says that *no* mechanism satisfying differential privacy (DP) can be more accurate.

One idea proves every lower bound here: accuracy is an attack. An accurate output tells an attacker which of many datasets was used, whether a person is in it, or what a secret bit was. DP limits every such attack, because no test can tell the outputs on two neighbouring datasets apart much better than chance. So if the attack built from an accurate mechanism would beat that limit, the mechanism cannot be both accurate and private, and solving the inequality for the error or for the number of records n gives the bound.

The running example is a survey in which each of n people answers d yes/no questions, and the release is the vector of the d attribute means, under replace neighbours. One question with $N = 10^6$ possible answers, a ZIP code, gives a histogram under add/remove neighbours. The examples use $\varepsilon = 1$, a failure probability $\beta = 0.05$ and $\delta = 10^{-6}$. Packing shows that under pure DP the histogram's error grows like $\ln N/\varepsilon$. Fingerprinting shows that under approximate DP the d means need n growing like $\sqrt{d}$, through a membership inference attack that you will run. The Dinur–Nissim attack of Reconstruction attacks shows that about n counting queries need error of order $\sqrt{n}$. Table 27.1 lists the symbols.

Table 27.1.: The symbols of this chapter.

Symbol	Meaning
M, $M(D)$	the mechanism and its random output on the dataset D
$D \sim D'$	neighbours: one record added or removed (histograms) or replaced (elsewhere)
ε, δ	the privacy parameters; pure DP is $\delta = 0$
α, β	the error and failure probability of an accuracy guarantee
n, d, N	the numbers of records, of attributes, and of histogram bins
m, k	the number of candidates in a packing, and their distance in records from the reference
p_j, x_{ij}, $\bar{x}$	the population mean of attribute j, person i's answer (± 1), and the sample means

27.1. Packing: pure DP pays the logarithm of the number of candidates

Suppose the output of a mechanism must point to one of m candidates, such as the most common ZIP code. For each candidate i you can build a dataset D_i on which an accurate mechanism lands in a region G_i of outputs almost always. Run the mechanism on one reference dataset D_0 instead, and on average each region gets at most a share $1/m$ of its probability. But DP says the output on D_0 cannot look very different from the output on a nearby D_i. For large m the two clash, and the clash is **packing**, the private version of Fano's method in Information theory.

Every bound in this chapter starts from an accuracy guarantee.

Definition 27.1 ((α, β)-accuracy)**.** A mechanism M is (α, β)**-accurate** for a quantity if, on *every* dataset, its output is within the **error** α of that quantity with probability at least $1 - \beta$, where β is the **failure probability**. These are not the error rates of a test, which other chapters write α and β.

The packing lemma compares D_0 with datasets k records away, so it uses group privacy, proved in Post-processing, group privacy and composition. Each of the k steps multiplies the bound by e^{ε} and adds a slack δ, which later steps multiply again. If M is (ε, δ)-DP and D, D'' differ in k records, then for every set of outputs S

$$\Pr[M(D) \in S] \le e^{k\varepsilon} \Pr[M(D'') \in S] + \delta_k, \qquad \delta_k = \delta \sum_{j=0}^{k-1} e^{j\varepsilon} \le k\, e^{(k-1)\varepsilon} \delta. \tag{27.1}$$

The slack grows geometrically: at $\varepsilon = 1$ and $\delta = 10^{-6}$, $\delta_5 = 8.6 \times 10^{-5}$ is small, while $\delta_{20} = 282$ bounds a probability by more than 1. So the lemma is stated for pure DP, where it says that m demands of size $(1 - \beta)e^{-k\varepsilon}$ must fit into a total of 1.

Lemma 27.1 (Packing lemma)**.** *Let $D_0, D_1, \dots, D_m$ be datasets with D_0 within k records of every D_i, and let $G_1, \dots, G_m$ be disjoint sets of outputs. If M is ε-DP and $\Pr[M(D_i) \in G_i] \ge 1 - \beta$ for every i, then*

$$m(1 - \beta)e^{-k\varepsilon} \le 1, \qquad \textit{that is,} \qquad k \ge \frac{\ln\left(m(1 - \beta)\right)}{\varepsilon}. \tag{27.2}$$

Proof.

1. *Each region gets a share of $M(D_0)$.* Accuracy says that G_i is likely under D_i, and group privacy Equation 27.1 with $\delta = 0$ says that it cannot be much less likely under D_0:

$$1 - \beta \le \Pr[M(D_i) \in G_i] \le e^{k\varepsilon} \Pr[M(D_0) \in G_i]. \tag{27.3}$$

   So $M(D_0)$ puts probability at least $(1 - \beta)e^{-k\varepsilon}$ on each G_i.
2. *The shares fit into one distribution.* The regions are disjoint, so no output is counted twice and the m shares add up to at most 1. Overlapping regions would let one output serve several candidates.
3. *Combine.* Adding the m bounds of step 1 and using step 2 gives the first form, and taking logarithms gives the second. Figure 27.1 draws this step.

□

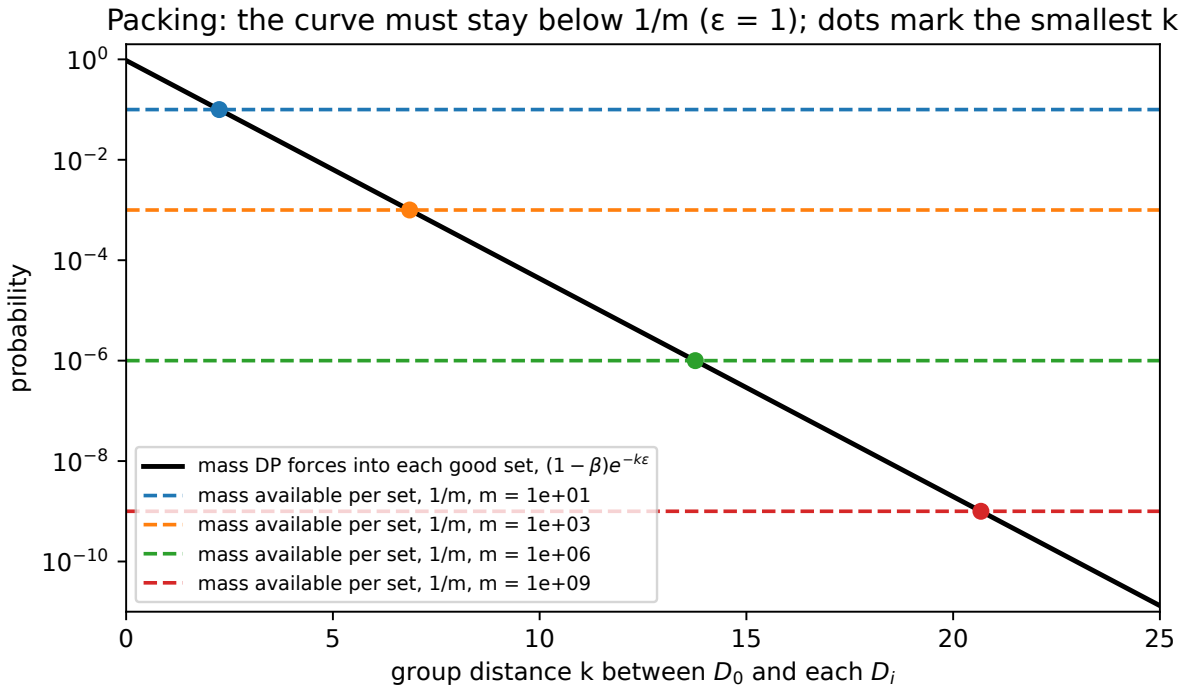

Figure 27.1.: The packing argument at $\varepsilon = 1$, $\beta = 0.05$. Black: the share $(1-\beta)e^{-k\varepsilon}$ that $M(D_0)$ must put on each good region. Dashed: the average share available with m regions. Accuracy at group distance k is impossible left of each dot.

Two consequences follow by choosing the datasets. The **mode** is the most frequent element of the data. A **histogram** is the vector of counts of N elements, and its ℓ_∞ error is its largest error over the bins. A histogram accurate to within α finds a spike of height above 2α, so it inherits the mode's bound, halved.

Theorem 27.1 (Mode and histogram lower bounds)**.** *Let M be ε-DP under add/remove neighbours, over a universe of N elements. If M returns the most frequent element with probability at least $1-\beta$ whenever that element appears k times and every other element appears 0 times, then*

$$k \geq \frac{\ln\left(N(1-\beta)\right)}{\varepsilon}. \tag{27.4}$$

If M releases a histogram over the N bins that is (α, β)-accurate in ℓ_∞ error, then

$$\alpha \geq \frac{1}{2}\left(\frac{\ln\left(N(1-\beta)\right)}{\varepsilon} - 1\right). \tag{27.5}$$

Proof. The plan is to build the candidates once, apply the lemma to the mode, and then show that an accurate histogram separates the same candidates.

1. *The candidates.* Take $D_0 = \varnothing$, the empty dataset, and for each element x let D_x be k copies of x. Each D_x is k additions from D_0, and there are $m = N$ of them.
2. *The mode.* On D_x a correct answer lands in $G_x = \{x\}$, and these regions are disjoint, so Lemma 27.1 gives Equation 27.4.
3. *Disjoint regions for the histogram.* The true histogram of D_x is $k\,e_x$, with k in bin x and 0 elsewhere, and a correct answer lies in the ball G_x of ℓ_∞ radius α around it. Two centres differ by k. A point in both balls would put the centres within 2α of each other, by the triangle inequality, so the balls are disjoint when $k > 2\alpha$.
4. *Pick the smallest such k.* The lemma's bound is strongest for the closest datasets, so take $k = \lfloor 2\alpha \rfloor + 1 \leq 2\alpha + 1$.
5. *Apply the lemma.* With step 4 it gives

$$2\alpha + 1 \geq \frac{\ln(N(1-\beta))}{\varepsilon}, \tag{27.6}$$

and subtracting 1 and halving gives Equation 27.5.

□

Both bounds are matched, up to constants, by mechanisms you already have. The Laplace mechanism adds independent $\mathrm{Lap}(1/\varepsilon)$ noise to every count, since one record moves one count by 1. Report-noisy-max adds the same noise and returns the bin with the largest noisy count (Selection).

Proposition 27.1 (Laplace histograms and report-noisy-max match packing)**.** *Under ε-DP with add/remove neighbours, the Laplace histogram over N bins has ℓ_∞ error, at failure probability β, of exactly $-\ln\left(1-(1-\beta)^{1/N}\right)/\varepsilon$, which is at most $\ln(N/\beta)/\varepsilon$. When one element leads by k records and every other count is 0, report-noisy-max returns the mode except with probability at most $(N-1)e^{-k\varepsilon}(2+k\varepsilon)/4$.*

Proof.

1. *One Laplace coordinate.* A $\mathrm{Lap}(b)$ variable, with density $\frac{1}{2b}e^{-|z|/b}$, exceeds α in absolute value with probability $e^{-\alpha/b}$, here $e^{-\alpha\varepsilon}$.
2. *All N bins at once.* The noises are independent, so all stay within α with probability $(1-e^{-\alpha\varepsilon})^N$, and setting this to $1-\beta$ gives the exact error. A union bound over the bins puts the failure probability at most $Ne^{-\alpha\varepsilon}$, and setting that to β gives $\ln(N/\beta)/\varepsilon$.
3. *Report-noisy-max.* It fails only if some other bin's noise exceeds bin x's noise by k or more. The difference of two independent $\mathrm{Lap}(1/\varepsilon)$ variables has density $\frac{\varepsilon}{4}(1+\varepsilon|z|)e^{-\varepsilon|z|}$, a convolution that Section E.5 works out. Substituting $u=\varepsilon z$, its tail beyond k is

$$\frac{1}{4}\int_{k\varepsilon}^{\infty}(1+u)e^{-u}\,\mathrm{d}u=\frac{e^{-k\varepsilon}(2+k\varepsilon)}{4}. \tag{27.7}$$

   A union bound over the $N-1$ other bins gives the claim.

□

Both the lower bound and the Laplace error grow like $\ln N/\varepsilon$ (Figure 27.2), with slopes $1/(2\varepsilon)$ and $1/\varepsilon$, so Laplace is optimal up to a factor of about 2. The lemma loses that factor in step 2, which counts only the mass inside the good regions, while the Laplace output on $\varnothing$ falls almost entirely outside every ball G_x. Under replace neighbours the Laplace error doubles while the lower bound barely moves (Exercise 1 in the exercise book).

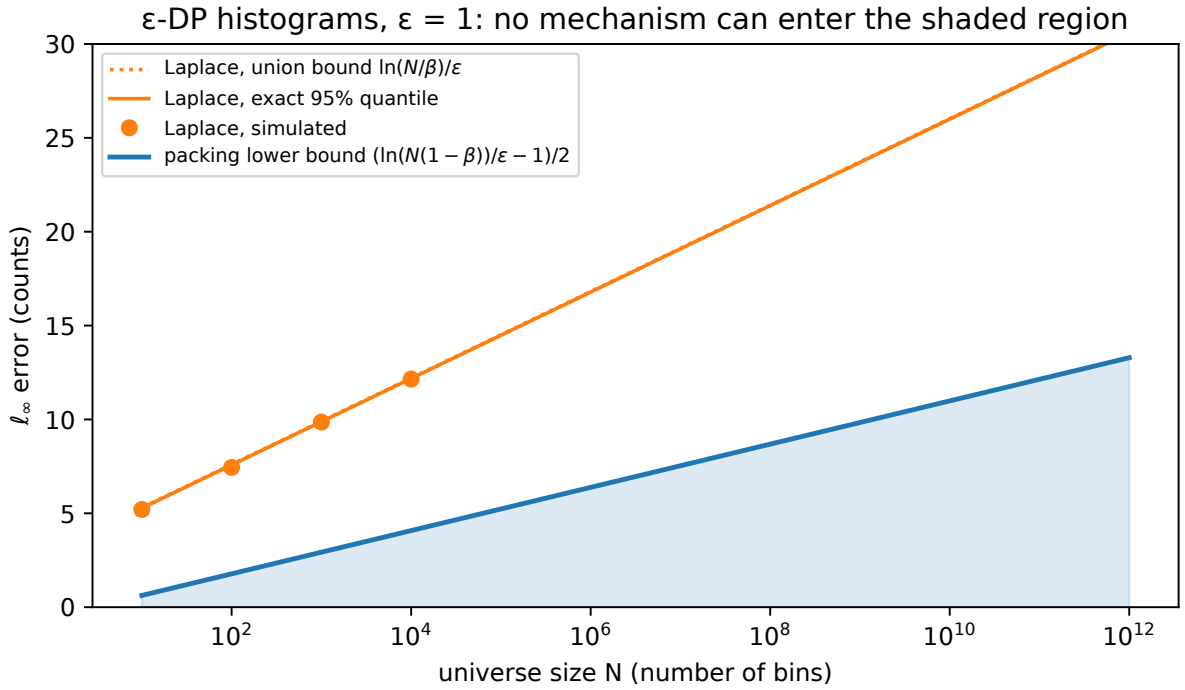

Figure 27.2.: ℓ_∞ error of ε-DP histograms over N bins at $\varepsilon=1$, failure probability 0.05. Orange: the Laplace mechanism, exact (line), union bound (dotted) and simulated (dots). Blue: the packing lower bound, with no ε-DP mechanism in the shaded region.

The lemma needs $\delta = 0$, because with slack the share in step 1 turns negative once $e^{-k\varepsilon}$ falls below about $k\delta$. What survives is a capped bound.

Proposition 27.2 (Packing under approximate DP)**.** *Let $D_0, \dots, D_m$ and the disjoint sets $G_1, \dots, G_m$ be as in Lemma 27.1, with $\Pr[M(D_i) \in G_i] \geq 1 - \beta$ for every i, but let M be (ε, δ)-DP. Then at least one of*

$$e^{-k\varepsilon}(1-\beta) \leq 2k\delta \qquad \text{or} \qquad m\, e^{-k\varepsilon}(1-\beta) \leq 2 \tag{27.8}$$

holds. In words, the group distance k must be at least about $\min(\ln m, \ln(1/\delta))/\varepsilon$.

Proof.

1. *The share with slack.* Group privacy Equation 27.1 applied to D_i, D_0 and G_i gives

$$\Pr[M(D_0) \in G_i] \geq e^{-k\varepsilon}(1-\beta) - e^{-k\varepsilon}\delta_k. \tag{27.9}$$

   The subtracted part is a sum of k terms $\delta e^{(j-k)\varepsilon}$, each at most $\delta e^{-\varepsilon} \leq \delta$, so the share is at least $e^{-k\varepsilon}(1-\beta) - k\delta$.
2. *Two cases.* If the first condition fails, $k\delta$ is less than half of $e^{-k\varepsilon}(1-\beta)$, so each share is more than $\frac{1}{2}e^{-k\varepsilon}(1-\beta)$.
3. *Fit into 1.* The m shares add up to at most 1, as in the lemma, which is the second condition.

□

The cap is real, because a mechanism reaches it. The stability-based histogram (Vadhan 2017) noises only the non-empty bins and releases those above a threshold of order $\ln(1/\delta)/\varepsilon$, so its error does not grow with N (Section J.3). On the mode's packing datasets, the stability-based release reports the mode once it leads by about $\ln(1/\delta)/\varepsilon$ replacements, however many values there are (Exercise 2 in the exercise book computes the cap).

Example 27.1. Table 27.2 compares the bounds at $\varepsilon = 1$ and $\beta = 0.05$. For $N = 10^6$ locations, the most common one must lead by at least $\ln(10^6 \times 0.95)/1 = 13.76$ records before an ε-DP release can report it reliably, and report-noisy-max needs 18.44. Every ε-DP histogram has, at the 95% level, an error of at least $\frac{1}{2}(13.76 - 1) = 6.38$ in some bin, and Laplace has 16.79. Simulated at $N = 1000$, the Laplace error is 9.84 against the exact 9.88, and report-noisy-max at the lead 11.09 fails 2.28% of the time against the union bound's 5%.

Table 27.2.: Packing lower bounds against the mechanisms that achieve them, $\varepsilon = 1$, $\beta = 0.05$, add/remove neighbours, in records.

N	Mode: lower bound on lead k	Report-noisy-max needs	Histogram: lower bound on error	Laplace error (exact)	Laplace error (union bound)
10^3	6.86	11.09	2.93	9.88	9.90
10^6	13.76	18.44	6.38	16.79	16.81
10^9	20.67	25.65	9.84	23.69	23.72

Each factor of 1000 in N adds $\ln 1000 = 6.9$ to every column that grows like $\ln N$, and half that to the histogram lower bound.

27.2. Sample complexity: how many records privacy costs

An error of 6 records is large in a dataset of 50 and negligible in one of a million, so a lower bound on error is a lower bound on the number of records. This section translates the packing bounds into records, where privacy can be compared with sampling error, a cost you pay anyway. It is also where pure and approximate DP part ways once the output has many dimensions.

For the histogram, an error of α in each frequency is an error of αn in each count.

Proposition 27.3 (Records for a private histogram)**.** *An ε-DP histogram over N bins whose ℓ_∞ error is at most αn with probability $1-\beta$, on every dataset of up to n records, needs*

$$n \geq \frac{\ln\left(N(1-\beta)\right) - \varepsilon}{2\alpha\varepsilon}. \tag{27.10}$$

Without privacy, estimating all N frequencies to within α with probability $1-\beta$ takes at most $n = \ln(2N/\beta)/(2\alpha^2)$ samples.

Proof.

1. *The private bound.* The packing datasets have $k \leq n$ records, so the guarantee covers them, and Equation 27.5 with the error αn gives

$$\alpha n \geq \frac{1}{2}\left(\frac{\ln(N(1-\beta))}{\varepsilon} - 1\right). \tag{27.11}$$

   Multiplying by 2ε and dividing by $2\alpha\varepsilon$ gives Equation 27.10.
2. *The sampling bound.* By Hoeffding's inequality (Concentration inequalities), an average of n independent variables in $[0,1]$ is more than α from its mean with probability at most $2e^{-2n\alpha^2}$. Each frequency is such an average, so a union bound over the N bins gives a failure probability of at most $2Ne^{-2n\alpha^2}$. Setting this to β and solving for n gives the claim.

□

So privacy adds a term of order $\ln N/(\alpha\varepsilon)$ to a statistical cost of order $\ln N/\alpha^2$, which Fano's method shows is really needed. Their ratio is about α/ε, so privacy dominates only for coarse answers at strong privacy.

The survey's d means make the candidates multiply. Records are $x \in \{-1,+1\}^d$, a person's d yes/no answers, and the release is the vector of means $\bar{x} \in [-1,1]^d$. Datasets made of copies of one corner of the cube $\{\pm 1\}^d$ give 2^d candidates, so packing charges $\ln 2^d = d\ln 2$.

Theorem 27.2 (Records for d marginals under pure DP)**.** *Any ε-DP mechanism under replace neighbours that releases the d attribute means with ℓ_∞ error at most α with probability $1-\beta$ needs*

$$n \geq \frac{1}{\alpha}\left(\frac{\ln\left((2^d-1)(1-\beta)\right)}{\varepsilon} - 1\right) \approx \frac{d\ln 2}{\alpha\varepsilon}. \tag{27.12}$$

The approximation holds for large d.

Proof. This is packing at a fixed size n, so the candidates replace records rather than add them.

1. *Candidates.* Fix a corner $u_0 \in \{\pm 1\}^d$ and let D_0 be n copies of it. For each of the $m = 2^d - 1$ other corners u, let D_u be D_0 with k records replaced by u.
2. *Disjoint regions.* The mean of D_u is $u_0 + \frac{k}{n}(u - u_0)$. Two corners differ in some coordinate by 2, so their means differ there by $2k/n$. As in step 3 of the proof of Theorem 27.1, the balls of radius α around the means are disjoint when $k > \alpha n$.
3. *Apply the lemma* with $k = \lfloor \alpha n \rfloor + 1 \le \alpha n + 1$:

$$\alpha n + 1 \ge \frac{\ln\left((2^d - 1)(1 - \beta)\right)}{\varepsilon}. \tag{27.13}$$

   Subtracting 1 and dividing by α gives Equation 27.12.

□

Two mechanisms come close. By Theorem 20.3 of the Laplace and Gaussian mechanisms, Gaussian noise of standard deviation σ on a query with ℓ_2 sensitivity Δ_2 is (ε, δ)-DP exactly when Δ_2/σ is at most the root $\mu(\varepsilon, \delta)$ of Equation 20.17, which is 0.2367 at $\varepsilon = 1$ and $\delta = 10^{-6}$.

Proposition 27.4 (Laplace and Gaussian upper bounds for d marginals)**.** *Under replace neighbours, the Laplace mechanism releases the d means with ℓ_∞ error at most α with probability $1 - \beta$, at ε-DP, once*

$$n = \frac{2d \ln(d/\beta)}{\alpha \varepsilon}. \tag{27.14}$$

The Gaussian mechanism does so at (ε, δ)-DP once $n = 2\sqrt{d}\, z/(\mu(\varepsilon, \delta)\, \alpha)$, where z is the number with $\Phi(-z) = \beta/(2d)$ and Φ is the standard normal cumulative distribution function.

Proof.

1. *Sensitivities.* Replacing one record moves each of the d means by at most $2/n$, so the ℓ_1 sensitivity is $\Delta_1 = 2d/n$ and the ℓ_2 sensitivity is $\Delta_2 = 2\sqrt{d}/n$.
2. *Laplace.* The noise ξ_j in coordinate j is $\mathrm{Lap}(b)$ with $b = \Delta_1/\varepsilon = 2d/(n\varepsilon)$, and it exceeds α with probability $e^{-\alpha/b}$. A union bound over the coordinates gives

$$\Pr\left[\max_j |\xi_j| > \alpha\right] \le d e^{-\alpha/b}. \tag{27.15}$$

   Setting this to β gives $\alpha n \varepsilon/(2d) = \ln(d/\beta)$, and solving for n gives the claim.
3. *Gaussian.* The noise has standard deviation $\sigma = \Delta_2/\mu(\varepsilon, \delta)$. A normal variable exceeds z standard deviations in absolute value with probability $2\Phi(-z)$, so a union bound gives

$$\Pr\left[\max_j |\xi_j| > \sigma z\right] \le 2d\, \Phi(-z) = \beta. \tag{27.16}$$

   Setting $\sigma z = \alpha$, that is $2\sqrt{d}\, z/(n\mu) = \alpha$, and solving for n gives the claim.

□

Pure DP pays linearly in the dimension, and Laplace matches it up to the factor $2\ln(d/\beta)/\ln 2$. The Gaussian requirement grows only like $\sqrt{d \ln d}$, because its noise follows Δ_2 rather than Δ_1, so for large d it beats *every* pure-DP mechanism. That is no contradiction, because under approximate DP (Proposition 27.2) the corners force only $k \geq 13$ at $\delta = 10^{-6}$, against $\ln(2^{1000} \times 0.95) = 693.10$ for pure DP at $d = 1000$. Approximate DP needs the idea of Section 27.3.

Packing also prices a question every analyst meets: what does it cost not to know where the data lie? Write the unknown mean as c, because μ is the Gaussian ratio here.

Proposition 27.5 (A mean known to lie in a range)**.** *Let the records be drawn from a normal distribution with unknown mean c and variance 1, and let $|c| \leq R$ be all that is known. An ε-DP mechanism under replace neighbours that returns an estimate closer than α to c, with probability at least $1 - \beta$ whatever c is, needs*

$$n \geq \frac{\ln\left(\lfloor R/\alpha \rfloor (1-\beta)\right)}{\varepsilon}, \tag{27.17}$$

where $\lfloor R/\alpha \rfloor$ is R/α rounded down.

Proof. This is the packing lemma with random datasets.

1. *Candidates.* Place $m = \lfloor R/\alpha \rfloor$ means $c_1, \ldots, c_m$ in $[-R, R]$, spaced at least 2α apart, and let G_j be the open interval of radius α around c_j. These intervals are disjoint.
2. *Every dataset is close to a reference.* Fix a reference dataset D_0 of size n. Any dataset D of size n is at most n replacements away, so group privacy with $\delta = 0$ gives
$$\Pr[M(D) \in G_j] \leq e^{n\varepsilon} \Pr[M(D_0) \in G_j]. \tag{27.18}$$
3. *Average over the data.* Draw the records of D from the normal distribution with mean c_j. Averaged over D, the left side is at least $1 - \beta$ by accuracy, while the right side does not depend on D. So $\Pr[M(D_0) \in G_j] \geq (1-\beta)e^{-n\varepsilon}$.
4. *Combine* as in the lemma: the m shares fit into a total of 1, which is Equation 27.17.

□

At $\alpha = 0.1$, $\beta = 0.05$ and $\varepsilon = 1$, the bound is $n \geq 4.55$ for $R = 10$, 9.16 for $R = 10^3$ and 16.07 for $R = 10^6$. Clipping to $[-R, R]$ needs records linear in R, and Private mean estimation closes the gap by first locating the data with a histogram. In d dimensions the cost is about $d \ln(R/\alpha)/\varepsilon$ (Exercise 8 in the exercise book).

Example 27.2. Table 27.3 gives the numbers for the survey at $\varepsilon = 1$ and $\beta = 0.05$. A histogram over $N = 10^6$ cells to within $\alpha = 0.1$ needs at least $(13.76 - 1)/(2 \times 0.1 \times 1) = 63.8$, so 64 records under ε-DP, and at most 875 for sampling error. At $\alpha = 0.01$ the numbers are 638 and 87,522, so privacy is the smaller cost in both cases.

Table 27.3.: Records needed to release d attribute means with ℓ_∞ error 0.1 (on the scale $[-1, 1]$) with probability 0.95, at $\varepsilon = 1$ and, for the Gaussian, $\delta = 10^{-6}$.

	Pure DP, packing (lower)	Pure DP, Laplace (upper)	Approximate DP, Gaussian (upper)
$d = 100$	683	15,202	2,941
$d = 1000$	6,921	198,070	10,836
$d = 10{,}000$	69,304	2,441,215	38,570
$d = 100{,}000$	693,137	29,017,315	134,299

The packing column grows tenfold with each tenfold increase in d, and the Gaussian column only 3.7-, 3.6- and 3.5-fold, close to $\sqrt{10}$. So from $d = 2731$ attributes on, the Gaussian mechanism needs fewer records than any pure-DP mechanism, which is one reason private machine learning uses approximate DP.

27.3. Fingerprinting: the √d lower bound for approximate DP

Packing fails under approximate DP because group privacy breaks down at large distances. Fingerprinting compares only neighbours, so δ never blows up. It asks whether an accurate release of one random dataset's d means agrees with a member's record more than with a stranger's. The **fingerprinting lemma** shows that accuracy forces agreement of order d in total, and DP caps each record's share, so n must be large. The idea comes from fingerprinting codes in cryptography, which Bun, Ullman & Vadhan (2014) brought to DP; this version follows Steinke & Ullman (2016).

Definition 27.2 (The random survey)**.** Draw attribute means $p_1, \dots, p_d$ independently and uniformly from $[-1, 1]$. Given p, draw n records independently, each coordinate $x_{ij} \in \{\pm 1\}$ independently with mean p_j, that is, $+1$ with probability $(1 + p_j)/2$ and -1 otherwise.

The means are random because, for a fixed p, a mechanism that ignores the data and outputs p would be accurate up to sampling error yet tell nothing about any record. A mechanism that must be accurate for every p has to learn p from the records, and so must correlate with them.

The lemma is about one attribute, so drop the index j and write $x = (x_1, \dots, x_n)$ for its column. It says that an estimate's correlation with the records' deviations $x_i - p$ cannot be small unless the estimate is inaccurate.

Lemma 27.2 (Fingerprinting lemma)**.** *For the column x of one attribute of Definition 27.2, with mean $\bar{x}$, and any estimate $f\colon \{\pm 1\}^n \to \mathbb{R}$ of p computed from it,*

$$\mathbb{E}\Big[f(x)\sum_{i=1}^{n}(x_i - p)\Big] = 2\,\mathbb{E}[p\,f(x)] \geq \frac{2}{3} - 2\,\mathbb{E}[|f(x) - \bar{x}|], \tag{27.19}$$

where the expectations are over p and the column.

Proof. The plan is to show that the correlation is the slope of the average estimate $g(p) = \mathbb{E}[f(x) \mid p]$, weighted by $1 - p^2$, and then to average that slope by integrating by parts. An accurate estimate rises from about -1 to about $+1$, so its slope cannot be small on average.

1. *How the data respond to p.* The column has probability $\prod_i \frac{1+x_i p}{2}$. Its log-derivative in p, the **score** of statistics, is $\sum_i \frac{x_i}{1+x_i p}$. Each term equals $\frac{x_i - p}{1-p^2}$, as you can check for $x_i = 1$ and for $x_i = -1$.
2. *Differentiate the average estimate.* Since $g(p) = \sum_x f(x) \Pr[x \mid p]$ and the derivative of $\Pr[x \mid p]$ is $\Pr[x \mid p]$ times its log-derivative, g' is the average of f times the score. Inserting step 1 and multiplying by $1 - p^2$ gives

$$(1 - p^2)\, g'(p) = \mathbb{E}\Big[f(x) \sum_i (x_i - p) \;\Big|\; p \Big]. \tag{27.20}$$

3. *Average over p and integrate by parts.* The density of p is $\frac{1}{2}$ on $[-1, 1]$. Integration by parts moves the derivative from g onto $1 - p^2$, whose derivative is $-2p$:

$$\frac{1}{2} \int_{-1}^{1} (1 - p^2) g'(p)\, \mathrm{d}p = \frac{1}{2} \Big[(1 - p^2) g(p) \Big]_{-1}^{1} + \int_{-1}^{1} p\, g(p)\, \mathrm{d}p. \tag{27.21}$$

   The boundary term vanishes because $1 - p^2 = 0$ at ± 1 and g, a polynomial, is finite there. The remaining integral is $2\,\mathbb{E}[p\, g(p)]$, which equals $2\,\mathbb{E}[p\, f(x)]$ because g is the average of f given p. This is the equality.
4. *Compare with the sample mean.* The sample mean has average p given p, so $\mathbb{E}[p\, \bar{x}] = \mathbb{E}[p^2] = \frac{1}{3}$. Any other estimate differs from it by $f - \bar{x}$, and $|p| \le 1$, so

$$\mathbb{E}[p\, f] = \tfrac{1}{3} + \mathbb{E}[p(f - \bar{x})] \ge \tfrac{1}{3} - \mathbb{E}[|f - \bar{x}|]. \tag{27.22}$$

   Multiplying by 2 gives the inequality.

□

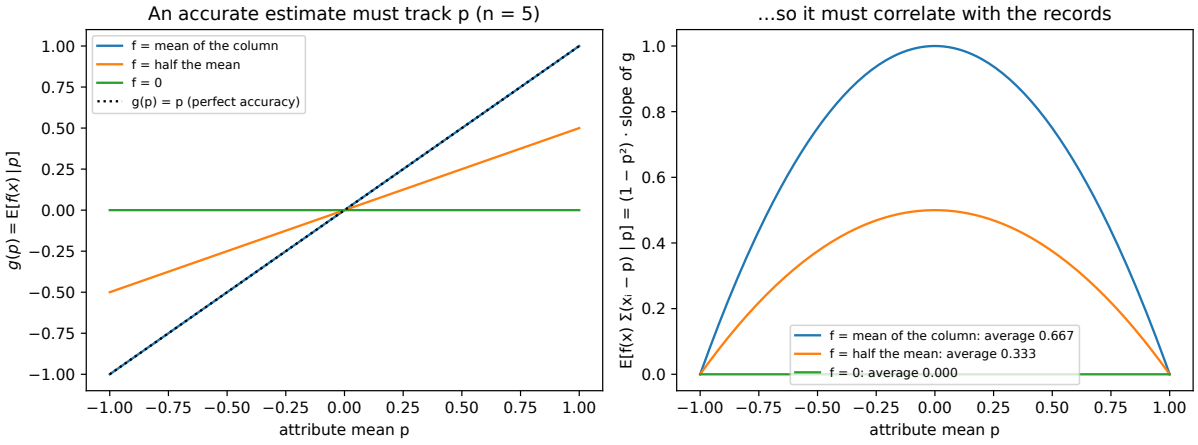

Figure 27.3.: The fingerprinting lemma for one attribute and $n = 5$ records. Left: the average estimate $g(p)$ for the sample mean, half the sample mean, and the constant 0. Right: each estimate's correlation with the records' deviations, $(1 - p^2)g'(p)$.

The lower bound below needs DP to bound the *average* of a score, while the definition bounds the probability of each event. The bridge is that an average is an integral of tail probabilities, and DP bounds each tail.

Lemma 27.3 (DP bounds the average of a bounded score)**.** *If M is (ε, δ)-DP, $D \sim D'$, and h is a function of the output with $|h| \le B$, then*

$$\mathbb{E}[h(M(D))] \le \mathbb{E}[h(M(D'))] + (e^{\varepsilon} - 1)\,\mathbb{E}[|h(M(D'))|] + 2\delta B. \tag{27.23}$$

Proof. The plan is to write the mean as an integral of tails, bound each tail by the definition, and integrate back.

1. *The mean as an integral of tails.* A variable Y with $0 \le Y \le B$ has $\mathbb{E}[Y] = \int_0^B \Pr[Y > t]\,\mathrm{d}t$, because each value y is counted once for every level t below it. For Y equal to 1, 2 or 3 with probability $\frac{1}{3}$ each, the integral is $1 + \frac{2}{3} + \frac{1}{3} = 2$. Splitting h into its positive part h_+ and negative part h_- gives

$$\mathbb{E}[h] = \int_0^B \Pr[h > t]\,\mathrm{d}t - \int_0^B \Pr[h < -t]\,\mathrm{d}t. \tag{27.24}$$

2. *Bound the positive part from above.* The definition applied to the event $\{h > t\}$ gives

$$\Pr[h(M(D)) > t] \le e^{\varepsilon} \Pr[h(M(D')) > t] + \delta. \tag{27.25}$$

3. *Bound the negative part from below,* since it is subtracted. The definition with D' on the left and the event $\{h < -t\}$, solved for the term on D, gives

$$\Pr[h(M(D)) < -t] \ge e^{-\varepsilon}(\,\Pr[h(M(D')) < -t] - \delta). \tag{27.26}$$

4. *Integrate over $t \in [0, B]$.* Write $h' = h(M(D'))$. By step 1 the integrated tails are means again, and each δ integrates to δB:

$$\mathbb{E}[h(M(D))] \le e^{\varepsilon}\,\mathbb{E}[h'_+] - e^{-\varepsilon}\,\mathbb{E}[h'_-] + (1 + e^{-\varepsilon})\delta B. \tag{27.27}$$

5. *Pull out the mean on D'.* Since $\mathbb{E}[h'] = \mathbb{E}[h'_+] - \mathbb{E}[h'_-]$, the first two terms equal

$$\mathbb{E}[h'] + (e^{\varepsilon} - 1)\mathbb{E}[h'_+] + (1 - e^{-\varepsilon})\mathbb{E}[h'_-]. \tag{27.28}$$

   The coefficient $1 - e^{-\varepsilon}$ is at most $e^{\varepsilon} - 1$, because their difference is $e^{\varepsilon} + e^{-\varepsilon} - 2 \ge 0$, so the middle terms are at most $(e^{\varepsilon} - 1)\mathbb{E}[|h'|]$. Finally $1 + e^{-\varepsilon} \le 2$.

□

So a score centred on D', with mean absolute value 1, has mean at most $e - 1 = 1.72$ on D at $\varepsilon = 1$, plus $2\delta B$. The lower bound plays the two lemmas against each other through an attack that scores each record x_i by its correlation with the release:

$$Z_i = \langle M(D),\ x_i - p \rangle = \sum_{j=1}^{d} M(D)_j\,(x_{ij} - p_j). \tag{27.29}$$

A member should score high, because the release follows the data, and a stranger should score around 0.

Theorem 27.3 (The fingerprinting lower bound)**.** *Let M be (ε, δ)-DP under replace neighbours, with outputs in $[-1,1]^d$, and let its average error on the random survey of Definition 27.2 be $\mathbb{E}[\|M(D) - \bar{x}\|_1] \le \alpha' d$, where α' is the average error per attribute. Then*

$$n \ge \frac{(2/3 - 2\alpha')\, d}{(e^\varepsilon - 1)\sqrt{d} + 4\delta d}. \tag{27.30}$$

Proof. The plan is that accuracy makes the members' scores total order d, while DP keeps each within a multiple of a stranger's spread $\sqrt{d}$, so the n members must carry the total.

1. *Accuracy makes the scores large on average.* Fix an attribute j and condition on the other columns, which leaves column j and p_j distributed as in the lemma. Apply Lemma 27.2 to f, the average of $M(D)_j$ over the mechanism's coins. That averaging leaves the correlation unchanged and cannot increase the error. Summing over j and swapping the sums over j and i gives
$$\sum_{i=1}^{n} \mathbb{E}[Z_i] \ge \frac{2}{3}d - 2\,\mathbb{E}[\|M(D) - \bar{x}\|_1] \ge \Big(\frac{2}{3} - 2\alpha'\Big)d. \tag{27.31}$$
2. *A stranger's score is small.* Let $D^{(i)}$ be D with record i replaced by a fresh one, and let $Z_i' = \langle M(D^{(i)}), x_i - p\rangle$ score x_i against a release that never saw it. Given p, the deviations $x_{ij} - p_j$ are independent of that release, with mean 0 and variance at most 1. So $\mathbb{E}[Z_i'] = 0$, the cross terms of $Z_i'^2$ average to 0, and $\mathbb{E}[Z_i'^2] \le d$ because each output coordinate lies in $[-1,1]$. By the Cauchy–Schwarz inequality, $\mathbb{E}[|Z_i'|] \le \sqrt{d}$.
3. *DP keeps a member's score close to a stranger's.* D and $D^{(i)}$ differ only in record i, so they are neighbours under replace. The score $h(y) = \langle y, x_i - p\rangle$ has $|h| \le 2d$, so Lemma 27.3 with $B = 2d$, averaged over the data and combined with step 2, gives
$$\mathbb{E}[Z_i] \le (e^\varepsilon - 1)\sqrt{d} + 4\delta d. \tag{27.32}$$
4. *Combine.* Summing step 3 over the n records bounds the total from above, and step 1 bounds it from below:
$$\Big(\frac{2}{3} - 2\alpha'\Big)d \le n((e^\varepsilon - 1)\sqrt{d} + 4\delta d), \tag{27.33}$$
which rearranges to Equation 27.30.

□

An (α, β)-accurate mechanism in ℓ_∞, clipped to $[-1,1]^d$, has $\alpha' \le \alpha + 2\beta$, since a coordinate off by more than α is off by at most 2. The $\sqrt{d}$ is the gap between signal and noise: a member scores of order d/n, and DP lets that exceed a stranger's spread $\sqrt{d}$ only by a constant factor. So δ must stay far below $1/\sqrt{d}$, and the term $4\delta d$ cannot be removed, because a mechanism that publishes each record with probability δ is $(0, \delta)$-DP (The definition of differential privacy).

The rate matches the Gaussian mechanism, but the constants are poor. At $\alpha = 0.1$, $\beta = 0.05$, $\varepsilon = 1$, $\delta = 10^{-6}$ the bound gives $n \ge 5.0$ for $d = 1000$ and $n \ge 15.8$ for $d = 10{,}000$, against the Gaussian mechanism's 10,836 and 38,570 (Figure 27.4). The lower bounds already gain a factor $1/\alpha$ by padding the dataset with fixed records (Exercise 4 in the exercise book). Drawing p from a sharper distribution gains a further $\sqrt{\ln(1/\delta)}$ (Steinke & Ullman 2016). The last gap, $\sqrt{\ln d}$, comes from the union bound in the Gaussian upper bound, not from privacy.

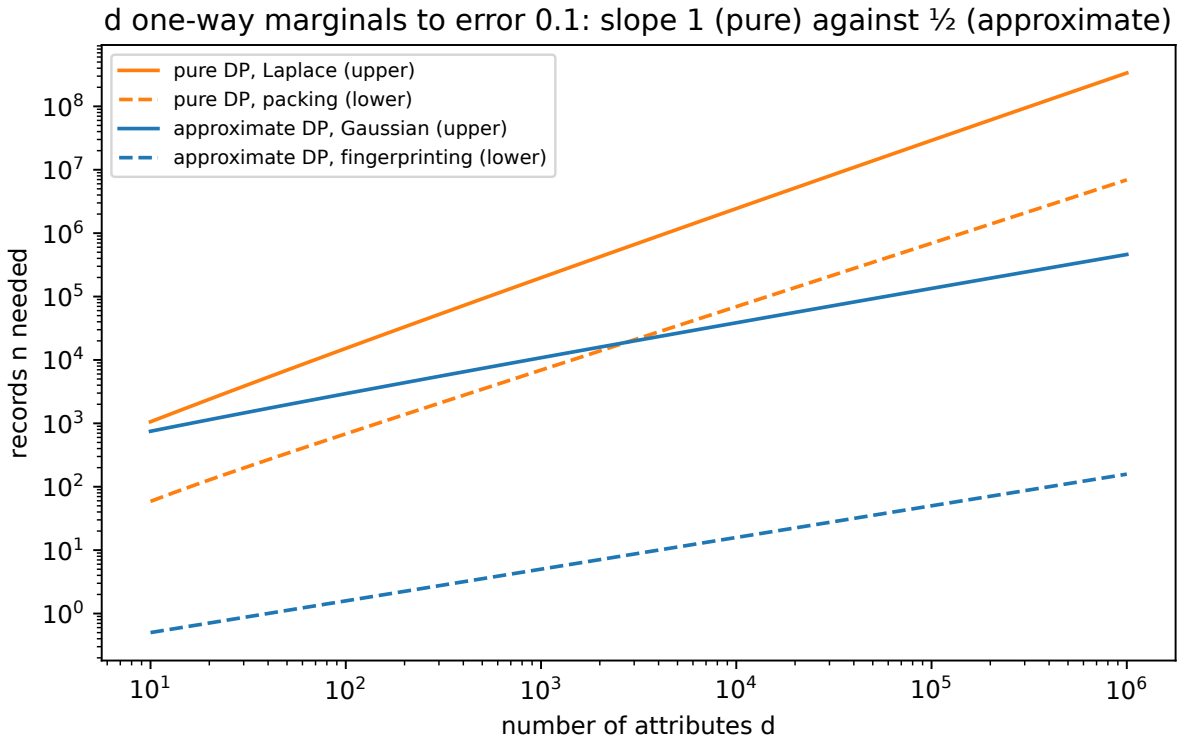

Figure 27.4.: Records needed to release d attribute means to ℓ_∞ error 0.1 with probability 0.95, at $\varepsilon = 1$ and $\delta = 10^{-6}$, on log–log axes. Orange: pure DP (Laplace upper bound, packing lower bound), slope 1. Blue: approximate DP (Gaussian upper bound, fingerprinting lower bound), slope ½.

Example 27.3. For $n = 5$ the script sums over all $2^5 = 32$ columns and integrates over p exactly, for the three estimates of Figure 27.3. For the sample mean, both sides of Equation 27.19 are 0.6667. For half the sample mean, the correlation is 0.3333 and the error is $\frac{1}{2}\mathbb{E}[|\bar{x}|] = 0.3000$, so the bound is $\frac{2}{3} - 0.6 = 0.0667$. For $f = 0$ the bound, $\frac{2}{3} - 1.2 = -0.5333$, is vacuous. So the lemma is tight for unbiased estimators and loose for shrunk ones (Exercise 3 in the exercise book).

27.4. Tracing attacks: the lower bound is a membership inference attack

In 2008 Homer et al. showed that the published allele frequencies of a genetic study revealed whether a given person's DNA was in it, and the US National Institutes of Health withdrew such summaries that year. Their test is, up to details, the score Z_i of Theorem 27.3. This section runs it on the random survey and compares its power with what DP allows. Dwork et al. (2015) proved it **robust**: it works on noisy means and with only a small reference sample (Exercise 6 in the exercise book).

The attacker sees $\hat{p} = \bar{x} + \xi$, the true means with Gaussian noise of standard deviation σ per coordinate, a target record x^* and the population means p. It scores $Z(x^*) = \langle \hat{p}, x^* - p \rangle$ and says "member" when the score is large. Each member pulls the release toward its own record by $1/n$ of its deviation, which shifts its score up. The attack's **advantage** is its true positive rate (TPR), how often it says "member" for a member, minus its false positive rate (FPR), how often it does so for a non-member.

Proposition 27.6 (Mean gap and spread of the tracing score)**.** *On the random survey of Definition 27.2, with the release $\hat{p} = \bar{x} + \xi$,*

$$\mathbb{E}[Z \mid \textit{member}] - \mathbb{E}[Z \mid \textit{non-member}] = \frac{2d}{3n}, \qquad \mathrm{Var}(Z \mid \textit{non-member}) = d\left(\frac{2}{15} + \frac{8}{15n} + \frac{2\sigma^2}{3}\right). \tag{27.34}$$

If the score is approximately normal with this mean gap κ and standard deviation s under both hypotheses, the best threshold has advantage $\mathrm{TPR} - \mathrm{FPR} = 2\Phi(\kappa/(2s)) - 1$.

Proof. For p uniform on $[-1, 1]$, $\mathbb{E}[p^2] = \frac{1}{3}$, $\mathbb{E}[p^4] = \frac{1}{5}$ and $\mathbb{E}[(1-p^2)^2] = \frac{8}{15}$. A ± 1 variable with mean p has square 1 and variance $1 - p^2$.

1. *Non-member mean.* A fresh x^* is independent of $\hat{p}$ given p, with deviations of mean 0, so $\mathbb{E}[Z] = 0$.
2. *Member mean.* For $x^* = x_i$, coordinate j contributes $\mathbb{E}[\bar{x}_j(x_{ij} - p_j)]$. In $\bar{x}_j$, other people's records are independent of x_{ij} and contribute 0. The member's own term contributes $\frac{1}{n}\mathbb{E}[x_{ij}(x_{ij} - p_j)] = \frac{1}{n}(1 - p_j^2)$. Averaging over p_j and summing over the d coordinates gives $\frac{2d}{3n}$.
3. *Non-member variance.* The deviations $x_j^* - p_j$ are independent of each other and of $\hat{p}$, so the cross terms of Z^2 vanish and

$$\mathrm{Var}(Z) = \sum_j \mathbb{E}[\hat{p}_j^2(1 - p_j^2)]. \tag{27.35}$$

Given p, the mean square of $\hat{p}_j$ is its squared mean plus the sampling and noise variances, $p_j^2 + \frac{1-p_j^2}{n} + \sigma^2$. Multiplying by $1 - p_j^2$ and averaging gives, per coordinate,

$$\mathbb{E}[p^2 - p^4] + \frac{1}{n}\mathbb{E}[(1-p^2)^2] + \sigma^2\,\mathbb{E}[1-p^2] = \frac{2}{15} + \frac{8}{15n} + \frac{2\sigma^2}{3}. \tag{27.36}$$

4. *Advantage of a threshold.* For $\mathcal{N}(0, s^2)$ against $\mathcal{N}(\kappa, s^2)$, the Neyman–Pearson lemma says that the best test thresholds the density ratio, which grows with the score, at the crossing point $\kappa/2$. A member exceeds it with probability $\Phi(\frac{\kappa}{2s})$ and a non-member with probability $\Phi(-\frac{\kappa}{2s}) = 1 - \Phi(\frac{\kappa}{2s})$, so the advantage is $2\Phi(\frac{\kappa}{2s}) - 1$. This is the total variation (TV) distance of the two normals, which Hypothesis testing shows to be the best advantage of any test.

□

Without noise, the signal-to-noise ratio $\kappa/s \approx \frac{2d}{3n}\big/\sqrt{2d/15}$ is of order $\sqrt{d}/n$, so tracing reaches advantage 0.5 once $d \approx 0.56\,n^2$ (Exercise 5 in the exercise book). Noise adds $2\sigma^2/3$ per coordinate, so the attack fails when $\sigma \gg \sqrt{d}/n$, the order of the Gaussian mechanism's $\sigma = 2\sqrt{d}/(n\mu)$. Aggregates are not safe because they are aggregates; what protects members is the ratio of n to $\sqrt{d}$, or noise.

DP bounds the attack for each target, because the game is a test between the neighbours $M(D)$ and $M(D^{(i)})$. By Corollary 18.1 of the definition of differential privacy, its advantage is at most $(e^\varepsilon - 1 + 2\delta)/(e^\varepsilon + 1)$ (Equation 18.20), which is 0.4621 at $\varepsilon = 1$ and $\delta = 0$. For the Gaussian mechanism, step 4 with $\kappa = \Delta_2$ and $s = \sigma$ bounds the TV distance of the two outputs by $2\Phi(\Delta_2/(2\sigma)) - 1$.

Example 27.4. The script draws 200 datasets of $n = 50$ records with $d = 2000$ attributes and scores the 50 members and 50 fresh non-members of each. Without noise, Equation 27.34 predicts a mean gap of $2 \times 2000/(3 \times 50) = 26.67$ and a spread of $\sqrt{2000(\frac{2}{15} + \frac{8}{750})} = 16.97$; the simulation gives 26.70 and 16.92. The normal approximation gives the advantage $2\Phi(0.786) - 1 = 0.568$. Table 27.4 shows three noise levels, the last being the $\sigma = 6.67$ of the $(1, 10^{-5})$-DP Gaussian mechanism.

Table 27.4.: The tracing attack on released attribute means, $n = 50$, $d = 2000$. The advantage is the best TPR − FPR over thresholds.

Noise σ	Advantage (simulated)	Advantage (normal approximation)	Worst-case TV bound	TPR at 1% FPR
0	0.578	0.568	1.000	0.242
1.00	0.264	0.259	0.629	0.052
6.67 (DP, $\varepsilon = 1$)	0.049	0.044	0.107	0.014

The worst-case TV column uses $\Delta_2 = 2\sqrt{2000}/50 = 1.79$. Without noise, a quarter of the members are identified at a 1% false-alarm rate from the means of 50 people, a failure in the sense of Membership inference. With DP noise, at $\delta = 10^{-5}$, the advantage is 0.049, under both the TV bound of 0.107 and the generic bound, still about 0.462. The TPR at 1% FPR is 0.014, under the

bound $e^1 \times 0.01 + 10^{-5} = 0.0272$ that the definition gives for the event "the test fires". Figure 27.5 shows the scores and Figure 27.6 the whole curve, which fades out around $\sigma = \sqrt{2000}/50 = 0.89$.

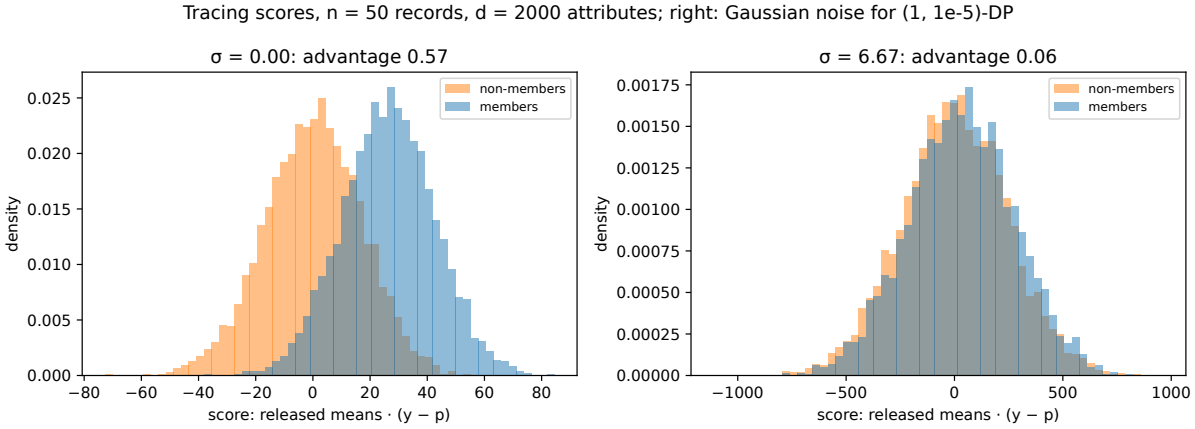

Figure 27.5.: Tracing scores of members (blue) and non-members (orange), $n = 50$, $d = 2000$. Left: exact means, with the members shifted by $2d/(3n) = 26.7$. Right: means with the noise of a $(1, 10^{-5})$-DP Gaussian mechanism.

27.5. Dinur–Nissim as a lower bound

Reconstruction attacks showed that n secret bits can be almost entirely reconstructed from about n random subset sums answered with error $o(\sqrt{n})$, error that grows more slowly than $\sqrt{n}$. Each query counts the 1s in a random subset of people, and the attacker fits the bits to the answers by least squares. Combined with DP's limit on guessing any single bit, it becomes a lower bound: a release that reveals most bits cannot be private.

The limit on guessing is Corollary 18.1 of the definition of differential privacy. If D and D' differ only in one uniformly random secret bit, every guess of that bit from the output of an (ε, δ)-DP mechanism is right with probability at most $(e^\varepsilon + \delta)/(e^\varepsilon + 1)$, which is $e/(e+1) = 0.7311$ at $\varepsilon = 1$ and $\delta = 0$. Read the other way, recovering a fraction r of the bits proves a lower bound on ε.

Theorem 27.4 (Reconstruction bounds ε from below)**.** *Let the database be n independent uniform bits, and call two databases neighbours when they differ in one bit. If M is (ε, δ)-DP, then the expected fraction r of bits that any reconstruction procedure recovers from M's output satisfies*

$$r \le \frac{e^\varepsilon + \delta}{e^\varepsilon + 1}, \qquad \text{so} \qquad \varepsilon \ge \ln \frac{r - \delta}{1 - r}. \tag{27.37}$$

In particular, a mechanism that answers $Q = O(n)$ random subset-sum queries with error $o(\sqrt{n})$ is not (ε, δ)-DP for any fixed ε and any $\delta < \frac{1}{2}$. Error $\Omega(\sqrt{n})$, at least a constant times $\sqrt{n}$, is necessary.

Proof.

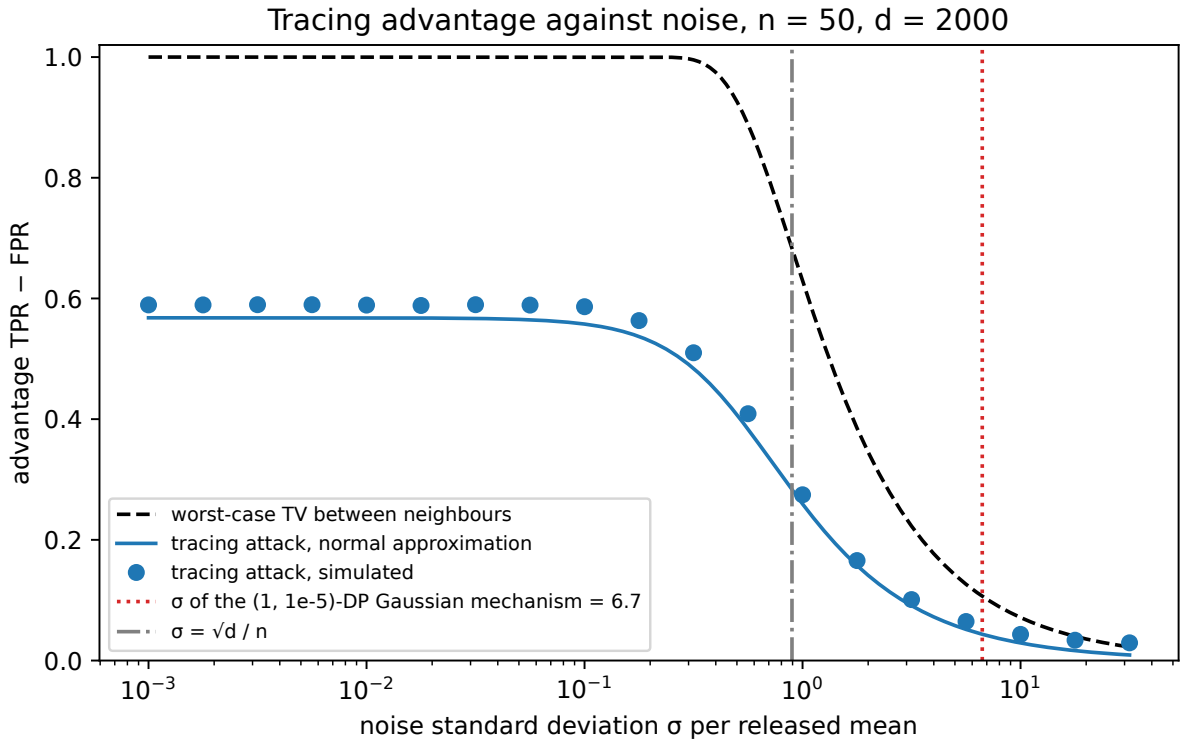

Figure 27.6.: Advantage of the tracing attack against the noise standard deviation, $n = 50$, $d = 2000$. Dots: simulation; solid: the normal approximation from Equation 27.34; dashed: the worst-case TV distance between neighbours' outputs, which bounds every attack.

1. *One bit at a time.* Fix i and every bit but x_i, which stays uniform because the bits are independent. Its two values give neighbouring databases, and the guess of x_i is a post-processing of M's output, so it is a test between them, right with probability at most $(e^\varepsilon + \delta)/(e^\varepsilon + 1)$. The uniform prior matters, because with a biased one guessing the likelier value already beats $\frac{1}{2}$.
2. *Average over the bits.* The expected fraction recovered is the average over i of the probability that bit i is guessed right, so it obeys step 1. Multiplying by $e^\varepsilon + 1$ gives $e^\varepsilon(1 - r) \geq r - \delta$, and dividing by $1 - r$ and taking logarithms gives the second form.
3. *Insert the attack.* By the Dinur–Nissim theorem, in the sharper form of Dwork, McSherry and Talwar (2007) that needs only $O(n)$ queries, errors of $o(\sqrt{n})$ let the decoder miss only $o(n)$ bits. So $r \to 1$, and the bound forces $\varepsilon \to \infty$.

□

The Gaussian mechanism matches it. Changing one bit changes by 1 the answer of every query whose subset contains that person, so the answers move by at most $\sqrt{Q}$ in ℓ_2, and σ proportional to $\sqrt{Q}/\mu(\varepsilon, \delta)$ suffices, of order $\sqrt{n}$ for $Q = 4n$. So independent noise costs error of order $\sqrt{Q}$ per query under approximate DP, and of order Q under pure DP. For many more than n queries, private multiplicative weights (Query release) answers every query from a small private synthetic dataset, with error that grows only like a small power of $\ln Q$.

The bound is crude, because least squares is not the best attack, so the ε it proves is far below the one the Gaussian mechanism guarantees. The true privacy loss lies between them. A lower bound from one attack is never a guarantee, and auditing, in a later part, narrows the gap with stronger attacks.

Example 27.5. The script answers $Q = 800$ random subset sums of $n = 200$ uniform bits with Gaussian noise of standard deviation σ, decodes by least squares and rounds at $\frac{1}{2}$, over 40 databases. Table 27.5 gives the fraction recovered, the ε it implies by Equation 27.37 at $\delta = 10^{-6}$, and the ε the Gaussian mechanism guarantees with $\mu = \sqrt{800}/\sigma$. For instance, recovering 0.9607 of the bits proves $\varepsilon \geq \ln\left((0.9607 - 10^{-6})/(1 - 0.9607)\right) = 3.20$.

Table 27.5.: Reconstruction from 800 noisy subset sums of 200 bits, and the privacy loss it proves, at $\delta = 10^{-6}$.

$\sigma/\sqrt{n}$	Fraction recovered	ε at least (attack)	ε at most (Gaussian mechanism)
0.1	1.0000	∞	294.17
0.25	0.9607	3.20	69.24
0.5	0.8058	1.42	26.36
1	0.6710	0.71	11.00
2	0.5810	0.33	4.89

At $\sigma = 0.1\sqrt{200} = 1.4$ every bit is recovered, so the release is not $(\varepsilon, 10^{-6})$-DP for any finite ε. A mechanism with $\varepsilon = 1$ lets an attacker recover at most 73.11% of the bits, which the table places between $0.5\sqrt{n}$ and $\sqrt{n}$ of noise per answer. Recovering 67% of the bits at $\sigma = \sqrt{n}$ proves only $\varepsilon \geq 0.71$, while the guarantee there is $\varepsilon \leq 11.00$. Figure 27.7 shows the whole range.

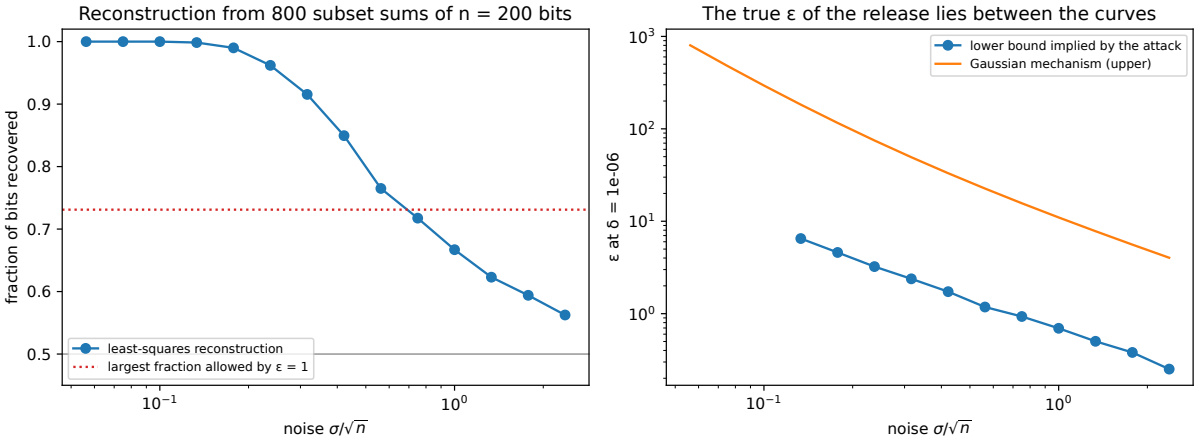

Figure 27.7.: Left: fraction of 200 secret bits recovered by least squares from 800 noisy subset sums, against $\sigma/\sqrt{n}$; dotted, the most any $\varepsilon = 1$ mechanism allows. Right: the ε the reconstruction proves (blue) and the ε the Gaussian mechanism guarantees (orange), at $\delta = 10^{-6}$.

27.6. Code

The script code/lower_bounds.py computes every number in this chapter and draws every figure. It checks the Laplace histogram, report-noisy-max, the tracing attack and the reconstruction attack against their formulas by simulation, and the fingerprinting lemma by exact summation. From the repository root:

```
uv run python code/part03-dp-foundations/lower_bounds.py
```

Table 27.6.: The script's output with the default seed.

Experiment	Result
What DP allows, $\varepsilon = 1$	Advantage at most 0.4621; bit guessed at most 0.7311 of the time; group $\delta_5 = 8.6 \times 10^{-5}$, $\delta_{20} = 282$ at $\delta = 10^{-6}$
Mode and histogram, $N = 10^6$	Lead $k \geq 13.76$ (noisy-max needs 18.44); error ≥ 6.38 (Laplace 16.79); full table in Table 27.2
Simulations at $N = 1000$	Laplace 95% error 9.84 (exact 9.88); noisy-max failure 0.0228 at lead 11.09 (union bound 0.05)
Packing under $\delta = 10^{-6}$, 2^d candidates	Forces $k \geq 7$ at $d = 10$ and $k \geq 13$ at $d = 100$ and 1000 (pure: 6.88, 69.26, 693.10); Equation 27.8: 7, 11, 11; $\ln(1/\delta)/\varepsilon = 13.82$
Packing for a mean, $\alpha = 0.1$	$n \geq 4.55$, 9.16, 16.07 for $R = 10$, 10^3, 10^6; under $\delta = 10^{-6}$: 4, 9, 11
Sample complexity, histogram $N = 10^6$	$\alpha = 0.1$: 64 private, 875 sampling. $\alpha = 0.01$: 638 private, 87,522 sampling

Experiment	Result
Sample complexity, marginals	Table 27.3; the Gaussian beats the pure-DP lower bound from $d = 2731$; $\mu(1, 10^{-6}) = 0.2367$
Fingerprinting lower bound	$n \geq 1.6$, 5.0, 15.8, 50.1 at $d = 10^2, 10^3, 10^4, 10^5$
Fingerprinting lemma, $n = 5$	Mean: 0.6667 (bound 0.6667). Half mean: 0.3333 (bound 0.0667). Zero: 0 (bound -0.5333)
Tracing, $n = 50$, $d = 2000$	Gap 26.70 (predicted 26.67), spread 16.92 (16.97); Table 27.4
Dinur–Nissim, $n = 200$, $Q = 800$	Table 27.5

tests/test_lower_bounds.py checks that the output still matches.

27.7. Summary

Table 27.7.: The results of this chapter, and where each is used.

Result	Statement	Use
Lemma 27.1	m disjoint good sets within k of D_0: $k \geq \ln(m(1-\beta))/\varepsilon$	Outputs that single out one of many candidates
Theorem 27.1	Mode: lead $k \geq \ln(N(1-\beta))/\varepsilon$; histogram: $\alpha \geq \frac{1}{2}(\ln(N(1-\beta))/\varepsilon - 1)$	Pure DP pays $\ln(\text{candidates})/\varepsilon$
Proposition 27.1	Laplace: $\alpha \leq \ln(N/\beta)/\varepsilon$; noisy-max fails with probability $\leq (N-1)e^{-k\varepsilon}(2 + k\varepsilon)/4$	Both optimal up to a factor of about 2
Proposition 27.2	$e^{-k\varepsilon}(1-\beta) \leq 2k\delta$ or $me^{-k\varepsilon}(1-\beta) \leq 2$	Packing forces at most about $\ln(1/\delta)/\varepsilon$
Proposition 27.3	$n \geq (\ln(N(1-\beta)) - \varepsilon)/(2\alpha\varepsilon)$; sampling $\approx \ln(2N/\beta)/(2\alpha^2)$	Privacy adds records, mostly for coarse answers
Theorem 27.2	$n \gtrsim d \ln 2/(\alpha\varepsilon)$	Pure DP pays linearly in the dimension
Proposition 27.4	Laplace: $n = 2d\ln(d/\beta)/(\alpha\varepsilon)$; Gaussian: $n = 2\sqrt{d}\, z/(\mu\alpha)$	The Gaussian beats pure DP from $d = 2731$
Proposition 27.5	$n \geq \ln(\lfloor R/\alpha \rfloor(1-\beta))/\varepsilon$	The cost of not knowing where the data lie
Lemma 27.2	$\mathbb{E}[f\sum_i (x_i - p)] = 2\mathbb{E}[pf] \geq \frac{2}{3} - 2\mathbb{E}[\lvert f - \bar{x}\rvert]$	Accuracy forces correlation with the records

Result	Statement	Use
Lemma 27.3	$\mathbb{E}[h(M(D))] \le \mathbb{E}[h(M(D'))] + (e^\varepsilon - 1)\mathbb{E}[\lvert h(M(D'))\rvert] + 2\delta B$	DP for averages, not only events
Theorem 27.3	$n \ge (\frac{2}{3} - 2\alpha')d/((e^\varepsilon - 1)\sqrt{d} + 4\delta d)$	Approximate DP pays $\sqrt{d}$; keep $\delta \ll 1/\sqrt{d}$
Proposition 27.6	Gap $2d/(3n)$; variance $d(\frac{2}{15} + \frac{8}{15n} + \frac{2\sigma^2}{3})$	Advantage 0.5 once $d \approx 0.56\,n^2$; $\sigma \gg \sqrt{d}/n$ stops it
Theorem 27.4	Recovering a fraction r proves $\varepsilon \ge \ln \frac{r-\delta}{1-r}$	Error $o(\sqrt{n})$ on $O(n)$ queries is never private

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

28. Private mean estimation

The mean is the statistic that private machine learning computes most often. Every step of private gradient descent clips per-example gradients, averages them and adds noise, and a survey that reports the share of people with some property releases a mean of yes/no answers. Earlier chapters released the mean of the dataset in hand. An analyst usually wants something else: the mean of the **population** the data were drawn from. So this chapter asks how many records a private estimate of a population mean needs, and what each thing you do not know about the data costs.

Two guarantees with different shapes meet here. Privacy must hold for every dataset, including ones that your assumptions say cannot happen, because a guarantee that fails when an assumption fails protects nobody. Accuracy, on the other hand, is a statement about data drawn from a distribution, such as "the records are normal with variance 1". So an assumption about the data may make a mechanism more accurate, but it may never enter the privacy proof. Every mechanism below respects that split: it clips the data to a range, which makes it private whatever the data are, and the assumption only says how often the clipping changes nothing. One idea then organizes the chapter: spend a small part of the budget to learn where the data are, then clip there and spend the rest on the mean. The noise of a clipped mean is proportional to the width of the clipping range, so a range set by your prior ignorance makes the noise pay for that ignorance in full. Finding the data privately first costs a number of records that grows only like the logarithm of the range, and the final step can then clip to a narrow window and add little noise.

The running example is a survey of $n = 1000$ people at $\varepsilon = 1$, and each section changes what is known about the records: yes/no answers first, then normal measurements whose mean could be anywhere up to a bound R, then vectors, then incomes with a heavy tail. Throughout, datasets have a fixed size n, and two datasets $D \sim D'$ are **neighbours** when they differ in one replaced record, as in Beyond global sensitivity. The records $X_1, \dots, X_n$ are drawn independently from a distribution whose mean μ is the target, and every statement of the form "the data lie in this range" is allowed to fail with probability $\beta = 0.05$. An estimate $\hat{\mu}$ is judged by its **root-mean-square error** (RMSE), the square root of the average of $(\hat{\mu} - \mu)^2$ over the data and the mechanism's noise. The guarantees are those of the definition of differential privacy (DP): a mechanism is (ε, δ)-DP when changing one record changes the probability of any set of outputs by at most a factor e^{ε} plus δ, and pure ε-DP when $\delta = 0$. Table 28.1 lists the symbols the chapter uses.

Table 28.1.: The symbols of this chapter.

Symbol	Meaning
n, ε, δ	the number of records, fixed and public; the parameters of DP

Symbol	Meaning
μ, σ^2	the mean and the variance of the distribution the records come from
α, β	the target RMSE; the probability that a "the data lie in this range" statement fails
w, R	the width of a known range; a bound on $\lvert\mu\rvert$, or on the length $\lVert\mu\rVert$
τ_1, τ_d	how far n normal records can lie from μ, in one and in d dimensions
b, m	the width and the number of the bins of the coarse step
d, r_t, c_t, s_t	the dimension; the radius, the centre and the noise standard deviation of round t of shrinking balls
$\kappa(\varepsilon, \delta)$	the largest ratio of ℓ_2 sensitivity to noise standard deviation at which Gaussian noise is (ε, δ)-DP
τ, τ_b	the clipping half-width for heavy-tailed data, and its worst-case choice

28.1. Bounded data

Start where nothing is unknown except the mean. The records lie in a known interval, such as yes/no answers coded 0 and 1, so no clipping is needed and no assumption about the data enters at all. The question is how many more records a private estimate needs than a non-private one. The answer is the best case of the chapter, and every later section tries to recover it when the data are not bounded.

Every estimator in this chapter has the same form: clip each record to an interval, average, and add Laplace noise. The lemma below says what such an estimator costs in privacy and in error, and every later proof starts from it. Its privacy part is the Laplace mechanism of the Laplace and Gaussian mechanisms applied to a mean. Its error part is the three-way split of the clipping section of Beyond global sensitivity: the clipped average varies from sample to sample, clipping shifts its expected value away from μ, and the noise adds its own spread.

Lemma 28.1 (A clipped mean with Laplace noise)**.** *Let each record X_i be replaced by a clipped value Y_i that depends on X_i alone and lies in an interval of width w, and release the average of the clipped values plus Laplace noise ξ,*

$$\hat{\mu} = \frac{1}{n}\sum_{i=1}^{n} Y_i + \xi, \qquad \xi \sim \mathrm{Lap}\Big(\frac{w}{n\varepsilon}\Big). \tag{28.1}$$

The release is ε-DP for every dataset. When the records are independent draws from a distribution with mean μ, the mean squared error of the release splits into three parts,

$$\mathbb{E}\big[(\hat{\mu}-\mu)^2\big] = \underbrace{\frac{\operatorname{Var}(Y)}{n}}_{\text{sampling}} + \underbrace{\big(\mathbb{E}[Y]-\mu\big)^2}_{\text{bias}^2} + \underbrace{\operatorname{Var}(\xi)}_{\text{noise}}, \qquad \operatorname{Var}(\xi) = \frac{2w^2}{n^2\varepsilon^2}. \tag{28.2}$$

Proof. The plan is to bound the sensitivity of the clipped average, calibrate the Laplace noise to it, then square the error and watch the cross terms vanish.

1. *Sensitivity.* Replacing one record changes one clipped value Y_i, by at most w since both values lie in the interval, and the other values stay put because each depends on its own record alone. So the sum moves by at most w and the average by at most w/n, which is its sensitivity under replace neighbours, as for the mean with public n in Proposition 20.2.
2. *Privacy.* By Theorem 20.1, Laplace noise with scale equal to the sensitivity divided by ε, here $w/(n\varepsilon)$, makes the release ε-DP. Nothing in steps 1 and 2 assumed anything about the data, because the clipping, not an assumption, keeps every Y_i in the interval.
3. *The three parts.* Write $\hat{\mu}-\mu$ as a sum of three pieces: the average of $Y_i-\mathbb{E}[Y]$ over the records, the constant $\mathbb{E}[Y]-\mu$, and the noise ξ. The first and the last have mean 0 and are independent of each other, so when the sum is squared and averaged, every cross term contains a mean-zero factor and vanishes. The average of n independent copies has $1/n$ times the variance of one, which gives the sampling part.
4. *The noise.* By Theorem 20.1 a Laplace variable with scale s has variance $2s^2$, which with $s = w/(n\varepsilon)$ is $2w^2/(n^2\varepsilon^2)$.

□

With the lemma in hand, the bounded case is a matter of reading off the error and solving for n. Bounded records need no clipping, so the bias is zero, and the only question is how the sampling term and the noise term add up.

Theorem 28.1 (Private mean of bounded data)**.** *Let the records be independent draws from a distribution on an interval of width w with variance σ^2, and release their average plus* $\operatorname{Lap}(w/(n\varepsilon))$ *noise. The release is ε-DP, and its RMSE is*

$$\operatorname{RMSE} = \sqrt{\frac{\sigma^2}{n} + \frac{2w^2}{n^2\varepsilon^2}}. \tag{28.3}$$

The RMSE is at most α once

$$n \geq \frac{\sigma^2 + \sqrt{\sigma^4 + 8w^2\alpha^2/\varepsilon^2}}{2\alpha^2}, \qquad \text{which is at most} \qquad \frac{\sigma^2}{\alpha^2} + \frac{\sqrt{2}\,w}{\alpha\varepsilon}. \tag{28.4}$$

Proof.

1. *Privacy and error.* The records already lie in the interval, so Lemma 28.1 applies with $Y_i = X_i$ and width w, and the release is ε-DP. In Equation 28.2 the bias is 0, the sampling term is σ^2/n and the noise term is $2w^2/(n\varepsilon)^2$, and their sum is the square of Equation 28.3.

2. *Solve for n.* Setting the square of Equation 28.3 equal to α^2 and multiplying by n^2 gives the quadratic $\alpha^2 n^2 - \sigma^2 n - 2w^2/\varepsilon^2 = 0$, whose positive root is the first form of Equation 28.4. The RMSE falls as n grows, so every n above the root reaches α.
3. *The simpler bound.* The square root of a sum is at most the sum of the square roots, so $\sqrt{\sigma^4 + 8w^2\alpha^2/\varepsilon^2} \le \sigma^2 + 2\sqrt{2}\, w\alpha/\varepsilon$. Inserting this and dividing by $2\alpha^2$ gives the second form.

□

The second form of Equation 28.4 reads as two costs added together. Sampling needs about σ^2/α^2 records whatever you do, and privacy adds about $w/(\alpha\varepsilon)$ more. The ratio of the privacy term to the sampling term is $\sqrt{2}\, w\alpha/(\varepsilon\sigma^2)$, so for a small target error α privacy costs a lower-order number of records. Halving ε doubles the privacy term and leaves the sampling term alone.

The privacy term grows with the width w and not with the variance σ^2, because the noise is set by the worst change one record can make, which is the width, whatever the data look like. The variance describes typical data, and typical data enter only the sampling term. That split between worst-case noise and typical-case sampling is the pattern of every section below.

Example 28.1. Take yes/no answers, so $w = 1$, and the worst case for sampling, a population that is half yes, so $\sigma = 0.5$. At $\varepsilon = 1$ the private RMSE is 0.0520 for 100 people, against 0.0500 without privacy. For 1,000 people it is 0.0159 against 0.0158, and at 10,000 both are 0.0050. To reach $\alpha = 0.05$ you need 108 people instead of 100, and to reach $\alpha = 0.01$ you need 2,508 instead of 2,500. Privacy costs eight people at a sample size where sampling already needs 2,500. Exercise 1 in the exercise book redoes the count at $\varepsilon = 0.1$, where the privacy term is no longer small.

28.2. Gaussian data with a known range

Now let the records be unbounded, but drawn from a normal distribution with unknown mean μ and variance 1, and suppose all you know about the mean is that $|\mu| \le R$. The bound R measures your ignorance. A height in centimetres might have R of a few hundred, while a feature of a model you have never looked at might need $R = 10^6$. Unbounded records have no finite sensitivity, so the estimator must clip, and the obvious choice is to clip to the whole range where the data could possibly be. This section works out what that costs, and the answer is the baseline that the next section improves on.

Clipping changes a record only if the record lies outside the range. To show that this is rare, the proof needs to know how far n normal draws can stray from their mean, which is the lemma below.

Lemma 28.2 (Normal draws stay close to their mean)**.** *Let $X_1, \dots, X_n$ be independent draws from a normal distribution with mean μ and variance 1, and let $\beta \in (0, 1)$. With probability at least $1 - \beta$, every draw lies within*

$$\tau_1 = \sqrt{2 \ln(2n/\beta)} \tag{28.5}$$

of μ.

Proof.

1. *One draw.* A standard normal variable exceeds a level t in absolute value with probability at most $2e^{-t^2/2}$, which is the Chernoff bound of Concentration inequalities applied to each of its two tails. Each $X_i - \mu$ is standard normal.
2. *All draws.* The probability that at least one of the n draws lies further than t from μ is at most the sum of their n probabilities, by the union bound, which is $2ne^{-t^2/2}$. Setting this equal to β and solving for t gives τ_1.

□

The bound is loose. Concentration inequalities proves a tail bound half as large for one draw, but the factor 2 changes τ_1 only slightly, so the chapter keeps the simpler form. For $n = 1000$ and $\beta = 0.05$ it gives $\tau_1 = 4.604$, and in 20,000 simulated datasets the largest distance exceeded τ_1 in a fraction 0.0039 of them, not 0.05.

The naive estimator widens the range $[-R, R]$ by τ_1 on each side and clips there, so that with high probability it clips nothing.

Proposition 28.1 (The naive estimator)**.** *Let the records be independent draws from a normal distribution with mean μ, where $|\mu| \le R$, and variance 1, and let τ_1 be as in Equation 28.5. Clip every record to $[-R - \tau_1, R + \tau_1]$, average, and add* $\mathrm{Lap}(2(R + \tau_1)/(n\varepsilon))$ *noise. The release is ε-DP for every dataset. With probability at least $1 - \beta$ the clipping changes no record. On that event the estimate is the plain average plus noise, and, ignoring the rare event where it fails, the error has no bias and*

$$\mathrm{RMSE} = \sqrt{\frac{1}{n} + \frac{8(R + \tau_1)^2}{n^2\varepsilon^2}}. \tag{28.6}$$

Proof.

1. *Privacy.* The clipping interval has width $w = 2(R + \tau_1)$, so Lemma 28.1 gives ε-DP for every dataset.
2. *Clipping changes nothing, usually.* By Lemma 28.2, with probability at least $1 - \beta$ every record lies within τ_1 of μ. Since $|\mu| \le R$, every record then lies in $[-R - \tau_1, R + \tau_1]$, where clipping leaves it alone. This is why the interval is widened by τ_1: a mean near R has half its records above R, and clipping them would bias the estimate toward 0.
3. *Error.* On that event the clipped average is the plain average, so Equation 28.2 has no bias, a sampling term $1/n$, and the noise term $2w^2/(n^2\varepsilon^2)$ with $w = 2(R + \tau_1)$, which is $8(R + \tau_1)^2/(n^2\varepsilon^2)$. Their sum is the square of Equation 28.6.

□

The noise grows linearly in R, so reaching an error α takes about $1/\alpha^2 + R/(\alpha\varepsilon)$ records. The estimator pays for R in full: doubling your uncertainty about where the data are doubles the noise, even though the data themselves have not changed. Normality entered only in step 2, to show that the clipping usually changes nothing, while the privacy of step 1 holds for every dataset.

The lower-bounds chapter shows that paying for R in full is not the price of privacy. Its packing argument gives a lower bound of only $\ln(R/\alpha)/\varepsilon$ records, so a cleverer mechanism should pay logarithmically, not linearly, for the range.

Example 28.2. Take $n = 1000$ records at $\varepsilon = 1$, with $\beta = 0.05$ so that $\tau_1 = 4.604$, and put the true mean at $\mu = R/2$. For $R = 10$, the noise standard deviation is 0.0413 and the RMSE is 0.0520, against 0.0316 without privacy. The error grows with the range, to 2.8416 for $R = 10^3$ and to 2828.44 for $R = 10^6$. That last estimate is useless, although the 1,000 records pin the mean down to within about 0.03. The script also computes the exact error, without conditioning on the event of Lemma 28.2, from the mean and variance of a clipped normal variable, and the two agree to the digits quoted.

28.3. Coarse then fine

The naive estimator wastes its noise on the empty parts of $[-R, R]$. Karwa & Vadhan (2018) split the work in two. A **coarse step** spends a small part of the budget to find, privately, a short interval that holds the data. A **fine step** then clips to that interval and spends the rest of the budget on the mean. The coarse step is a selection problem among about R candidate intervals, and selection costs only the logarithm of the number of candidates, which is how the range drops out of the noise.

Two earlier results carry the proof. The first is the utility bound of the exponential mechanism (Selection). When the mechanism chooses among m candidates with a score of sensitivity 1 at budget ε_1, it picks a candidate whose score is at least g below the best with probability at most $m\,e^{-\varepsilon_1 g/2}$, which is Equation 22.4 with $t = \varepsilon_1 g/2 - \ln m$. The second is adaptive basic composition (Post-processing, group privacy and composition). If a first step is ε_1-DP and a second step, which may use the first step's output, is ε_2-DP for each value of that output, then together they are $(\varepsilon_1 + \varepsilon_2)$-DP. That is what allows the coarse step to choose the clipping window of the fine step.

Theorem 28.2 (Coarse then fine)**.** *Let the records be independent draws from a normal distribution with mean μ, where $|\mu| \le R$, and variance 1, let τ_1 be as in Equation 28.5, and split the budget as $\varepsilon = \varepsilon_1 + \varepsilon_2$. Cut $[-R - b, R + b]$ into $m = \lceil 2(R + b)/b \rceil$ bins of width $b = 2\tau_1$, where $\lceil \cdot \rceil$ rounds up.*

1. Coarse step. *Choose a bin J with the exponential mechanism at ε_1, with the number of records in the bin as its score.*
2. Fine step. *Clip every record to the **window** made of bin J and its two neighbours, an interval of width $3b$. Average, and add* $\mathrm{Lap}(3b/(n\varepsilon_2))$ *noise.*

The mechanism is ε-DP for every dataset. With probability at least $1 - \beta - m e^{-\varepsilon_1 n/4}$, no record is clipped. On that event the estimate is the plain average plus noise, and, ignoring the rare event where it fails,

$$\mathrm{RMSE} = \sqrt{\frac{1}{n} + \frac{18 b^2}{n^2 \varepsilon_2^2}}, \tag{28.7}$$

which does not depend on R. The coarse step fails with probability at most β once

$$n \ge \frac{4 \ln(m/\beta)}{\varepsilon_1}. \tag{28.8}$$

Proof. The plan is to show that the two steps are private by composition, that the data fill at most two bins, that the coarse step therefore picks a non-empty bin, that the window around a non-empty bin holds every record, and finally to read the error off Equation 28.2.

1. *Privacy.* Replacing one record takes it out of one bin and puts it into another, so every count changes by at most 1, and the coarse step is the exponential mechanism with a score of sensitivity 1, which is ε_1-DP. For each value of J, the fine step is a clipped mean over a window of width $3b$, which is ε_2-DP by Lemma 28.1. By adaptive basic composition the two steps together are ε-DP. The window depends on the data only through J, which was chosen privately, so no leak of the kind seen in Beyond global sensitivity arises.
2. *The data fill at most two bins.* By Lemma 28.2, with probability at least $1 - \beta$ every record lies within $\tau_1 = b/2$ of μ. Then the records span an interval of length at most b, which meets at most two neighbouring bins. So the fullest bin holds at least $n/2$ records, and every other bin except one is empty.
3. *The coarse step picks a non-empty bin.* An empty bin has score 0, at least $n/2$ below the best. The utility bound with the m bins as candidates and the gap $g = n/2$ bounds the chance of picking one by $me^{-\varepsilon_1 n/4}$. Setting this equal to β and solving for n gives Equation 28.8.
4. *The window holds every record.* A non-empty bin J contains a record within $b/2$ of μ, so μ lies within $b/2$ of the bin. Every record lies within $b/2$ of μ, hence within b of the bin, which is inside the window. Clipping to bin J alone would not do, because the data can straddle two bins and J may be the less full one.
5. *Error.* On the events of steps 2 and 3, the fine step clips nothing, so Equation 28.2 has no bias, a sampling term $1/n$, and the noise term with $w = 3b$ and budget ε_2, which is $18b^2/(n^2\varepsilon_2^2)$. That is Equation 28.7.

□

The range R now enters only through the number of bins m, and only inside a logarithm in Equation 28.8. So an error α needs about $1/\alpha^2 + 1/(\alpha\varepsilon) + \ln R/\varepsilon$ records in total, up to factors of $\sqrt{\ln n}$ hidden in b. The packing bound Equation 27.17 of the lower-bounds chapter says a pure-DP mechanism must pay that logarithm, so the coarse step is optimal up to constants. The fine step pays for a window of width $3b = 6\sqrt{2\ln(2n/\beta)}$, a few standard deviations, which is where the $\ln n$ factors come from. The bins cannot be much narrower, because step 2 needs the data to fill at most two of them, so that the fullest bin leads every empty one by $n/2$.

The split has a cost when you already know a lot. The fine step gets only ε_2 and clips to a window wider than the spread of the data, so for small R the naive estimator wins. With $n = 1000$, $\varepsilon = 1$ and a quarter of the budget for the coarse step, the crossover is at $R = 13.81$ (Figure 28.2). The quarter is a simple default rather than the best split, and Exercise 2 in the exercise book sizes the coarse budget from Equation 28.8 instead.

Example 28.3. Take $n = 1000$, $\varepsilon = 1$ and $\beta = 0.05$ again, with $\varepsilon_1 = 0.25$ and $\varepsilon_2 = 0.75$. The bins have width $b = 9.207$ and the window 27.62. Table 28.2 compares the two estimators. The fine step's noise has standard deviation 0.0521 and the RMSE is 0.0609 for every R, while the naive estimator's error grows with R. The number of records the coarse step needs, by Equation 28.8, grows from 74 to 245 as R grows by a factor of 10^5. The bound on its failure probability is below 10^{-21} in all three cases, because 1,000 records is far more than it needs.

Table 28.2.: The naive and coarse-then-fine estimators of a normal mean, $n = 1000$, $\varepsilon = 1$, $\beta = 0.05$, a quarter of the budget for the coarse step: the formulas Equation 28.6 and Equation 28.7, and simulations with 4,000 repetitions, whose own error is about 2%.

Range R	Bins m	Coarse step needs $n \geq$	Naive RMSE	Coarse then fine: RMSE	Simulated, naive	Simulated, coarse then fine
10	5	74	0.0520	0.0609	0.0517	0.0588
10^3	220	135	2.8416	0.0609	2.7615	0.0606
10^6	217,223	245	2828.44	0.0609	2803.08	0.0596

Figure 28.1 shows the coarse step on one dataset with $R = 100$ and $\mu = 37$, which has 24 bins. On the script's own draw of such a dataset, 876 and 124 records fall into the two non-empty bins. The exponential mechanism picks the fuller one with a probability that prints as 1 to twelve digits, and any given empty bin with probability about 2.8×10^{-48}.

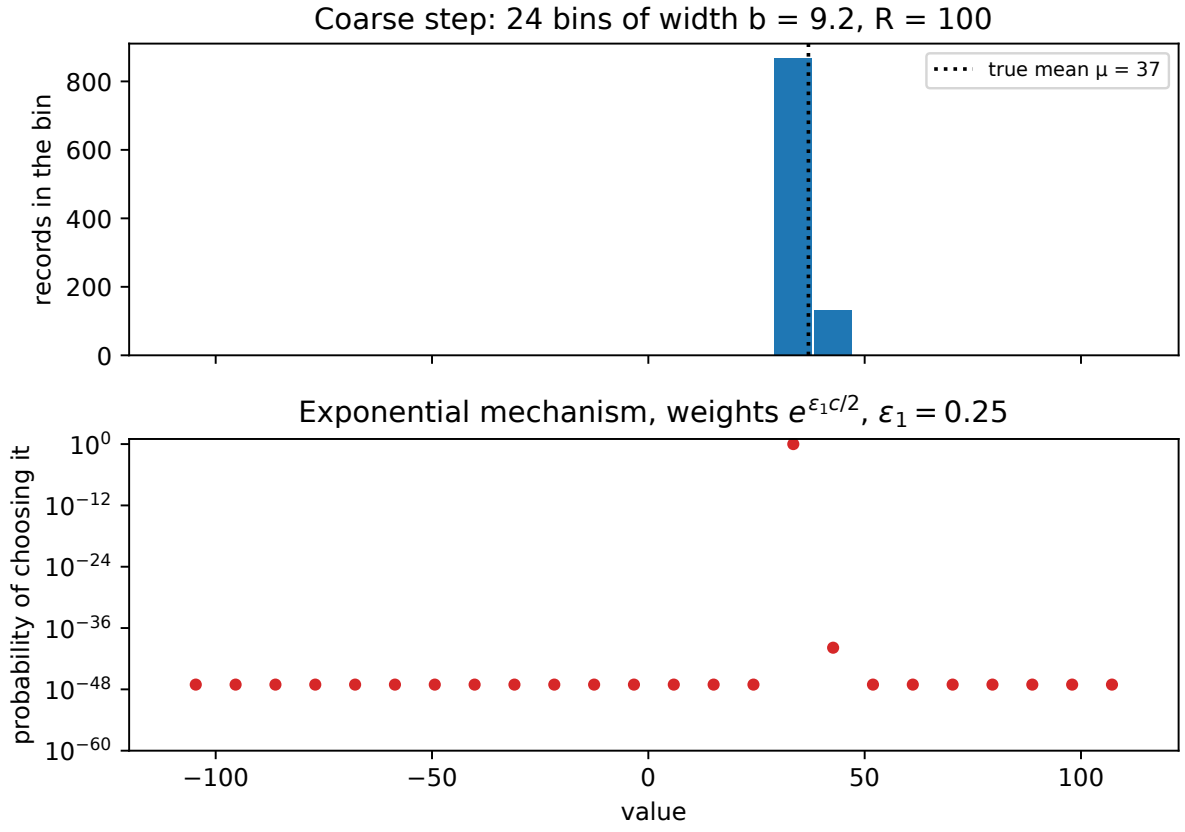

Figure 28.1.: Top: the coarse histogram of 1,000 normal records with mean 37, in 24 bins of width 9.2 covering a range with $R = 100$ (a fresh draw). Bottom: the probability that the exponential mechanism with $\varepsilon_1 = 0.25$ picks each bin, on a log scale.

Under approximate DP the range can go altogether. The stability-based release reports the fullest bin exactly, with high probability, once it leads the others by about $2\ln(1/\delta)/\varepsilon$ records, whatever

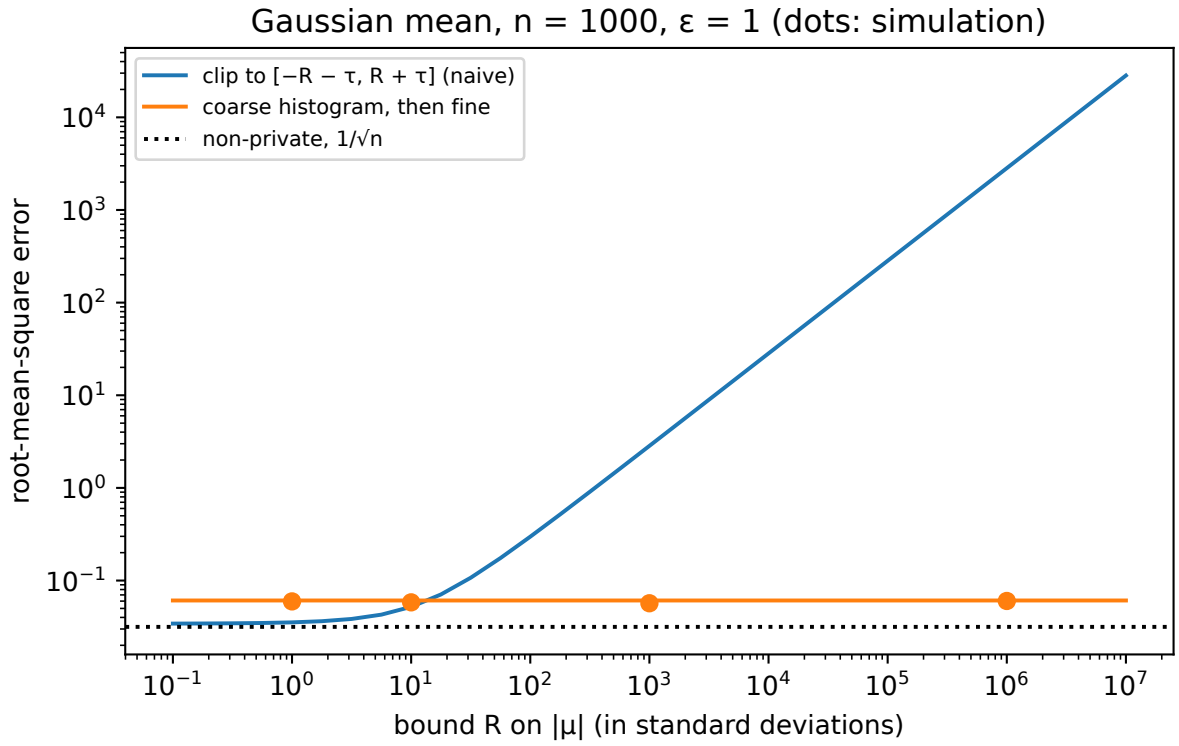

Figure 28.2.: Root-mean-square error of the naive estimator and of coarse then fine, against the bound R on the mean, for $n = 1000$ normal records and $\varepsilon = 1$. The dots are simulations of coarse then fine; the dotted line is the non-private error $1/\sqrt{n}$.

the number of bins. Its test is noisy, so a smaller lead gives a refusal rather than a wrong bin. Karwa & Vadhan use a stability-based histogram of this kind, so their (ε, δ)-DP coarse step needs a number of records of order $\ln(1/\delta)/\varepsilon$ and works even with no bound R at all, which matches the packing bound under approximate DP, Equation 27.8. Section J.3 in the appendices proves the histogram's guarantee for added or removed records; under this chapter's replaced records two bins change, so the histogram is run at $\varepsilon/2$ and $\delta/2$, which changes only the constant.

The same trick handles an unknown variance. Differences of pairs of records, $X_2 - X_1$ and so on, have mean 0 and a spread set by the variance alone. Put the sizes $|X_2 - X_1|, |X_4 - X_3|, \ldots$ into bins whose edges double, from $[1, 2)$ to $[2, 4)$ and so on, scaled to the possible range of the standard deviation σ. Most sizes fall within a factor of a few of σ, so the fullest bins locate σ within a constant factor. With σ known to lie between $\sigma_{\min}$ and $\sigma_{\max}$ there are about $\log_2(\sigma_{\max}/\sigma_{\min})$ bins, and choosing a full one with the exponential mechanism costs, by the same utility bound, records of order the logarithm of that number divided by ε (Karwa & Vadhan 2018 give the details).

28.4. Many dimensions: shrinking balls

Now each record is a vector in d dimensions, drawn from a normal distribution with mean μ and identity covariance, and all you know is that the length of μ, $\|\mu\|$, is at most R. Error is measured by the length of $\hat{\mu} - \mu$. The coarse step of Section 28.3 does not carry over cheaply, because a histogram over cells of a grid would need about $(R/b)^d$ cells, and the logarithm of that is $d \ln(R/b)$, a cost linear in d. Biswas, Dong, Kamath & Ullman (2020) shrink a ball instead. Keep a ball that contains μ, clip the data to a slightly larger ball, take a noisy mean, and use it to draw a smaller ball. A few rounds take the ball from radius R down to the spread of the data.

Two tools replace the one-dimensional ones. The noise is Gaussian rather than Laplace, because one record moves a vector average in every coordinate at once, and Gaussian noise is calibrated to the ℓ_2 sensitivity, the most one record can move the answer in length (Proposition 20.3). Write $\kappa(\varepsilon, \delta)$ for the largest ratio of ℓ_2 sensitivity to noise standard deviation at which Gaussian noise is (ε, δ)-DP, the root that Corollary 20.1 finds by bisection and calls μ^*; this page writes it κ because μ is the mean here. Gaussian noise of standard deviation $\Delta_2/\kappa(\varepsilon, \delta)$ on a query of ℓ_2 sensitivity Δ_2 is then (ε, δ)-DP, and so is any larger noise. The second tool is the d-dimensional version of Lemma 28.2, which the proof needs twice: once to say how far records stray from μ, and once to bound the length of a round's noise.

Lemma 28.3 (Normal vectors stay close to their mean)**.** *Let Z be a standard normal vector in d dimensions, that is, a vector of d independent standard normal coordinates. For every $t \geq 0$,*

$$\Pr\left[\|Z\| > \sqrt{d} + t\right] \leq e^{-t^2/2}. \tag{28.9}$$

So k independent such vectors all have length at most $\sqrt{d} + \sqrt{2\ln(k/\beta)}$ with probability at least $1 - \beta$.

Proof.

1. *One vector.* The length $\|Z\|$ changes by at most the length of the move when Z moves, and such functions of a normal vector concentrate around their average. That average is at most $\sqrt{d}$, because the mean of a length is at most the square root of its mean square, which is d. The tail bound is Boucheron, Lugosi & Massart (2013, ch. 5), and Section E.4 in the appendices proves the same bound with the Chernoff method alone.
2. *Several vectors.* Give each of the k vectors a share β/k of the failure probability. Setting $e^{-t^2/2} = \beta/k$ gives $t = \sqrt{2\ln(k/\beta)}$, and the probability that at least one vector is longer is at most the sum of the k shares, by the union bound, which is β.

□

The mechanism below keeps two lengths fixed before it sees the data: a radius τ_d that every record stays within, from the lemma with $k = n$, and a margin u that bounds the sampling error and the noise of each step, from the lemma with $k = 1$.

Theorem 28.3 (Shrinking balls)**.** *Let the records be independent draws from a normal distribution in d dimensions with mean μ, where $\|\mu\| \le R$, and identity covariance, and let $T \ge 0$ be a number of rounds. Two lengths set the scale. The first bounds how far records lie from the mean,*

$$\tau_d = \sqrt{d} + \sqrt{2\ln(2n/\beta)}, \tag{28.10}$$

and the second, u, is a margin for the $T+1$ steps of the mechanism, T rounds and a final step:

$$u = \sqrt{2\ln(4(T+1)/\beta)}. \tag{28.11}$$

Give each step a budget $(\varepsilon_t, \delta_t)$ such that all the steps add up to ε and δ. Start from the ball of radius $r_0 = R$ around the centre $c_0 = 0$. In round $t = 0, \dots, T-1$:

1. *Move every record that lies outside the ball of radius $r_t + \tau_d$ around c_t onto its surface.*
2. *Release the average plus Gaussian noise with standard deviation $s_t = 2(r_t + \tau_d)/(n\,\kappa(\varepsilon_t, \delta_t))$ in each coordinate, and call the result c_{t+1}.*
3. *Set the next radius to*

$$r_{t+1} = \frac{\sqrt{d} + u}{\sqrt{n}} + s_t(\sqrt{d} + u). \tag{28.12}$$

A final step does steps 1 and 2 once more, with the rest of the budget and noise s_T, and releases the noisy average. The mechanism is (ε, δ)-DP for every dataset. With probability at least $1 - \beta$, every ball contains μ and no record is ever moved. On that event the final release is the plain average plus noise, and, ignoring the rare event where it fails,

$$\mathrm{RMSE} = \sqrt{\frac{d}{n} + d\,s_T^2}. \tag{28.13}$$

Proof. The plan is to show that each step is a Gaussian mechanism and compose them, then that, as long as the current ball holds μ, nothing is clipped and the next ball holds μ too, and finally to read the error off the last step.

1. *Privacy of one step.* After the move of step 1 every record lies in a ball of radius $r_t + \tau_d$, whose diameter is $2(r_t + \tau_d)$. Replacing one record therefore moves the sum by a vector of length at most $2(r_t + \tau_d)$, and the average by that divided by n, which is the ℓ_2 sensitivity. The noise s_t is this sensitivity divided by $\kappa(\varepsilon_t, \delta_t)$, so the step is $(\varepsilon_t, \delta_t)$-DP for each value of the centre, which was chosen privately. Adaptive basic composition (Post-processing, group privacy and composition) adds the budgets of the $T + 1$ steps.
2. *Records stay within τ_d of the mean.* Each $X_i - \mu$ is a standard normal vector, so Lemma 28.3 with $k = n$ vectors and failure probability $\beta/2$ says that, with probability at least $1 - \beta/2$, every record lies within $\sqrt{d} + \sqrt{2\ln(2n/\beta)} = \tau_d$ of μ.
3. *The balls keep the mean.* Suppose μ lies in the ball of round t and the event of step 2 holds. Then every record lies within τ_d of μ, hence inside the clipping ball, and nothing moves. So $c_{t+1} - \mu$ is the sampling error $\bar{X} - \mu$ plus the noise. The sampling error is a normal vector with variance $1/n$ in each coordinate, so $\sqrt{n}$ times it is a standard normal vector, and the noise divided by s_t is one too. By Lemma 28.3 with $k = 1$ and failure probability $\beta/(4(T + 1))$ for each of the two, the sampling error has length at most $(\sqrt{d} + u)/\sqrt{n}$ and the noise has length at most $s_t(\sqrt{d} + u)$, so μ lies in the next ball, of radius Equation 28.12. The $2(T + 1)$ shares of $\beta/(4(T + 1))$ and the $\beta/2$ of step 2 add up to β, which is the total failure probability.
4. *Final error.* On that event the final release is $\bar{X}$ plus independent noise. The expected squared length of $\bar{X} - \mu$ is d/n, the sum of d variances of $1/n$, and that of the noise is $d\, s_T^2$, and the cross term has mean 0 as in Lemma 28.1. That gives Equation 28.13.

□

In a round, the radius drops from r_t to about $2(r_t + \tau_d)\sqrt{d}/(n\,\kappa(\varepsilon_t, \delta_t))$. When n is larger than a constant times $\sqrt{d}/\kappa(\varepsilon_t, \delta_t)$, which is of order $\sqrt{d\ln(1/\delta)}/\varepsilon_t$, that is a reduction by a constant factor, and about $\ln R$ rounds bring the radius down to the order of $\tau_d \approx \sqrt{d}$. Below that the ball cannot shrink, because the records themselves are spread about $\sqrt{d}$ around μ and the clipping ball must leave them alone; Exercise 4 in the exercise book computes the n a round needs to halve the radius. In the final step the sensitivity is then about $2\sqrt{d}/n$, so $d\, s_T^2$ is about $4d^2/(n\kappa)^2$, and an error α needs n of order $d/(\alpha\kappa)$, that is, $d\sqrt{\ln(1/\delta)}/(\alpha\varepsilon)$. Reaching an error α therefore takes about $d/\alpha^2 + d\sqrt{\ln(1/\delta)}/(\alpha\varepsilon) + \sqrt{d}\ln R/\varepsilon$ records, up to logarithmic factors.

Without privacy the error is $\sqrt{d/n}$. The privacy noise is about $d/(n\varepsilon)$ up to logarithmic factors, so it grows like d instead of $\sqrt{d}$, and it is larger than the sampling error unless n is above about d/ε^2. That is not a weakness of the method. The fingerprinting lower bound says that releasing d means with an error α' in each coordinate needs about $\sqrt{d}/(\alpha'\varepsilon)$ records. An ℓ_2 error α spread over d coordinates is an error of about $\alpha/\sqrt{d}$ in each, so substituting $\alpha' = \alpha/\sqrt{d}$ gives $d/(\alpha\varepsilon)$. Exercise 5 in the exercise book does the substitution with the constants, and Kamath, Li, Singhal & Ullman (2019) prove the matching lower bound directly for normal data.

The range costs $\sqrt{d}\ln R/\varepsilon$, which is less than the $d\ln R/\varepsilon$ of a grid histogram, because each round makes progress in all d directions at once. The rounds compose here by basic composition, which adds the budgets; the tighter accountants of Part 4 make several rounds cheaper, and the original method uses one of them. This is the shape of every private average of vectors, including the average of clipped gradients in private training. There the clipping norm is a fixed number rather than a shrinking ball, and choosing it is the clipping trade-off of Beyond global sensitivity in many dimensions.

Example 28.4. The running example needs more records here, because an error below 1 in $d = 1000$ dimensions is out of reach for 1,000 records even without privacy, where the sampling error alone is $\sqrt{d/n} = 1$. Take $n = 100{,}000$ records with $\|\mu\| \le 1000$, at $\varepsilon = 1$ and $\delta = 10^{-6}$, with $\beta = 0.05$ and a quarter of the budget for the rounds. Here $\kappa(1, 10^{-6}) = 0.2367$. Table 28.3 compares the naive estimator, which clips to the ball of radius $R + \tau_d$, with shrinking balls. The script tries every number of rounds up to 29 and keeps the best, which is two for each d. For $d = 100$ the radius falls from 1000 to 8.54 after one round and to 0.243 after the second. The ratio of the privacy noise to $d/(n\varepsilon)$ falls from 32.2 at $d = 10$ to 14.2 at $d = 1000$, as the terms in $\sqrt{d}$ give way to the term in d. A simulation at $d = 100$ with 40 datasets gives an RMSE of 0.0363 against the formula's 0.0366, and every ball contained μ in all 40.

Table 28.3.: The mean of $n = 100{,}000$ normal vectors in d dimensions with $\|\mu\| \le 1000$, at $(1, 10^{-6})$-DP, by the naive estimator and by shrinking balls: the ℓ_2 RMSE from Equation 28.13.

d	Non-private $\sqrt{d/n}$	Naive RMSE	Rounds	Radii	Shrinking balls: RMSE
10	0.0100	0.2697	2	1000, 4.12, 0.0725	0.0105
100	0.0316	0.8586	2	1000, 8.54, 0.243	0.0366
1000	0.1000	2.7730	2	1000, 22.9, 1.43	0.1736

28.5. Heavy tails: clip into the data

Normal data rarely stray far, so every estimator so far could clip without touching a record. Many real quantities have heavy tails: incomes, session lengths, the norms of per-example gradients. Suppose all you know is that the variance is at most σ^2. Chebyshev's inequality then only says that a record is more than $\sigma\sqrt{n/\beta}$ from the mean with probability at most β/n, so a clipping range wide enough to touch no record has half-width $\sigma\sqrt{n/\beta}$, and its noise is enormous. The way out is to clip into the data on purpose and accept a bias, and the question is how wide to clip.

The estimator clips around a centre that a coarse step has placed near the mean; to keep the formulas clean, the theorem takes the centre to be μ itself, and writes τ for the clipping half-width. The bias of clipping is the average amount by which records stick out of the window, and a variance bound controls that amount: a record that sticks out contributes to the variance a squared distance at least τ times its distance, so the excess of all such records together is at most σ^2/τ.

Theorem 28.4 (Clipping into heavy-tailed data)**.** *Let the records be independent draws from any distribution with mean μ and variance at most σ^2. Clip every record to $[\mu - \tau, \mu + \tau]$ for a half-width $\tau > 0$, average, and add* $\mathrm{Lap}(2\tau/(n\varepsilon))$ *noise. The release is ε-DP for every τ and every dataset, and*

$$\mathrm{RMSE} \le \frac{\sigma}{\sqrt{n}} + \frac{\sigma^2}{\tau} + \frac{2\sqrt{2}\,\tau}{n\varepsilon}. \tag{28.14}$$

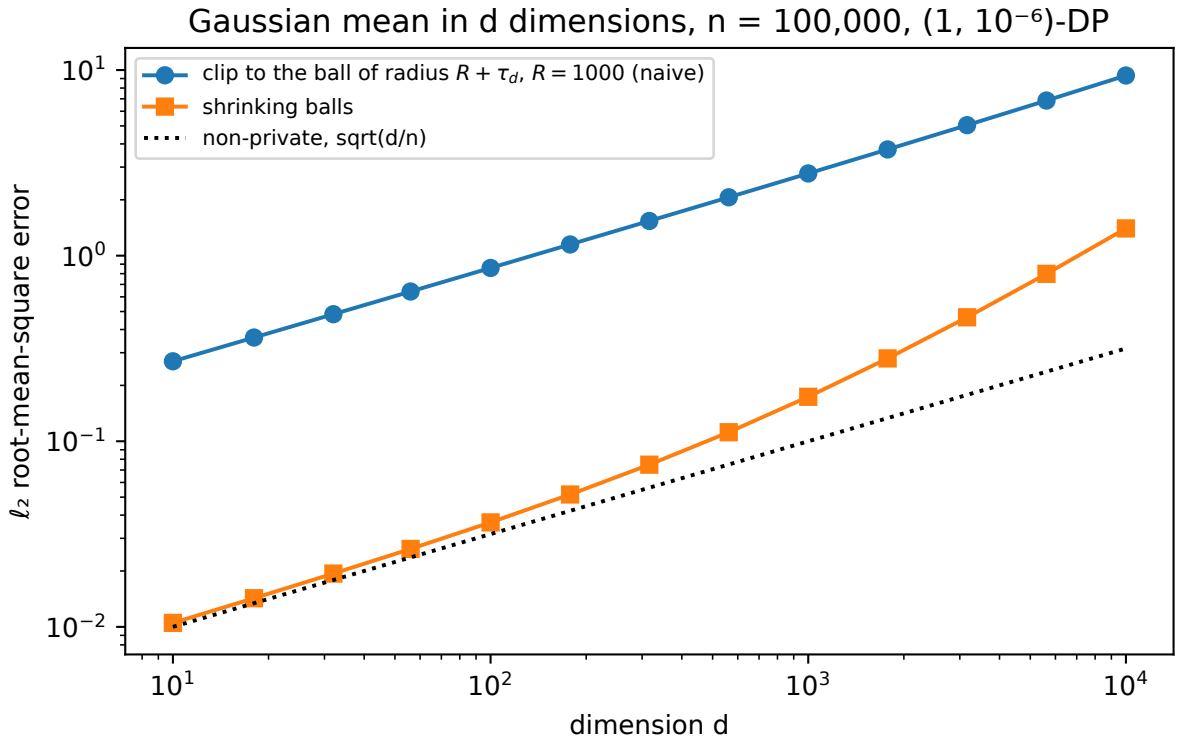

Figure 28.3.: The ℓ_2 root-mean-square error of the mean of 100,000 normal vectors against the dimension d, at $(1, 10^{-6})$-DP with $\|\mu\| \leq 1000$: clipping to the ball of radius $R + \tau_d$, shrinking balls, and the non-private error $\sqrt{d/n}$.

The right side is smallest at

$$\tau_b = \sigma\sqrt{\frac{n\varepsilon}{2\sqrt{2}}}, \qquad \textit{where it equals} \qquad \frac{\sigma}{\sqrt{n}} + 2\sigma\sqrt{\frac{2\sqrt{2}}{n\varepsilon}}. \tag{28.15}$$

Proof. The plan is to bound the three parts of Equation 28.2 one at a time, add them, and minimize over τ.

1. *Privacy.* The clipping interval has width 2τ, so Lemma 28.1 gives ε-DP for every dataset, whatever τ is.
2. *Bias.* Clipping moves a record X toward μ by $(|X-\mu|-\tau)_+$, the amount by which its distance from μ exceeds τ, or 0. So the bias is at most the average of that amount. The amount is positive only where $|X-\mu| > \tau$, and there it is at most $|X-\mu| \le (X-\mu)^2/\tau$, because dividing $|X-\mu|$ by τ gives a number above 1. Averaging, the bias is at most $\mathbb{E}[(X-\mu)^2]/\tau \le \sigma^2/\tau$.
3. *Sampling.* A variance is half the average squared difference between two independent copies of a variable. Clipping to an interval never moves two values further apart, so the clipped record varies at most as much as the record itself, and its variance is at most σ^2. The sampling term of Equation 28.2 is at most σ^2/n.
4. *Noise.* The clipping interval has width 2τ, so by Equation 28.2 the noise standard deviation is $\sqrt{2}\cdot 2\tau/(n\varepsilon)$.
5. *Add.* By Equation 28.2, the RMSE is the length of a vector with these three components, and a length is at most the sum of its components. That gives Equation 28.14.
6. *Minimize.* The two terms that depend on τ are σ^2/τ, falling, and $2\sqrt{2}\,\tau/(n\varepsilon)$, rising. The derivative of their sum, $-\sigma^2/\tau^2 + 2\sqrt{2}/(n\varepsilon)$, is zero at τ_b, and there the two terms are equal, each $\sigma\sqrt{2\sqrt{2}/(n\varepsilon)}$. That gives Equation 28.15.

□

Requiring the second term of Equation 28.15 to be at most α and squaring shows that an error α needs about $\sigma^2/\alpha^2 + 8\sqrt{2}\,\sigma^2/(\alpha^2\varepsilon)$ records, of order $1/(\alpha^2\varepsilon)$. Without clipping into the data, at $\tau = \sigma\sqrt{n/\beta}$, it would need of order $1/(\beta\alpha^2\varepsilon^2)$. With heavy tails, then, privacy stops being a lower-order cost. For bounded data the privacy term in Equation 28.4 had a single $1/\alpha$, while here it has $1/\alpha^2$, the same power as sampling, divided by ε. Kamath, Singhal & Ullman (2020) show that this is unavoidable: no ε-DP mechanism does better for every distribution with bounded variance. Section J.4 in the appendices derives this lower bound, and its k-th moment version, from a two-point distribution and group privacy. They also show what more knowledge buys. If the k-th moment $\mathbb{E}[|X-\mu|^k]$ is bounded for some $k > 2$, the cost falls to about $1/(\varepsilon\,\alpha^{k/(k-1)})$ records, and as k grows it approaches the $1/(\alpha\varepsilon)$ of bounded data.

The bound Equation 28.14 is a worst case, and it is tight up to a constant factor. A sharper version of step 2 gives $\sigma^2/(4\tau)$, because $(|y|-\tau)_+ \le y^2/(4\tau)$ for every y, and a distribution that puts a little mass at distance 2τ on one side of the mean attains that. So the worst case hides its variance in a few far-out records on one side. For an ordinary heavy-tailed distribution the bias falls faster than σ^2/τ, the best τ is smaller than τ_b, and the error is lower. But τ_b uses only n, ε and the variance bound, so it can be set without looking at the data; if the variance bound is four times too large, τ_b doubles, the release stays private and only the accuracy suffers. Setting τ

from the data, such as to the observed maximum, would bring back the leak of Beyond global sensitivity.

Example 28.5. Take a Pareto distribution with shape 3, the law of $x_m U^{-1/3}$ for a uniform U on $(0, 1)$, scaled so that its variance is 1. Its smallest value is $x_m = 1.1547$ and its mean is 1.7321, and its third moment is infinite. With $n = 1000$ and $\varepsilon = 1$, Table 28.4 compares three choices of τ. Clipping wide enough to touch nothing costs an RMSE of 0.4012. The worst-case choice $\tau_b = 18.80$ gives 0.0607, and the best τ for this particular distribution, 5.36, gives 0.0329, close to the non-private 0.0316. The bound Equation 28.15 promises 0.1380, which is loose for this distribution, as predicted: for this law the average excess beyond a point falls like the inverse square of the point rather than its inverse, and Exercise 3 in the exercise book computes the exact bias. At $n = 100{,}000$ the pattern repeats, with RMSE 0.0401, 0.0062 and 0.0032 for the three choices.

Table 28.4.: Clipped private means of Pareto records with variance 1, $n = 1000$, $\varepsilon = 1$: the exact terms of Equation 28.2 for three clipping half-widths τ around the mean, and simulations with 4,000 repetitions.

τ	Bias	Sampling sd	Noise sd	RMSE	Simulated
141.42 (no record clipped)	0.0000	0.0313	0.4000	0.4012	0.3997
18.80 (worst-case best, τ_b)	−0.0018	0.0293	0.0532	0.0607	0.0591
5.36 (best for this distribution)	−0.0153	0.0249	0.0152	0.0329	0.0325

28.6. Code

The script code/mean_estimation.py computes every number in this chapter and draws its figures. Each estimator and each error formula is a small typed function. The exact errors use the mean and variance of a clipped normal or Pareto variable, and the simulations run the mechanisms on fresh data. From the repository root:

```
uv run python code/part03-dp-foundations/mean_estimation.py
```

Table 28.5.: The script's output with seed 0.

Experiment	Result
Spread of 1,000 normal records, $\beta = 0.05$	$\tau_1 = 4.604$; exceeded in a fraction 0.0039 of 20,000 simulated datasets

Experiment	Result
Survey proportion, $\varepsilon = 1$	108 records for RMSE 0.05 (100 without privacy); 2,508 for 0.01 (2,500)
Naive estimator, $n = 1000$	RMSE 0.0520, 2.8416 and 2828.44 for $R = 10$, 10^3, 10^6
Coarse then fine, $n = 1000$	RMSE 0.0609 for every R (simulated 0.0588, 0.0606, 0.0596); coarse step needs 74, 135, 245 records; beats naive from $R = 13.81$
Shrinking balls, $n = 100{,}000$, $R = 1000$	RMSE 0.0105, 0.0366, 0.1736 for $d = 10$, 100, 1000, against 0.0100, 0.0316, 0.1000 without privacy; simulated 0.0363 at $d = 100$
Pareto records, $n = 1000$	RMSE 0.4012 without clipping into the data, 0.0607 at τ_b, 0.0329 at the best τ; bound 0.1380

tests/test_mean_estimation.py checks that the output still matches this table.

28.7. Summary

Table 28.6.: The results of this chapter, and where each is used.

Result	Statement	Use
Lemma 28.1	Clip to width w, average, add $\mathrm{Lap}(w/(n\varepsilon))$: ε-DP for every dataset; error^2 = sampling + bias^2 + $2w^2/(n\varepsilon)^2$	Privacy comes from the clipping alone; let assumptions about the data enter only through how often clipping changes nothing
Theorem 28.1	RMSE $= \sqrt{\sigma^2/n + 2w^2/(n\varepsilon)^2}$; error α from $\sigma^2/\alpha^2 + \sqrt{2}\,w/(\alpha\varepsilon)$ records	Proportions, surveys, clipped sums: privacy is a lower-order cost
Lemma 28.2	n normal draws lie within $\tau_1 = \sqrt{2\ln(2n/\beta)}$ of μ with probability $1-\beta$	Widening a clipping range so that it touches no record
Proposition 28.1	Clip to $[-R-\tau_1, R+\tau_1]$: error α from about $1/\alpha^2 + R/(\alpha\varepsilon)$ records	The baseline; never clip to a range set by your ignorance
Theorem 28.2	Exponential mechanism on bins of width $2\tau_1$, then clip to 3 bins: $1/\alpha^2 + 1/(\alpha\varepsilon) + \ln R/\varepsilon$ records; the coarse step needs $4\ln(m/\beta)/\varepsilon_1$	Means with unknown location; choosing a clipping range privately with a quarter of the budget or less; under approximate DP a stability-based histogram replaces $\ln R$ by $\ln(1/\delta)$

Result	Statement	Use
Lemma 28.3	$\Pr[\|Z\| > \sqrt{d} + t] \le e^{-t^2/2}$ for a standard normal vector	The radius τ_d and the margin u of shrinking balls
Theorem 28.3	Shrinking balls with Gaussian noise, radius Equation 28.12: $d/\alpha^2 + d\sqrt{\ln(1/\delta)}/(\alpha\varepsilon) + \sqrt{d}\ln R/\varepsilon$ records	Private averages of vectors, such as gradients: budget about $d\sqrt{\ln(1/\delta)}/(\alpha\varepsilon)$ records for privacy on top of d/α^2 for sampling
Theorem 28.4	Clip to $\mu \pm \tau_b$ with $\tau_b = \sigma\sqrt{n\varepsilon/(2\sqrt{2})}$: $\sigma^2/\alpha^2 + 8\sqrt{2}\,\sigma^2/(\alpha^2\varepsilon)$ records; with a bounded k-th moment, $1/\alpha^2 + 1/(\varepsilon\,\alpha^{k/(k-1)})$	Incomes, session lengths, gradient norms: clip into the data, with a width set from n, ε and a variance bound, never from the data

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

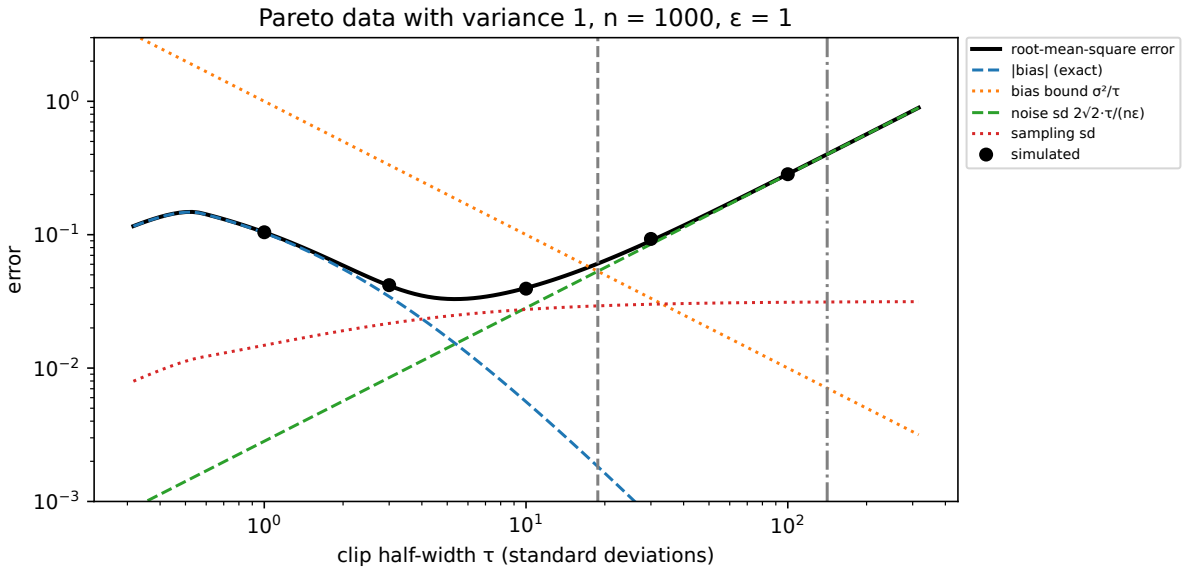

Figure 28.4.: Error of the clipped private mean of Pareto records with variance 1, $n = 1000$, $\varepsilon = 1$, against the clipping half-width τ: the RMSE, the exact bias and its bound σ^2/τ, the noise and the sampling standard deviations, and simulated points. The dashed vertical line is τ_b and the dash-dotted one the width that clips no record.

Part IV.

Privacy accounting

The previous part defined differential privacy (DP), built the basic mechanisms and proved how (ε, δ) guarantees compose. This part answers the question that decides whether a trained model's privacy claim means anything: **after thousands of noisy steps, each on a random subset of the data, how large is ε, really?** The answer is never read off a single theorem. It comes from an **accountant**, a procedure that tracks some summary of each step's privacy loss, combines the summaries, and converts the result into the (ε, δ) you report. The running case throughout is stochastic gradient descent (SGD) with per-example clipping and Gaussian noise, called DP-SGD, and the workhorse summary is Rényi differential privacy (RDP). Two accountants given the same training run can report values of ε that differ by a large factor. Both can be correct upper bounds, but only the tighter one tells you what the noise actually bought.

Who this part is for

You are expected to have read the prerequisites and the part on DP foundations. From Divergences you need the Rényi divergence D_α, the hockey-stick divergence E_γ and the data-processing inequality. From Hypothesis testing you need trade-off functions $T(P, Q)$ and the Gaussian trade-off curve. From Concentration inequalities you need Hoeffding's lemma, and from Optimization the contraction of a gradient step. From the DP foundations you need randomized response and the hypothesis-testing reading of DP, basic composition, the privacy loss random variable with advanced and optimal composition from Composition, the Gaussian mechanism and its exact $\delta(\varepsilon)$ from the Laplace and Gaussian mechanisms, and the local and shuffle models from Trust models. Each chapter restates the facts it uses in one line and links to them.

The common thread

Composition is easy for the privacy loss itself. If you run k mechanisms, the privacy loss of the whole run is the sum of the k per-step losses, and its distribution is a convolution. Composition is hard for (ε, δ), because a pair of numbers forgets almost everything about that distribution. Advanced composition recovers part of what is lost. The rest of the field rests on one move: **track a richer summary of the privacy loss, one that composes simply, and convert to (ε, δ) only once, at the end.**

The summaries differ in how much they keep, and Table 28.7 lists them.

Table 28.7.: The chapters of this part, the question each one answers, the summary of the privacy loss it tracks, and the earlier chapters it uses.

Chapter	The question it answers	Summary it tracks	Builds on
Rényi DP	Which summary of the privacy loss adds up under composition?	The curve $\varepsilon(\alpha)$ of Rényi divergences	2, 3, 18–21

Chapter	The question it answers	Summary it tracks	Builds on
From Rényi DP to (ε, δ) and to tests	How much does converting an RDP curve to (ε, δ) lose, and what is unavoidable?	The same curve, read as a constraint on tests	3, 4, 18, 21, 29
Concentrated differential privacy	When does one number ρ describe the whole curve, and when not?	A line $\rho\alpha$ above the curve	2, 3, 19–21, 25, 29, 30; one formula from 33
f-DP and Gaussian differential privacy	What is the most informative description of a mechanism's privacy?	The full trade-off function; μ for Gaussian ones	3, 4, 18, 21, 29, 30
Amplification by subsampling	How much privacy does using each record only with probability q buy?	RDP of the subsampled Gaussian	3, 18–21, 29, 30
Numerical accounting with privacy loss distributions	How do you compute the exact ε of a composition, with error bars?	The discretized distribution of the privacy loss	3, 18, 20, 21, 29, 30, 32, 33
Amplification by shuffling and by iteration	What other sources of uncertainty amplify privacy?	Bounds for shuffled reports and hidden iterates	3, 6, 7, 18, 26, 29, 30, 32, 33
Adaptive composition: filters, odometers and individual accounting	What changes when the privacy parameters are chosen on the fly, or differ per record?	Running sums checked by filters and odometers	2, 21, 29, 31, 33
Choosing an accountant	Which accountant should you use for DP-SGD, and what should you report?	All of the above, side by side	3, 21, 29–36

Read the table from top to bottom as a ladder. An RDP curve is a lossy summary of the trade-off function, a zero-concentrated DP (zCDP) parameter ρ is a lossy summary of the RDP curve, and (ε, δ) is a lossy summary of all three. Numerical accounting keeps the whole privacy loss distribution and loses only discretization error, which it bounds. Amplification (chapters 33 and 35) is a separate axis. It is about which pair of distributions you account for in the first place, and every accountant above must use the pair that matches the sampling scheme the training code actually runs.

The running example

Every chapter that can compute it reports the same number: the ε at $\delta = 10^{-5}$ of DP-SGD with Poisson sampling rate $q = 0.01$, noise multiplier $\sigma = 1$ and up to $T = 10{,}000$ steps. That is about one hundred epochs at a typical setting. A single Gaussian mechanism with $\sigma = 1$ serves as the small example. Watching the same number move from chapter to chapter shows what each tool gains. Choosing an accountant puts all the values side by side.

How to read this part

Order. Read chapters 29 and 30 first: every later chapter uses the RDP curve and its conversion. Chapter 30 ends by reading the curve as a constraint on tests, and chapter 32 develops that trade-off view in full, so read it next. Chapters 33 and 34 form the practical core and should be read in order. Chapter 31 can be read any time after chapter 30, except its section on subsampling, which uses one formula from chapter 33; read it before chapter 36, which uses its conversion. Chapter 35 needs chapter 33. Chapter 36 needs chapters 31 and 33. Chapter 37 closes the part and uses all the others, so read it last.

Structure. The chapters follow the shape of the earlier parts: why the topic matters, a toolkit, one section per result with a derivation, interpretation, worked example and two check-yourself questions, then code, references and a cheat sheet. Exercises with worked solutions are collected in the exercise book, a companion website, with a link at the end of each chapter.

Run the code. Each chapter has a script in `code/` that prints every number its text quotes, except values attributed to an external library or paper, and regenerates its figures, for example

```
uv run python code/part04-privacy-accounting/renyi_dp.py
```

None of the scripts uses an accounting library. Each accountant is implemented from its definition in a few dozen lines of NumPy, so you can read exactly what it computes. As an exercise, compare them with Google's `dp_accounting` or Opacus.

Notation

The part uses the notation of the DP foundations part, extended in Table 28.8.

Table 28.8.: Notation used throughout this part, in addition to that of the earlier parts.

Symbol	Meaning
M, $D \sim D'$	A mechanism; neighbouring datasets (add/remove-one unless replace-one is named)
y, $P = M(D)$, $Q = M(D')$	An output; the two output distributions being compared

Symbol	Meaning
$D' = D \cup \{x\}$; FPR, FNR	As in the DP foundations part, under add/remove D' is the dataset that holds the record x and D the one without it. A test of P against Q has type I error FPR, its false positive rate, the rate of saying D' when the data were D, and type II error FNR, its false negative rate, the rate of saying D when they were D'. A guarantee covers both orders of the pair; a chapter that needs one order says so, as the subsampling chapters do for the remove direction, which puts the dataset with the record first
$L_{D,D'}(y) = \ln \frac{p_{M(D)}(y)}{p_{M(D')}(y)}$	The privacy loss of output y; $L_{D,D'}(Y)$ with $Y \sim M(D)$ is the privacy loss random variable
$\delta(\varepsilon) = E_{e^\varepsilon}(P\|Q)$	The smallest δ for a given ε, as a hockey-stick divergence
D_α, $\varepsilon(\alpha)$	Rényi divergence of order $\alpha > 1$; the RDP curve of a mechanism
ρ	The zCDP parameter
$T(P, Q)$, G_μ, μ	Trade-off function; the Gaussian trade-off function $T(\mathcal{N}(0,1), \mathcal{N}(\mu,1))$; the parameter of Gaussian differential privacy, so a Gaussian mechanism with noise multiplier σ has $\mu = 1/\sigma$
$\Delta_2 f$, σ	ℓ_2 sensitivity; noise multiplier (noise standard deviation per unit of sensitivity)
q, k, T	Sampling rate; number of mechanisms composed; number of steps of one iterative algorithm, such as DP-SGD
h	Grid width of a discretized privacy loss distribution

Two symbols do double duty, and each chapter warns you when it happens. α is the Rényi order throughout this part, but the f-DP literature uses it for the type I error, so the chapters of this part write the errors as false positive and false negative rates, FPR and FNR. q is the sampling rate, so the chapters in which a sampling rate appears write output densities with capital letters, such as $Q(y)$ or $P_q(y)$, never $q(y)$.

What you will be able to do

By the end of this part you should be able to:

- compute the RDP curve of the Gaussian, Laplace and randomized-response mechanisms, compose them, and convert the result to (ε, δ) with both the classic and the improved conversion;
- explain what an RDP curve, a zCDP parameter and a trade-off function each keep and lose about the privacy loss;
- derive privacy amplification by subsampling, and compute the RDP of the Poisson-subsampled Gaussian;
- build a privacy-loss-distribution accountant with pessimistic and optimistic error bounds, and use it to check any other accountant;
- say when shuffling or hiding intermediate iterates gives extra privacy, and when it does not apply;
- run a privacy filter, and compute per-record privacy spend in DP-SGD;
- pick an accountant for a DP-SGD run, state its assumptions, and report ε in a way that someone else can check.

29. Rényi differential privacy

29.1. Why this matters

You train a model with 1000 steps of full-batch noisy gradient descent. Each step computes a quantity whose **sensitivity** is 1, meaning that changing one person's record moves it by at most 1, and releases it with Gaussian noise whose standard deviation is $\sigma = 20$ times that sensitivity; σ is the **noise multiplier**. What is the total differential privacy (DP) guarantee at $\delta = 10^{-5}$? Recall what such a guarantee says: a mechanism is (ε, δ)-DP if, for any two neighbouring datasets (datasets that differ in one person's record) and any set of outputs, the probability of that set under one dataset is at most e^{ε} times its probability under the other, plus a small slack δ.

Part 3 gives one answer. Turn each step into a single guarantee $(\varepsilon_0, \delta_0)$, then apply advanced composition (Composition), the theorem that says k such steps cost roughly $\varepsilon_0\sqrt{k}$ rather than $k\varepsilon_0$. With the best split of δ between the steps and the final tail, over the grid of splits Part 3 searches, that gives $\varepsilon = 68.01$. The true answer is $\varepsilon = 7.51$. You can compute it exactly because 1000 Gaussian steps behave like one Gaussian mechanism with noise $\sigma/\sqrt{1000}$: the 1000 shifts of 1 form a vector of Euclidean length $\sqrt{1000}$, and a Gaussian with shift $\sqrt{1000}$ and noise σ is the same as one with shift 1 and noise $\sigma/\sqrt{1000}$. The bound is nine times too large ($68.01/7.51 \approx 9$).

The loss comes from the very first move. A Gaussian step does not have one $(\varepsilon_0, \delta_0)$. For each ε_0 there is a smallest δ_0 that works, so it has a whole curve of valid pairs, its **privacy curve**. Collapsing the curve to a single point throws away the information about how the step behaves at every other point, and that is exactly the information composition needs. After that, no composition theorem can recover it.

29.1.1. The one idea: track a curve that adds

Rényi differential privacy (RDP) keeps a whole curve instead of a point, and it chooses a curve that is easy to compose. For each mechanism and each pair of neighbouring datasets, consider how much more likely an output is under one dataset than under the other. RDP summarizes that likelihood ratio by its moments: for each **order** $\alpha > 1$ it records the Rényi divergence D_α between the two output distributions, which is, up to a logarithm and a factor $1/(\alpha - 1)$, the average of the likelihood ratio raised to the power α (the Toolkit below restates it). Taking the worst pair of neighbours at each order gives a function $\alpha \mapsto \varepsilon(\alpha)$, the **RDP curve**.

Two facts make this curve the workhorse of privacy accounting. First, curves add under composition. When you run several mechanisms in sequence, even when each is chosen after seeing the earlier outputs, the curve of the whole run is at most the pointwise sum of their curves, with equality for independent steps. The reason is that a moment of a product of independent likelihood ratios is a product of moments, and the logarithm turns that product into a sum. No δ is spent along the way. Second, any point of the curve converts to an (ε, δ) guarantee at the end. The conversion

is a Chernoff bound, Markov's inequality applied to an exponential, which turns a bound on a moment of the privacy loss into a bound on how often the loss is large. So you compose curves, and choose the best order once, after composing.

For the 1000 Gaussian steps, adding curves and converting once gives $\varepsilon = 8.84$, 18% above the exact 7.51 ($8.84/7.51 = 1.177$). The same bookkeeping, under the name *moments accountant*, is what made differentially private deep learning practical.

Table 29.1 lists the results of this chapter and where each is used.

Table 29.1.: The results of this chapter and where each is used.

Result	Where it is used
Definition of (α, ε)-RDP; limits $\alpha \to 1$ and $\alpha \to \infty$	Every accountant in this part; ε-DP is the point $\alpha = \infty$
RDP curves of the Gaussian, Laplace and randomized response mechanisms	The inputs to every accountant; the Gaussian curve is the base of accounting for differentially private stochastic gradient descent (SGD), DP-SGD for short
Composition adds curves	Accounting for thousands of training steps in one line
Post-processing; weak group privacy	Releasing models and predictions; correlated records
The moments accountant is RDP	Reading Abadi et al. (2016) and the libraries built on it
Conversion RDP $\Rightarrow (\varepsilon, \delta)$	Reporting a guarantee; From RDP to (ε, δ) and to tests sharpens it

What you need. The Rényi divergence, its limits, its monotonicity in α and the data-processing inequality are in Divergences (Section 3.4, Section 3.10). The Chernoff method is in Concentration. From Part 3 you need the definition of DP (Definition), the Laplace and Gaussian mechanisms (Laplace and Gaussian mechanisms), randomized response (Definition, Section 18.3) and the privacy loss random variable (Composition). The Toolkit restates the facts this chapter uses, and each mechanism is restated where it first appears.

Notation. M is a mechanism and $D \sim D'$ are neighbouring datasets. $P = M(D)$ and $Q = M(D')$ are the output distributions, with densities (or probability mass functions) p and q. The **privacy loss** at output y is $L(y) = \ln \frac{p(y)}{q(y)}$, the log of how much more likely y is under D than under D': positive when y points to D, negative when it points to D'. The **privacy loss random variable** is $L(Y)$ with $Y \sim P$, the loss of an output actually drawn from the mechanism on D. The Gaussian mechanism adds $\mathcal{N}(0, \sigma^2\Delta_2^2)$ noise to a query f of ℓ_2-sensitivity $\Delta_2 f$ (the largest Euclidean distance between the query's answers on neighbours), so σ is the noise multiplier. Logarithms are natural. Whenever this part optimizes over the order, it uses the same grid of orders: 99 orders from 1.1 to 10.9 in steps of 0.1, the 52 integers from 12 to 63, and 128, 256 and 512, which is $99 + 52 + 3 = 154$ orders from 1.1 to 512:

```
ORDERS = [1 + x / 10 for x in range(1, 100)] + list(range(12, 64)) + [128, 256, 512]
```

29.2. Toolkit: four facts from Part 1

Every derivation below reuses four facts about the Rényi divergence of order $\alpha > 1$. They are proved in Divergences and Concentration; each is restated here with the short reason it holds. Throughout, $r = p/q$ is the **likelihood ratio**, how many times more likely an output is under P than under Q, and $L = \ln r$ is the privacy loss.

29.2.1. Fact 1 — A moment of the likelihood ratio

The Rényi divergence of order α is defined as

$$D_\alpha(P\|Q) = \frac{1}{\alpha - 1} \ln \int p^\alpha q^{1-\alpha}\, dy. \tag{29.1}$$

The integral inside is an average of a power of the likelihood ratio, and you can take that average under either distribution. Multiply both sides of the definition by $\alpha - 1$ and exponentiate:

$$e^{(\alpha-1)D_\alpha(P\|Q)} = \int p^\alpha q^{1-\alpha}\, dy = \mathbb{E}_Q\big[r^\alpha\big] = \mathbb{E}_P\big[r^{\alpha-1}\big] = \mathbb{E}_P\big[e^{(\alpha-1)L}\big]. \tag{29.2}$$

The first equality after the integral holds because $p^\alpha q^{1-\alpha} = q\,(p/q)^\alpha$, and integrating q times something is averaging that something under Q. The next one is the **change of measure** $\mathbb{E}_P[g] = \mathbb{E}_Q[rg]$, which holds because $\int p\, g = \int q\,(p/q)\, g$: an average under P is an average under Q with each output reweighted by its likelihood ratio. Applied with $g = r^{\alpha-1}$, it turns $\mathbb{E}_Q[r \cdot r^{\alpha-1}]$ into $\mathbb{E}_P[r^{\alpha-1}]$. The last form uses $r^{\alpha-1} = e^{(\alpha-1)L}$. It says that $(\alpha-1)D_\alpha$ is the logarithm of the **moment generating function** (MGF) of L under P, the function $\lambda \mapsto \mathbb{E}_P[e^{\lambda L}]$, evaluated at $\lambda = \alpha - 1$ (Equation 3.12). That is why a Rényi divergence is a statement about the exponential moments of the privacy loss.

29.2.2. Fact 2 — Limits and monotonicity

D_α is non-decreasing in α. As $\alpha \to 1$ it tends to the Kullback–Leibler (KL) divergence $\mathbb{E}_P[L]$, the average privacy loss, and as $\alpha \to \infty$ it tends to the **max-divergence** $D_\infty = \sup_y L(y)$, the largest privacy loss of any output.

The reason is a picture. Write $\psi(\lambda) = \ln \mathbb{E}_P[e^{\lambda L}]$, the log-MGF of Fact 1. It passes through the origin, since $\psi(0) = \ln 1 = 0$, and it is convex, as every log-MGF is. By Fact 1, $D_\alpha = \psi(\alpha-1)/(\alpha-1)$, the slope of the chord of ψ from the origin to the point at $\lambda = \alpha - 1$. Chords of a convex function from a fixed point get steeper as their far end moves right, so D_α grows with α. As $\alpha \to 1$ the chord shrinks to the tangent at 0, whose slope is $\psi'(0) = \mathbb{E}_P[L]$, the KL divergence. As $\alpha \to \infty$, D_α is the log of $\big(\mathbb{E}_P[r^{\alpha-1}]\big)^{1/(\alpha-1)}$, a power mean of r with a growing exponent, and such a mean is pulled toward the largest value of r; its logarithm tends to $\sup_y L(y)$.

29.2.3. Fact 3 — Data processing

Processing the output cannot make two distributions easier to tell apart. For any **channel** K, a randomized map applied to the output that does not depend on which distribution produced it, $D_\alpha(PK\|QK) \le D_\alpha(P\|Q)$, for every α including ∞ (Section 3.10). Here PK is the distribution of the processed output when the input is drawn from P. The idea is that the likelihood ratio of a processed output is an average of the ratios of the original outputs that could have produced it, and averaging pulls ratios toward each other. Since $x \mapsto x^\alpha$ is convex for $\alpha > 1$, Jensen's inequality (the power of an average is at most the average of the powers) says that averaging can only lower the moment $\mathbb{E}_Q[r^\alpha]$, and with it D_α.

29.2.4. Fact 4 — Markov on an exponential (the Chernoff method)

For any random variable X, any c and any $\lambda > 0$,

$$\Pr[X \ge c] \le e^{-\lambda c}\,\mathbb{E}\big[e^{\lambda X}\big]. \tag{29.3}$$

The reason is one line. On the event $X \ge c$ the non-negative quantity $e^{\lambda X}$ is at least $e^{\lambda c}$, so its average is at least $e^{\lambda c}\Pr[X \ge c]$; divide by $e^{\lambda c}$. This is how an exponential moment, which is what a Rényi divergence controls, becomes a bound on a tail probability.

29.3. Rényi differential privacy

29.3.1. Context

ε-DP bounds the privacy loss $L(y)$ at *every* output. That is a statement about the maximum of L, which is the max-divergence. (ε, δ)-DP allows the bound to be exceeded on outputs carrying a small amount of probability mass, measured by δ. Both summarize the distribution of the privacy loss by one point of its upper tail. The Rényi divergence of order α summarizes it differently, by an exponential moment $\mathbb{E}_P[e^{(\alpha-1)L}]$ (Fact 1). An exponential moment weights large losses more heavily than small ones, and the larger the order, the more heavily. So small orders look at the typical loss and large orders at the worst case (Fact 2). Requiring a bound at every order describes the whole upper tail of the loss, not one point of it.

29.3.2. Statement

The definition asks for the same bound on the Rényi divergence for every pair of neighbours. A mechanism M is (α, ε)-**RDP**, for an order $\alpha > 1$, if for all neighbouring datasets $D \sim D'$

$$D_\alpha(M(D)\,\|\,M(D')) \le \varepsilon. \tag{29.4}$$

The **RDP curve** of M records, at each order, the smallest ε that works, which is the divergence of the worst pair of neighbours:

$$\varepsilon_M(\alpha) = \sup_{D \sim D'} D_\alpha(M(D)\,\|\,M(D')). \tag{29.5}$$

The curve has three properties, which tie its two ends to familiar quantities.

1. $\alpha = \infty$ **is pure DP.** M is ε-DP if and only if $\varepsilon_M(\infty) \le \varepsilon$.
2. **Monotone.** $\varepsilon_M(\alpha)$ is non-decreasing in α. So an ε-DP mechanism is (α, ε)-RDP at every order.
3. $\alpha \to 1$ **is KL.** As $\alpha \to 1$, $\varepsilon_M(\alpha)$ tends to a limit at least the largest KL divergence between neighbours, with equality for every mechanism in this chapter.

29.3.3. Derivation

1. **Pure DP is the max-divergence.** ε-DP says $P(S) \le e^{\varepsilon} Q(S)$ for every event S, that is, $\ln \frac{P(S)}{Q(S)} \le \varepsilon$. The largest value of that log ratio over events equals the largest privacy loss of a single output, which is the event form of the max-divergence (Section 3.4). The reason: $\frac{P(S)}{Q(S)} = \frac{\int_S q\, r}{\int_S q}$ is an average of the likelihood ratio r over the outputs in S, weighted by q, so it can never exceed the largest r, and an event concentrated on the outputs where r is largest comes as close to it as you like. So $\sup_S \ln \frac{P(S)}{Q(S)} = D_\infty(P\|Q)$, and ε-DP holds exactly when $D_\infty(M(D)\|M(D')) \le \varepsilon$ for all neighbours, that is, when $\varepsilon_M(\infty) \le \varepsilon$.
2. **Monotonicity passes through the supremum.** For each pair, D_α is non-decreasing in α (Fact 2). A supremum of non-decreasing functions is non-decreasing, because if every function in the family is larger at α' than at α, so is the largest of them. Combined with step 1, $\varepsilon_M(\alpha) \le \varepsilon_M(\infty) \le \varepsilon$ for an ε-DP mechanism.
3. **The KL limit.** For each pair, $D_\alpha \ge D_{\mathrm{KL}}$ and $D_\alpha \to D_{\mathrm{KL}}$ as $\alpha \to 1$ (Fact 2). So $\varepsilon_M(\alpha) \ge \sup_{D \sim D'} D_{\mathrm{KL}}(M(D)\|M(D'))$ at every order, and the limit is at least the largest KL. Equality would need the limit and the supremum to commute, which can fail in general: each pair's divergence could approach its KL at a different speed. For the mechanisms below the curves are explicit, and you can check the limit directly.

29.3.4. Interpretation

An RDP guarantee is a curve, not a number. "Randomized response with $p = 0.75$ is $(2, 0.8473)$-RDP" (from the example below) is one point of it. What accountants store is the curve on a grid of orders. Each point is a valid guarantee, and different orders serve different purposes: composition works at every order at once, and the conversion to (ε, δ) picks the best order at the end.

The curve sits between the average case and the worst case. As $\alpha \to 1$ it sees only the average loss, the KL divergence. A mechanism whose loss is usually small but occasionally large has a small KL divergence, because the rare large losses barely move the average, but large high-order divergences, because a high exponential moment is dominated by those rare large losses. So it is caught at large orders. Pure DP, at $\alpha = \infty$, is the most demanding point of the curve.

Why only $\alpha > 1$? Orders below 1 exist as divergences, but they are not used for privacy. The conversion to (ε, δ) applies the Chernoff method to the loss, which needs an exponential moment $\mathbb{E}_P[e^{\lambda L}]$ with $\lambda = \alpha - 1 > 0$, and only orders above 1 provide one (Section 29.8).

29.3.5. Example: randomized response, outcome by outcome

Randomized response reports one person's bit truthfully with probability $p > \frac{1}{2}$, the keep-probability, and flips it otherwise. The two neighbouring inputs are the two values of the bit. Take $p = 0.75$. The likelihood ratio of any output is $0.75/0.25 = 3$ or its inverse, so the mechanism is ε-DP with $\varepsilon = \ln \frac{p}{1-p} = \ln 3$. Table 29.2 lists the outputs when the true bit is 1 (P) and 0 (Q).

Table 29.2.: Randomized response with keep-probability $p = 0.75$. With an argument, $p(y)$ and $q(y)$ are output probabilities; p alone is the keep-probability. The last column gives the terms of $\int p^2 q^{-1}$, the order-2 moment of Fact 1.

Output y	$p(y)$ (bit is 1)	$q(y)$ (bit is 0)	$r(y)$	$L(y)$	$p(y)^2/q(y)$
1	0.75	0.25	3	1.0986	2.2500
0	0.25	0.75	1/3	−1.0986	0.0833

At order 2, Fact 1 says $e^{(2-1)D_2}$ is the sum of $p(y)^2 q(y)^{-1}$ over the outputs, which is the last column: $e^{D_2} = 2.2500 + 0.0833 = 2.3333$, so $\varepsilon(2) = \ln 2.3333 = 0.8473$. The same recipe works at any order: sum $p(y)^\alpha q(y)^{1-\alpha}$ over the two outputs, take the logarithm, and divide by $\alpha - 1$. The output 1 contributes $p^\alpha (1-p)^{1-\alpha}$ and the output 0 contributes $(1-p)^\alpha p^{1-\alpha}$, so

$$\varepsilon(\alpha) = \frac{1}{\alpha - 1} \ln \Big(p^\alpha (1-p)^{1-\alpha} + (1-p)^\alpha p^{1-\alpha} \Big). \tag{29.6}$$

Swapping the roles of the bits swaps the two rows of the table and gives the same sum, so both directions of the pair have the same curve. Table 29.3 gives it at a few orders.

Table 29.3.: The RDP curve of randomized response with $p = 0.75$.

α	1 (KL)	1.5	2	5	10	64	∞
$\varepsilon(\alpha)$	0.5493	0.7340	0.8473	1.0267	1.0666	1.0940	1.0986

The curve rises from the KL value to the pure DP level (Figure 29.1). The KL value is the average loss under P: the loss is $\ln 3$ with probability 0.75 and $-\ln 3$ with probability 0.25, so $\mathbb{E}_P[L] = (0.75 - 0.25) \ln 3 = 0.5 \ln 3 = 0.5493$. The pure DP level is the largest loss, $\ln 3 = 1.0986$. The script also evaluates the formula at $\alpha = 1.0001$ (0.5494) and $\alpha = 1000$ (1.0983), approaching both ends. Randomized response is already a pure DP mechanism, so here the curve says little that $\ln 3$ did not. The curve matters most for mechanisms whose D_∞ is large or infinite.

29.3.6. Check yourself

- A mechanism is (α, ε)-RDP. Is it (α', ε)-RDP for $\alpha' < \alpha$? For $\alpha' > \alpha$? *(For $\alpha' < \alpha$ yes, by monotonicity: the curve at α' is at most the curve at α. For $\alpha' > \alpha$ not in general: the curve can keep rising, as the Gaussian's does.)*
- Why is $\varepsilon(\alpha)$ for randomized response the same in both directions of the pair? *(Swapping the bit swaps $p(y)$ and $q(y)$ between the two outputs, and the sum $p^\alpha q^{1-\alpha}$ over both outputs is unchanged.)*

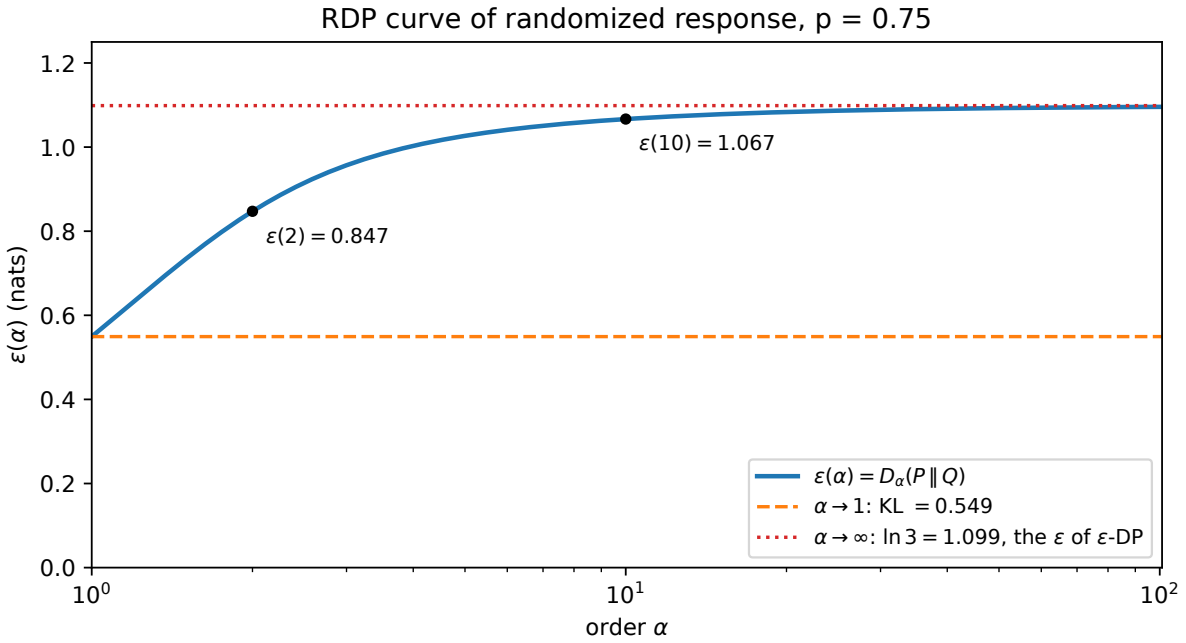

Figure 29.1.: The RDP curve $\varepsilon(\alpha)$ of randomized response with $p = 0.75$, on a log scale in α. It starts at the KL divergence 0.549 as $\alpha \to 1$ and rises to the pure DP level $\ln 3 = 1.099$ as $\alpha \to \infty$.

29.4. RDP curves of the basic mechanisms

29.4.1. Context

To account for a mechanism you need its curve. For a mechanism that adds noise to a query's answer, the two outputs on neighbours are the same noise distribution centred at two different answers. So the curve comes from the Rényi divergence between the noise distribution and a shifted copy of itself, which Part 1 computed for the normal and the Laplace distributions. The only new step is the supremum over neighbours: you need to know which pair of neighbouring inputs is the worst, and for these mechanisms it is the pair whose answers are furthest apart.

29.4.2. Statement

With sensitivity 1, the three curves are as follows. The Gaussian mechanism adds normal noise with standard deviation σ (the noise multiplier). The **Laplace mechanism** adds noise from the Laplace distribution with scale b, whose density $\frac{1}{2b}e^{-|y|/b}$ falls off exponentially on both sides. Randomized response has keep-probability p. The Gaussian curve is a straight line in α, the Laplace curve is the Part 1 formula for a shift of one scale unit $1/b$, and the randomized response curve is the sum over two outputs from the previous section:

$$\text{Gaussian:} \quad \varepsilon(\alpha) = \frac{\alpha}{2\sigma^2}, \tag{29.7}$$

$$\text{Laplace:}\quad \varepsilon(\alpha) = \frac{1}{\alpha-1}\ln\left(\frac{\alpha}{2\alpha-1}e^{(\alpha-1)/b} + \frac{\alpha-1}{2\alpha-1}e^{-\alpha/b}\right), \tag{29.8}$$

$$\text{randomized response:}\quad \varepsilon(\alpha) = \frac{1}{\alpha-1}\ln\left(p^\alpha(1-p)^{1-\alpha} + (1-p)^\alpha p^{1-\alpha}\right). \tag{29.9}$$

These are Corollaries 3 and 2 and the randomized response entry of Table 2 in Mironov (2017). The Laplace formula is for a real-valued query. Section B.4 in the appendices derives the Gaussian curve by completing the square.

29.4.3. Derivation

Gaussian. The plan is to reduce any pair of neighbours to two one-dimensional normals a distance s apart, use the Part 1 formula, and then take the largest s.

1. *One pair.* With $\Delta_2 f = 1$ the noise is $\mathcal{N}(0, \sigma^2 I)$. On neighbours with answers $f(D)$ and $f(D')$, the outputs are $\mathcal{N}(f(D), \sigma^2 I)$ and $\mathcal{N}(f(D'), \sigma^2 I)$.
2. *Divergence of the pair.* Translating and rotating the output space is a bijection, a relabelling of the outputs that can be undone, so it changes no divergence (apply Fact 3 in both directions). So you can move $f(D)$ to 0 and $f(D') - f(D)$ onto the first axis. The noise is the same in every direction, so after the rotation the two distributions differ only in the first coordinate; the other coordinates are identical, independent normals under both. Rényi divergence is additive over independent coordinates (Section 3.4), because the moment of Fact 1 factorizes into a product over coordinates, and identical coordinates contribute 0. What remains is the one-dimensional divergence $D_\alpha(\mathcal{N}(0,\sigma^2)\|\mathcal{N}(s,\sigma^2)) = \alpha s^2/(2\sigma^2)$ (Equation 3.15), with $s = \|f(D) - f(D')\|_2$. Part 1 derives it by noting that the privacy loss of a normal pair is itself normal, with mean $s^2/(2\sigma^2)$ and variance s^2/σ^2, and a normal variable's log-MGF is known in closed form.
3. *Supremum.* The divergence grows with s, and $s \le \Delta_2 f = 1$ for neighbours. So the worst pair has $s = 1$ and gives Equation 29.7. The script also integrates $p^\alpha q^{1-\alpha}$ numerically and gets 1.0000 at $\alpha = 2$ and 5.0000 at $\alpha = 10$ for $\sigma = 1$, matching $2/2$ and $10/2$.

Laplace. The plan is the same: reduce to a shift, use Part 1's closed form, and show the worst shift is the largest.

1. *One pair.* The outputs are $\mathrm{Lap}(f(D), b)$ and $\mathrm{Lap}(f(D'), b)$. After a translation, this is $\mathrm{Lap}(0, b)$ against $\mathrm{Lap}(s, b)$ with $s = |f(D) - f(D')| \le 1$.
2. *Divergence of the pair.* Part 1 computes it by splitting the integral $\int p^\alpha q^{1-\alpha}$ at the two kinks of the densities, 0 and s, where the absolute values change sign; on each of the three pieces the integrand is a plain exponential (Equation 3.19). With $t = s/b$, the shift in units of the scale, the result is the formula above with $1/b$ replaced by t.
3. *Supremum.* You need the divergence to grow with the shift, so that the largest shift is the worst. Write the argument of the logarithm as $g(t) = \frac{\alpha}{2\alpha-1}e^{(\alpha-1)t} + \frac{\alpha-1}{2\alpha-1}e^{-\alpha t}$. Its derivative is $g'(t) = \frac{\alpha(\alpha-1)}{2\alpha-1}(e^{(\alpha-1)t} - e^{-\alpha t})$, which is positive for $t > 0$ because the first exponent is positive and the second negative. So $\ln g(t)/(\alpha-1)$ increases with t. The reverse direction, $\mathrm{Lap}(s, b)$ against $\mathrm{Lap}(0, b)$, gives the same value, because the reflection $y \mapsto s - y$ swaps the two distributions and changes no divergence. So the worst pair has $s = 1$, $t = 1/b$, and gives Equation 29.8.

4. *Numerical check.* The script integrates $p^\alpha q^{1-\alpha}$ on a grid of step 10^{-4}, with both kinks as grid points. For $b \in \{0.5, 1, 4\}$ and $\alpha \in \{1.5, 2, 10, 64\}$, the largest difference from Equation 29.8 is 1.3×10^{-8}.

Randomized response. There is only one pair of inputs, the two values of the bit, so no supremum is needed, and Table 29.2 is its distribution. Fact 1 sums $p^\alpha q^{1-\alpha}$ over the two outputs, as in the previous section.

29.4.4. Interpretation

Figure 29.2 draws the three curves. Two shapes appear, and which one you get depends on whether the privacy loss is bounded.

When the privacy loss is bounded, the curve levels off. For randomized response the loss is $\pm \ln 3$. For Laplace the loss at y is $(|y-1| - |y|)/b$, and by the triangle inequality $\big||y-1| - |y|\big| \le 1$, so $|L| \le 1/b$. Since every D_α is at most D_∞, the largest loss (Fact 2), the curves rise towards $1/b$ and $\ln 3$ and stay below them. For large α you can see the approach. The first term of Equation 29.8 dominates, because $e^{(\alpha-1)/b}$ grows while $e^{-\alpha/b}$ shrinks. Keeping only it, the logarithm splits as $\ln \frac{\alpha}{2\alpha-1} + \frac{\alpha-1}{b}$, and dividing by $\alpha - 1$ gives $\varepsilon(\alpha) \approx \frac{1}{b} + \frac{1}{\alpha-1} \ln \frac{\alpha}{2\alpha-1}$. As α grows, $\frac{\alpha}{2\alpha-1}$ tends to $\frac{1}{2}$, so $\varepsilon(\alpha) \approx \frac{1}{b} - \frac{\ln 2}{\alpha-1}$: the curve approaches $1/b$ from below at rate $1/(\alpha-1)$. At $\alpha = 512$ and $b = 1$, both the formula and this approximation give 0.9986.

When the privacy loss is unbounded, the curve grows linearly. The Gaussian privacy loss is a straight line in the output y (the squares in the two exponents cancel, leaving a linear term), so it has no maximum, and the curve $\alpha/(2\sigma^2)$ grows without bound. The Gaussian mechanism is therefore not ε-DP for any ε. It is still (α, ε)-RDP at every finite order, and that is all composition and conversion need.

The straight-line shape of the Gaussian curve has a meaning of its own. For a single pair, a curve of the form $\rho\alpha$ means the privacy loss is exactly normal, $\mathcal{N}(\rho, 2\rho)$. The reason is Fact 1: $(\alpha-1)\varepsilon(\alpha)$ is the log-MGF of the loss at $\lambda = \alpha - 1$, and with $\varepsilon = \rho\alpha = \rho(\lambda+1)$ it is $\rho\lambda + \rho\lambda^2$. The log-MGF of a normal variable with mean m and variance v is $m\lambda + v\lambda^2/2$, so this one has $m = \rho$ and $v = 2\rho$. Concentrated DP builds a definition on it.

29.4.5. Example: the three curves at a few orders

Table 29.4 gives the curves at four orders, from the script.

Table 29.4.: RDP curves of the three basic mechanisms with sensitivity 1.

Mechanism	$\varepsilon(1.5)$	$\varepsilon(2)$	$\varepsilon(10)$	$\varepsilon(64)$	$\varepsilon(\infty)$
Gaussian, $\sigma = 1$	0.7500	1.0000	5.0000	32.0000	∞
Laplace, $b = 1$	0.5129	0.6191	0.9287	0.9891	1

Mechanism	$\varepsilon(1.5)$	$\varepsilon(2)$	$\varepsilon(10)$	$\varepsilon(64)$	$\varepsilon(\infty)$
Randomized response, $p = 0.75$	0.7340	0.8473	1.0666	1.0940	1.0986

The Gaussian row is $\alpha/2$, read off at each order. You can check the Laplace row by hand at order 2: the coefficients in Equation 29.8 are $\frac{2}{3}$ and $\frac{1}{3}$, the prefactor $1/(\alpha-1)$ is 1, and with $b = 1$ the curve is $\ln\left(\frac{2}{3}e + \frac{1}{3}e^{-2}\right) = 0.6191$, the same number as in Part 1's Laplace example. As $\alpha \to 1$ the Laplace curve tends to the KL divergence $1/b + e^{-1/b} - 1 = 0.3679$. You can see this from Equation 29.8: at $\alpha = 1$ the argument of the logarithm is 1, and its derivative in α there is $\frac{1}{b} - 1 + e^{-1/b}$, so for α near 1 the logarithm is about $(\alpha - 1)$ times that derivative, and dividing by $\alpha - 1$ leaves the derivative. At $b = 1$ it is $1 + e^{-1} - 1 = e^{-1} = 0.3679$.

29.4.6. Check yourself

- What is the RDP curve of the Gaussian mechanism with $\sigma = 2$ and sensitivity 1, and at which order is it 1? *($\varepsilon(\alpha) = \alpha/(2 \cdot 2^2) = \alpha/8$, which equals 1 at $\alpha = 8$.)*
- For the Gaussian mechanism on a vector query, why does only the ℓ_2 sensitivity matter, and not the ℓ_1? *(The divergence between two isotropic normals depends only on the Euclidean distance between their means, by rotation invariance.)*

29.5. Composition adds curves

29.5.1. Context

Training a model runs thousands of mechanisms, each chosen after seeing the outputs of the earlier ones. You need the curve of the whole run. For a product of independent distributions, Part 1 showed that Rényi divergences add: the moment of Fact 1 is an integral of a product, which splits into a product of integrals, and the logarithm turns the product into a sum. Adaptive composition is not a product of independent distributions, because the second mechanism depends on the first output. The chain rule below shows that the curves still add, as long as each step's curve is bounded whatever the earlier outputs were.

29.5.2. Statement

Let M_1 have RDP curve ε_1. Let $M_2(\cdot\,; y_1)$ be a mechanism chosen using the first output y_1, whose RDP curve is at most ε_2 for every y_1. The **adaptive composition** releases both outputs, $M(D) = (y_1, y_2)$, with $y_1 \sim M_1(D)$ and $y_2 \sim M_2(D; y_1)$. Its curve is at most the sum of the two curves:

$$\varepsilon_M(\alpha) \le \varepsilon_1(\alpha) + \varepsilon_2(\alpha) \qquad \text{for every } \alpha > 1. \tag{29.10}$$

By induction, treating the first $k-1$ steps as one mechanism, k adaptively chosen mechanisms have curve at most $\sum_{i=1}^{k} \varepsilon_i(\alpha)$. This is Mironov (2017), Proposition 1. Section B.4 in the

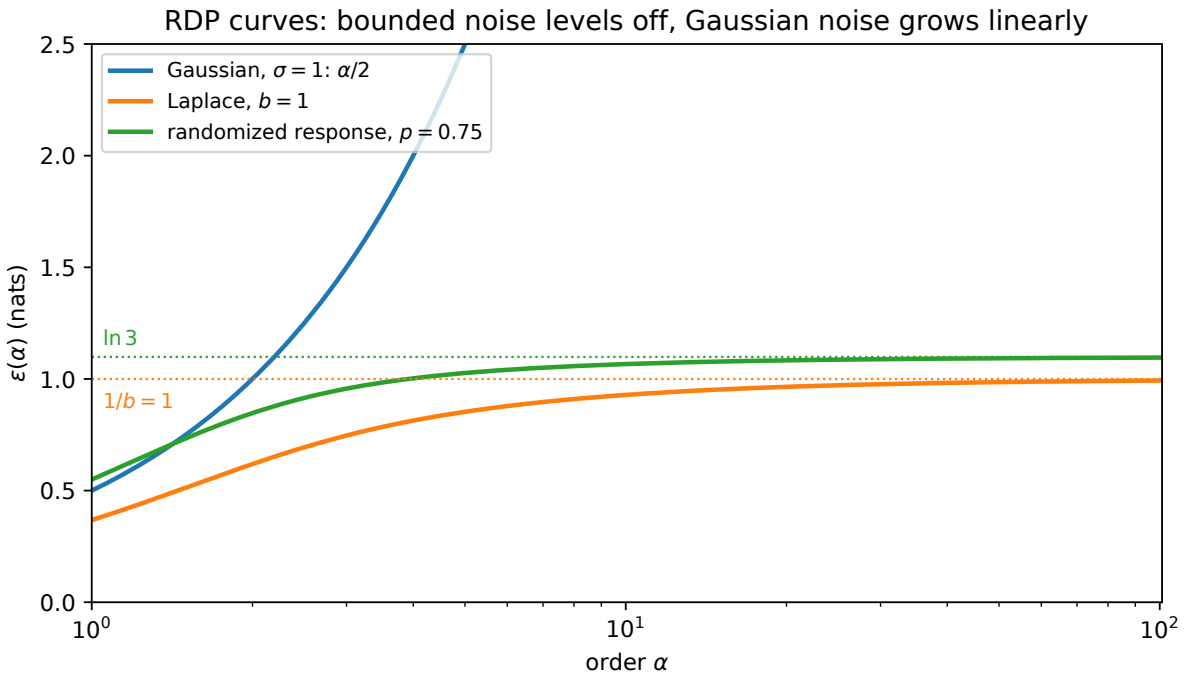

Figure 29.2.: RDP curves of the Gaussian mechanism ($\sigma = 1$), the Laplace mechanism ($b = 1$) and randomized response ($p = 0.75$), all with sensitivity 1, on a log scale in α (so the straight line $\alpha/2$ looks curved). The Laplace and randomized response curves level off at their pure DP levels $1/b$ and $\ln 3$ (dotted). The Gaussian curve $\alpha/2$ grows linearly.

appendices derives it from scratch, and Section B.5 compares it with the other accountants on one mechanism.

29.5.3. Derivation

The idea is to write the order-α moment of the pair of outputs as a double integral, bound the inner integral (over y_2) by the worst case of the second step, and recognise what is left as the moment of the first step. Fix neighbours $D \sim D'$ and an order $\alpha > 1$. Write p_1, q_1 for the densities of y_1 under D and D', and $p_2(\cdot \mid y_1), q_2(\cdot \mid y_1)$ for those of y_2 given y_1.

1. **Factor the joint densities.** By the definition of the adaptive composition, y_1 is drawn first and y_2 is drawn given y_1, so $p(y_1, y_2) = p_1(y_1)\, p_2(y_2 \mid y_1)$, and the same for q.
2. **Write the order-α moment as a double integral** (Fact 1):

$$e^{(\alpha-1)D_\alpha(P\|Q)} = \iint p_1^\alpha q_1^{1-\alpha}\; p_2(y_2 \mid y_1)^\alpha q_2(y_2 \mid y_1)^{1-\alpha}\, dy_2\, dy_1. \tag{29.11}$$

   The integrand splits into a factor for y_1 and a factor for y_2 given y_1, because a power of a product is the product of the powers.
3. **Do the inner integral first, with y_1 fixed.** It is $e^{(\alpha-1)D_\alpha(P_2(\cdot|y_1)\|Q_2(\cdot|y_1))}$, by Fact 1 again. For fixed y_1, $P_2(\cdot \mid y_1)$ and $Q_2(\cdot \mid y_1)$ are the outputs of the mechanism $M_2(\cdot\,; y_1)$ on D and D', so the divergence is at most $\varepsilon_2(\alpha)$. Since $\alpha - 1 > 0$, the exponential is increasing, and the inner integral is at most $e^{(\alpha-1)\varepsilon_2(\alpha)}$, whatever y_1 is.
4. **The outer integral.** Pull that constant out. What is left is $\int p_1^\alpha q_1^{1-\alpha}\, dy_1$, which by Fact 1 is $e^{(\alpha-1)D_\alpha(P_1\|Q_1)} \le e^{(\alpha-1)\varepsilon_1(\alpha)}$. So the double integral is at most $e^{(\alpha-1)\varepsilon_2(\alpha)} e^{(\alpha-1)\varepsilon_1(\alpha)}$.
5. **Take logarithms and divide by $\alpha - 1$.** This gives $D_\alpha(P\|Q) \le \varepsilon_1(\alpha) + \varepsilon_2(\alpha)$ for this pair. The right side does not depend on the pair, so the supremum over neighbours satisfies the same bound.

To see the steps on numbers, take an adaptive pair of randomized responses. The first step reports the bit with keep-probability 0.75. The second reports it again, with keep-probability 0.75 if the first output was 1 and 0.6 if it was 0. Table 29.5 lists the four joint outcomes when the true bit is 1 (P) and 0 (Q). Each joint probability is the first step's probability times the second's, as in step 1.

Table 29.5.: Two adaptive randomized responses: the second keep-probability depends on the first output. The last column gives the terms of the order-2 moment.

(y_1, y_2)	$p(y_1, y_2)$	$q(y_1, y_2)$	p^2/q
(1, 1)	$0.75 \times 0.75 = 0.5625$	$0.25 \times 0.25 = 0.0625$	5.0625
(1, 0)	$0.75 \times 0.25 = 0.1875$	$0.25 \times 0.75 = 0.1875$	0.1875
(0, 1)	$0.25 \times 0.6 = 0.15$	$0.75 \times 0.4 = 0.3$	0.0750
(0, 0)	$0.25 \times 0.4 = 0.1$	$0.75 \times 0.6 = 0.45$	0.0222

The terms sum to 5.3472, so $D_2 = \ln 5.3472 = 1.6766$. The bound adds the first step's curve to the worst curve the second step can have. At order 2 the second step's curve is $\varepsilon_{0.75}(2) = 0.8473$ on the branch $y_1 = 1$ and $\varepsilon_{0.6}(2) = 0.1542$ on the branch $y_1 = 0$, writing ε_p for the curve of

randomized response with keep-probability p. So the bound is $\varepsilon_1(2) + \max\left(\varepsilon_{0.75}(2), \varepsilon_{0.6}(2)\right) = 0.8473 + \max(0.8473, 0.1542) = 1.6946$. The bound holds, and it is not tight here, because step 3 replaced the inner divergence by its worst case, 0.8473, on the branch $y_1 = 0$ where it is really 0.1542. When the second step does not adapt (keep-probability 0.75 on both branches), the joint distribution is a product and $D_2 = 1.6946$ exactly.

29.5.4. Interpretation

The bound is tight for products and exact for the Gaussian. When the mechanisms are independent, the inner divergence in step 3 is the same for every y_1, so replacing it by its worst case loses nothing and the curves add exactly (additivity, Section 3.4). A sum of independent Gaussian steps is again Gaussian, so for Gaussian steps the composed curve is exactly the curve of a single mechanism.

This is why composition works for RDP and not for (ε, δ) directly. The order-α moment is an integral of a product, so it factorizes over the steps, as step 2 used. The smallest δ that works for a given ε is the **hockey-stick divergence** $\delta(\varepsilon) = \int (p - e^{\varepsilon} q)_+$, the total probability by which P exceeds e^{ε} times Q, where $(x)_+ = \max(x, 0)$. A positive part of a difference does not factorize over the steps. That is why composing (ε, δ) points needs a separate theorem with its own slack.

One condition remains. The mechanisms can be chosen adaptively, but each step's curve bound ε_i must be fixed in advance; it must not depend on the data. When the budget itself is chosen on the fly, you need the filters and odometers of Adaptive composition.

29.5.5. Example: k Gaussian steps

With $\sigma = 20$, each step has $\varepsilon(\alpha) = \alpha/(2 \cdot 20^2) = \alpha/800$. After k steps, the curve is $k\alpha/800$. Setting $k\alpha/800 = \alpha/(2\sigma'^2)$ shows that this is the curve of one Gaussian step with noise multiplier $\sigma' = 20/\sqrt{k}$:

- $k = 10$: $0.0125\,\alpha$, the curve of one Gaussian with $\sigma = 6.3246$;
- $k = 100$: $0.1250\,\alpha$, one Gaussian with $\sigma = 2.0000$;
- $k = 1000$: $1.2500\,\alpha$, one Gaussian with $\sigma = 0.6325$.

In general, k Gaussian steps with noise multiplier σ have the curve of one Gaussian with noise multiplier $\sigma/\sqrt{k}$. The function `compose_rdp` adds 1000 copies of the curve on the grid of orders and returns 2.5000 at $\alpha = 2$, which is $1000 \times 2/800$.

Different mechanisms compose just as easily, because their curves are added order by order. A Laplace step with $b = 1$ followed by a Gaussian step with $\sigma = 1$ has $\varepsilon(2) = 0.6191 + 1 = 1.6191$ and $\varepsilon(10) = 0.9287 + 5 = 5.9287$, reading both terms from Table 29.4.

Full-batch DP-SGD. The part's running example runs 10,000 steps of DP-SGD with $\sigma = 1$. If each step used the whole dataset, each would have the curve $\alpha/2$, and the composed curve would be $10{,}000\,\alpha/2 = 5000\,\alpha$. The converted guarantee at $\delta = 10^{-5}$ would be $\varepsilon = 5425.5$ even when computed exactly. That is no guarantee at all. With the conversion of Section 29.8, which adds a tail term $\ln(1/\delta)/(\alpha - 1)$ with $\ln(1/\delta) = 11.5129$, RDP on `ORDERS` gives $5000 \times 1.1 + 11.5129/0.1 = 5615.1$ at $\alpha = 1.1$, the lowest order of the grid. The continuous optimum (Equation 29.18 with the composed noise multiplier $1/\sqrt{10{,}000} = 0.01$) is $\alpha^* = 1 + 0.01 \times 4.7985 = 1.048$, with

$5000 + 4.7985/0.01 = 5479.9$. A curve this steep needs orders just above 1. DP-SGD is private only because each step touches a random 1% of the data. Amplification by subsampling computes the curve of a subsampled step.

29.5.6. Check yourself

- Two mechanisms with curves $\alpha/8$ and $\alpha/2$ are composed. Which single Gaussian mechanism has the same curve? *(The sum is $5\alpha/8 = \alpha/(2\sigma^2)$ with $\sigma^2 = 0.8$, so $\sigma = 0.8944$.)*
- In Table 29.5, where does the derivation lose $1.6946 - 1.6766 = 0.0180$ nats? *(In step 3, which bounds the inner divergence on the branch $y_1 = 0$ by the worst case 0.8473, while the keep-probability 0.6 gives only 0.1542.)*

29.6. Post-processing and group privacy

29.6.1. Context

Two properties of DP carry over to RDP. Post-processing matters because a released model or its predictions must not leak more than the training procedure that produced them. Group privacy matters because records are correlated: a family shares a household, and a user contributes many rows. For ε-DP, a group of k records gets $k\varepsilon$ (Properties of DP), because the likelihood ratios along a chain of k neighbours multiply. For RDP the answer is weaker: the Rényi divergence does not satisfy a plain triangle inequality, so going through an intermediate dataset costs a higher order, and the order of the group guarantee must shrink as the group grows.

29.6.2. Statement

Post-processing. Applying any randomized map g that does not look at the data to the output cannot raise the curve: $\varepsilon_{g\circ M}(\alpha) \le \varepsilon_M(\alpha)$ for every α.

Weak triangle inequality (Mironov 2017, Proposition 11). To bound the divergence from P to Q through an intermediate distribution R, you pay with higher orders on the two legs, and the exponents u and v choose how the cost is split between them. For distributions P, R, Q, an order $\alpha > 1$ and exponents $u, v > 1$ with $\frac{1}{u} + \frac{1}{v} = 1$,

$$D_\alpha(P\|Q) \le \frac{\alpha - 1/u}{\alpha - 1} D_{u\alpha}(P\|R) + D_{v(\alpha-1)+1}(R\|Q). \tag{29.12}$$

The even split $u = v = 2$ (Corollary 4 there) doubles the order on the first leg and nearly doubles it on the second:

$$D_\alpha(P\|Q) \le \frac{\alpha - 1/2}{\alpha - 1} D_{2\alpha}(P\|R) + D_{2\alpha-1}(R\|Q). \tag{29.13}$$

Group privacy (Mironov 2017, Proposition 2). If M is (α, ε)-RDP and $\alpha \ge 2^{c+1}$, then on inputs that differ in 2^c records M satisfies the RDP bound of order $\alpha/2^c$ with ε replaced by $3^c\varepsilon$.

29.6.3. Derivation

Post-processing. $g \circ M(D)$ is $M(D)$ passed through the channel g, the same channel whichever dataset was used, so D_α can only decrease (Fact 3). Take the supremum over neighbours. For a concrete case, pass the output of randomized response ($p = 0.75$) through a channel that flips it with probability 0.2. When the bit is 1, the final output is 1 if the first output was 1 and was kept, or was 0 and was flipped: $0.75 \times 0.8 + 0.25 \times 0.2 = 0.65$. When the bit is 0, it is $0.25 \times 0.8 + 0.75 \times 0.2 = 0.35$. The two outputs are now closer in probability, and D_2 drops from 0.8473 to $\ln(0.65^2/0.35 + 0.35^2/0.65) = 0.3333$, while D_∞ drops from 1.0986 to $\ln(0.65/0.35) = 0.6190$.

Weak triangle inequality. The idea is to write the moment for P against Q as an average under R of a product of two likelihood ratios, p/r and r/q, and then separate the two factors with Hölder's inequality. Write p, r, q for the densities of P, R, Q.

1. **Insert the middle distribution.** Multiply and divide by powers of r: since $(p/r)^\alpha (r/q)^{\alpha-1} r = p^\alpha r^{-\alpha+\alpha-1+1} q^{1-\alpha} = p^\alpha q^{1-\alpha}$, Fact 1 gives
$$e^{(\alpha-1)D_\alpha(P\|Q)} = \int p^\alpha q^{1-\alpha} = \mathbb{E}_R\Big[\Big(\frac{p}{r}\Big)^\alpha \Big(\frac{r}{q}\Big)^{\alpha-1}\Big]. \tag{29.14}$$
2. **Separate the two ratios with Hölder's inequality.** Hölder's inequality bounds the average of a product of two non-negative quantities by a product of their higher moments: for $u, v > 1$ with $\frac{1}{u} + \frac{1}{v} = 1$, $\mathbb{E}_R[XY] \le (\mathbb{E}_R X^u)^{1/u} (\mathbb{E}_R Y^v)^{1/v}$. (With $u = v = 2$ it is the Cauchy–Schwarz inequality.) Apply it with $X = (p/r)^\alpha$ and $Y = (r/q)^{\alpha-1}$.
3. **The first factor** is $\mathbb{E}_R[(p/r)^{u\alpha}]$, the moment of the ratio p/r at order $u\alpha$ under R. By Fact 1 at order $u\alpha$, it equals $e^{(u\alpha-1)D_{u\alpha}(P\|R)}$.
4. **The second factor** is $\mathbb{E}_R[(r/q)^{v(\alpha-1)}]$. By the change of measure ($\mathbb{E}_R[g] = \mathbb{E}_Q[(r/q)g]$) it equals $\mathbb{E}_Q[(r/q)^{v(\alpha-1)+1}]$, and by Fact 1 at order $v(\alpha-1)+1$ that is $e^{v(\alpha-1)D_{v(\alpha-1)+1}(R\|Q)}$.
5. **Combine.** Raise the two factors to the powers $1/u$ and $1/v$ and take logarithms: $(\alpha-1)D_\alpha(P\|Q) \le \frac{u\alpha-1}{u} D_{u\alpha}(P\|R) + (\alpha-1) D_{v(\alpha-1)+1}(R\|Q)$. Divide by $\alpha - 1$ to get Equation 29.12, since $\frac{u\alpha-1}{u} = \alpha - \frac{1}{u}$. With $u = v = 2$, $v(\alpha-1)+1 = 2\alpha - 1$, which gives Equation 29.13.

Group privacy, two records ($c = 1$). The idea is to walk from D to D' through a dataset that differs from each in one record, and apply the weak triangle inequality to the two neighbouring steps. Let D and D' differ in two records, and let D_1 be the dataset in between, a neighbour of both. Put $P = M(D)$, $R = M(D_1)$, $Q = M(D')$ and let $\beta = \alpha/2 \ge 2$ be the order of the group guarantee.

1. **Apply Equation 29.13 at order β.** Its orders become $2\beta = \alpha$ and $2\beta - 1 = \alpha - 1$: $D_\beta(P\|Q) \le \frac{\beta-1/2}{\beta-1} D_\alpha(P\|R) + D_{\alpha-1}(R\|Q)$.
2. **Both pairs are neighbours**, so $D_\alpha(P\|R) \le \varepsilon$, and $D_{\alpha-1}(R\|Q) \le D_\alpha(R\|Q) \le \varepsilon$ by monotonicity (Fact 2).
3. **Bound the factor.** The factor $\frac{\beta-1/2}{\beta-1} = 1 + \frac{1/2}{\beta-1}$ decreases in β and equals $\frac{1.5}{1} = \frac{3}{2}$ at $\beta = 2$, so it is at most $\frac{3}{2}$ for $\beta \ge 2$. So $D_\beta(P\|Q) \le \frac{3}{2}\varepsilon + \varepsilon = \frac{5}{2}\varepsilon \le 3\varepsilon$. Mironov states the bound with the constant 3; the argument gives $\frac{5}{2}$.

For $c > 1$, repeat: a group of 2^c records is two groups of 2^{c-1}, so each round halves the order and multiplies ε by 3. After c rounds the order is $\alpha/2^c$ and the bound is $3^c\varepsilon$; the condition $\alpha \geq 2^{c+1}$ keeps the order of the last round at least 2.

29.6.4. Interpretation

Each doubling of the group costs half the order as well as a factor in ε. The reason is step 2 of the Hölder argument: the divergence across two steps involves the product of two likelihood ratios, and to control the average of a product you need higher moments of each factor. A bound at order α for one record therefore buys a bound at only about order $\alpha/2$ for two.

How loose is this? Test it on the Gaussian, where the exact answer is known. A group of 2^c records shifts a Gaussian query of sensitivity 1 by up to 2^c, so the exact group curve is Equation 29.7 with the shift 2^c in place of 1, $\alpha(2^c)^2/(2\sigma^2)$. Table 29.6 compares it with the bounds at $\sigma = 1$. For two records, the weak triangle inequality loses little once $\beta \geq 4$, and Proposition 2's constant 3 costs a factor 1.5, because the exact value is $2\varepsilon(2\beta)$ ($4\beta/2 = 2 \cdot 2\beta/2$) and Proposition 2 gives $3\varepsilon(2\beta)$. The loss compounds with c: 3^c against 2^c gives a factor 1.5^c.

So use the mechanism when you can. For the Gaussian, the exact group curve is just the curve with sensitivity 2^c. The generic bound matters for mechanisms whose curve on far-apart inputs you cannot compute.

Table 29.6.: Group privacy for the Gaussian mechanism with $\sigma = 1$: the exact curve on inputs 2^c records apart against the two bounds.

Group size 2^c, order	Exact	Weak triangle, iterated	Proposition 2: $3^c\varepsilon(2^c\beta)$	Proposition 2 / exact
2, $\beta = 2$	4.0000	4.5000	6.0000	1.5000
2, $\beta = 4$	8.0000	8.1667	12.0000	1.5000
2, $\beta = 10$	20.0000	20.0556	30.0000	1.5000
4, $\beta = 2$	16.0000	18.5000	36.0000	2.2500
8, $\beta = 2$	64.0000	74.5000	216.0000	3.3750

You can check the first row by hand. The exact value is $2 \cdot 2^2/2 = 4$. The weak triangle inequality at $\beta = 2$ gives $\frac{1.5}{1}\varepsilon(4) + \varepsilon(3) = 1.5 \times 2 + 1.5 = 4.5$. Proposition 2 gives $3\varepsilon(4) = 3 \times 2 = 6$, and $6/4 = 1.5$.

29.6.5. Example: two records under Gaussian and Laplace noise

Figure 29.3 draws the two-record case for the Gaussian with $\sigma = 1$. The weak-triangle bound hugs the exact line 2β for $\beta \geq 3$ and blows up near $\beta = 1$, where its factor $\frac{\beta - 1/2}{\beta - 1}$ does. Proposition 2 applies only from $\beta = 2$, and its line has slope 3 instead of 2.

For the Laplace mechanism with $b = 1$ at order 2, two records apart, the exact value is the Laplace curve with shift 2, that is Equation 29.8 with $1/b$ replaced by 2: 1.5958. The weak triangle gives 1.9674 and Proposition 2 gives 2.4411. The pure DP group bound, $2/b = 2$, is better than Proposition 2 here. Because the Laplace mechanism is $1/b$-DP, a group of two is $2/b$-DP, and by

monotonicity that bound holds at every order. In general, for a mechanism that is already ε-DP, the group bound $k\varepsilon$ of pure DP holds at every order, and it can beat the RDP route.

Figure 29.3.: RDP of the Gaussian mechanism ($\sigma = 1$) on inputs two records apart, as a function of the order β of the group guarantee. Black: the exact curve 2β. Dashed: the weak triangle inequality with $u = v = 2$. Dotted: Proposition 2's bound $3\varepsilon(2\beta)$, drawn from $\beta = 2$, where its condition $\alpha = 2\beta \geq 4$ starts to hold.

29.6.6. Check yourself

- A mechanism is $(8, 1)$-RDP. What does Proposition 2 give for groups of two and of four records? *(Two records: order $8/2 = 4$ and $\varepsilon = 3$. Four records: order $8/4 = 2$ and $\varepsilon = 3^2 = 9$.)*
- Why does post-processing need g to ignore the data? *(If g reads the data, $g \circ M$ is not a channel applied to M's output, and Fact 3 does not apply: g could simply print a record.)*

29.7. The moments accountant is RDP in disguise

29.7.1. Context

Abadi et al. (2016) introduced the **moments accountant** to train neural networks with DP. For each $\lambda > 0$ (in practice, the integers up to 32), it tracks the logarithm of the moment generating function (MGF) of the privacy loss, $\ln \mathbb{E}[e^{\lambda L}]$. It adds these numbers over the training steps and converts the total to (ε, δ) with a tail bound. Their paper predates RDP and is written in different notation. But Fact 1 already says that the log-MGF of the privacy loss at λ is $(\alpha - 1)D_\alpha$

at $\alpha = \lambda + 1$. This section makes that precise: the moments accountant tracks the same object as the RDP curve, so everything in this chapter applies to it.

29.7.2. Statement

Abadi et al. define the log-moment $\alpha_M(\lambda) = \sup_{D \sim D'} \ln \mathbb{E}_{Y \sim M(D)}[e^{\lambda L(Y)}]$, the log-MGF of the privacy loss for the worst pair of neighbours. Their letter α clashes with our order, so write it $K_M(\lambda)$. It is the RDP curve one order up, multiplied by λ:

$$K_M(\lambda) = \lambda\, \varepsilon_M(\lambda + 1), \qquad \text{equivalently} \qquad \varepsilon_M(\alpha) = \frac{K_M(\alpha - 1)}{\alpha - 1}. \tag{29.15}$$

The two parts of their Theorem 2 (Abadi et al. 2016) then become the two results of this chapter that RDP needs.

1. **Composability:** $K_M(\lambda) \le \sum_i K_{M_i}(\lambda)$. This is Equation 29.10 at order $\lambda + 1$, multiplied by λ.
2. **Tail bound:** M is (ε, δ)-DP with $\delta = \min_\lambda \exp\big(K_M(\lambda) - \lambda\varepsilon\big)$. This is the conversion of Section 29.8, read in the other direction: it fixes ε and solves for δ instead of fixing δ and solving for ε (Exercise 3 in the exercise book).

29.7.3. Derivation

The identity is Fact 1 written out, with one change of measure.

1. **Write the moment as a sum** over outputs (for densities, an integral). Since $e^{\lambda L} = (p/q)^\lambda$, $\mathbb{E}_P[e^{\lambda L}] = \sum_y p(y) \left(\frac{p(y)}{q(y)}\right)^\lambda$.
2. **Change of measure.** Move one factor of p/q onto the weight: $p\,(p/q)^\lambda = q\,(p/q)^{\lambda+1}$. So the sum is an average under Q, $\mathbb{E}_Q[r^{\lambda+1}]$.
3. **Fact 1 at order $\alpha = \lambda + 1$:** $\mathbb{E}_Q[r^\alpha] = e^{(\alpha-1)D_\alpha(P\|Q)} = e^{\lambda D_\alpha(P\|Q)}$.
4. **Take logarithms and the supremum** over neighbours. The factor $\lambda > 0$ does not change which pair is worst, so $K_M(\lambda) = \lambda\, \varepsilon_M(\lambda + 1)$.

As a concrete check, take randomized response with $p = 0.75$ at $\lambda = 1$, using Table 29.2. The output 1 has $p(1) = 0.75$ and $e^L = 3$, the output 0 has $p(0) = 0.25$ and $e^L = 1/3$. So $\mathbb{E}_P[e^L] = 0.75 \times 3 + 0.25 \times \frac{1}{3} = 2.2500 + 0.0833 = 2.3333$, the same two terms as in the order-2 column of Table 29.2. Its logarithm, 0.8473, is $1 \cdot \varepsilon(2)$. At $\lambda = 2$, the direct sum and $2\varepsilon(3)$ both give 1.9136.

29.7.4. Interpretation

The two accountants give the same numbers with different bookkeeping. The moments accountant stores $(\alpha - 1)\varepsilon(\alpha)$ where RDP stores $\varepsilon(\alpha)$, and both add over steps. Libraries that say "moments accountant" and libraries that say "RDP accountant" compute the same thing.

The identity itself is simple, so what was new in 2016? The contribution of Abadi et al. was a bound on $K(\lambda)$ for the *subsampled* Gaussian step of DP-SGD, where each step uses a random fraction of the data. Amplification by subsampling derives it in RDP form.

There is also a statistical reading. The log of a moment generating function is called the **cumulant generating function**: its derivatives at 0 are the mean, the variance and the higher cumulants of the variable. So $K_M(\lambda)$ is the cumulant generating function of the privacy loss of the worst pair (more precisely, the supremum over neighbours of their cumulant generating functions). If the loss is normal, all cumulants beyond the variance vanish, K is a quadratic in λ, and the RDP curve is linear in α, as for the Gaussian.

29.7.5. Example: the Gaussian privacy loss

Take the Gaussian pair $P = \mathcal{N}(0,1)$, $Q = \mathcal{N}(\mu,1)$. The log-ratio of the two densities is $-\frac{y^2}{2} + \frac{(y-\mu)^2}{2} = \frac{\mu^2}{2} - \mu y$, so the privacy loss $L(Y) = \frac{\mu^2}{2} - \mu Y$ with $Y \sim P$ is a linear function of a standard normal. It is therefore normal, with mean $\mu^2/2$ and variance μ^2 (Divergences). The log-MGF of a normal variable with mean m and variance v is $m\lambda + v\lambda^2/2$, so

$$K(\lambda) = \lambda\frac{\mu^2}{2} + \frac{\lambda^2\mu^2}{2} = \lambda \cdot \frac{(\lambda+1)\mu^2}{2} = \lambda\,\varepsilon(\lambda+1), \tag{29.16}$$

with $\varepsilon(\alpha) = \alpha\mu^2/2$, as Equation 29.15 says. At $\mu = 1$, the formula gives $K(1) = \frac{1}{2} + \frac{1}{2} = 1.0000$ and $K(2) = 1 + 2 = 3.0000$. Averaging $e^{\lambda L}$ over a million draws of Y gives 1.0000 and 3.0003.

29.7.6. Check yourself

- A mechanism has $K_M(\lambda) = \lambda(\lambda+1)/8$. What is its RDP curve? *($\varepsilon(\alpha) = K(\alpha-1)/(\alpha-1) = (\alpha-1)\alpha/(8(\alpha-1)) = \alpha/8$, a Gaussian with $\sigma = 2$.)*
- Why does Abadi et al.'s composability theorem need no new proof once you know Equation 29.10? *(Multiplying Equation 29.10 at order $\lambda+1$ by $\lambda > 0$ gives it.)*

29.8. From RDP to (ε, δ)

29.8.1. Context

After composing, you hold a curve. What you report is an (ε, δ) pair, because that is the guarantee with a direct meaning for an event: no set of outputs becomes more than e^{ε} times likelier, up to an additive δ (Definition). The conversion rests on one observation. Outputs whose privacy loss is at most some threshold c already satisfy the e^c bound, so only the outputs with loss above c can break it, and their total probability can be charged to δ. That probability is a tail of the privacy loss, and a Chernoff bound controls a tail with an exponential moment, which is exactly what each point of the RDP curve provides. Every order gives a valid (ε, δ), and you pick the best one.

29.8.2. Statement

Mironov's conversion (Mironov 2017, Proposition 3). The converted ε is the RDP value plus a tail term, which pays for δ and shrinks as the order grows. If M is $(\alpha, \varepsilon(\alpha))$-RDP, then for every $0 < \delta < 1$ it is $(\varepsilon_\delta, \delta)$-DP with

$$\varepsilon_\delta = \varepsilon(\alpha) + \frac{\ln(1/\delta)}{\alpha - 1}. \tag{29.17}$$

If you hold the whole curve, take the best order: $\varepsilon_\delta = \min_\alpha \big[\varepsilon(\alpha) + \ln(1/\delta)/(\alpha - 1)\big]$. For the Gaussian curve $\alpha/(2\sigma^2)$, the first term grows with α and the second falls, and over all real $\alpha > 1$ the minimum is where they balance:

$$\alpha^* = 1 + \sigma\sqrt{2\ln(1/\delta)}, \qquad \varepsilon_\delta = \frac{1}{2\sigma^2} + \frac{\sqrt{2\ln(1/\delta)}}{\sigma}. \tag{29.18}$$

29.8.3. Derivation

The conversion. The plan is to split every event into outputs with small loss, which satisfy the e^c bound, and outputs with large loss, whose probability is the tail, then bound the tail with Chernoff. Fix neighbours, with privacy loss L, and a threshold c to be chosen.

1. **Split any event S by the size of the loss:** $P(S) = P(S \cap \{L \le c\}) + P(S \cap \{L > c\})$.
2. **Bound each part.** On $\{L \le c\}$, $\ln(p/q) \le c$, so $p \le e^c q$ by the definition of L. Integrating over $S \cap \{L \le c\}$, the first term is at most $e^c Q(S)$. The second term is at most $\Pr_P[L > c]$, since $S \cap \{L > c\}$ is a subset of $\{L > c\}$.
3. **Chernoff on the loss.** Apply Fact 4 with $\lambda = \alpha - 1$ and then Fact 1, which says $\mathbb{E}_P[e^{(\alpha-1)L}] = e^{(\alpha-1)D_\alpha(P\|Q)}$: $\Pr_P[L > c] \le e^{-(\alpha-1)c}\,\mathbb{E}_P[e^{(\alpha-1)L}] = e^{(\alpha-1)(D_\alpha(P\|Q)-c)} \le e^{(\alpha-1)(\varepsilon(\alpha)-c)}$.
4. **Choose c to make the tail δ.** Setting $(\alpha-1)(\varepsilon(\alpha)-c) = \ln\delta$ gives $c = \varepsilon(\alpha)+\ln(1/\delta)/(\alpha-1)$. Then $P(S) \le e^c Q(S) + \delta$ for every S and every pair of neighbours, which is (c, δ)-DP.

Mironov proves the same bound by a different route, through Hölder's inequality ("probability preservation").

The Gaussian optimum. The plan is to minimize the converted ε over the order with calculus. Write $a = \alpha - 1 > 0$ and $\ell = \ln(1/\delta)$. Substituting the Gaussian curve $\alpha/(2\sigma^2) = (a+1)/(2\sigma^2)$ into Equation 29.17 gives $\varepsilon_\delta(a) = \frac{a+1}{2\sigma^2} + \frac{\ell}{a}$.

1. **Set the derivative to zero:** $\frac{1}{2\sigma^2} - \frac{\ell}{a^2} = 0$, so $a^2 = 2\sigma^2\ell$ and $a = \sigma\sqrt{2\ell}$. The function is convex in $a > 0$ (a line plus ℓ/a, whose second derivative $2\ell/a^3$ is positive), so this is the minimum.
2. **Substitute:** $\frac{a}{2\sigma^2} = \frac{\sqrt{2\ell}}{2\sigma}$ and $\frac{\ell}{a} = \frac{\ell}{\sigma\sqrt{2\ell}} = \frac{\sqrt{2\ell}}{2\sigma}$. The two terms that depend on a are equal at the optimum, and they add to $\sqrt{2\ell}/\sigma$. With the constant $\frac{1}{2\sigma^2}$, this is Equation 29.18.

29.8.4. Interpretation

The conversion gives something away in two places. Step 2 charges the whole tail $\Pr_P[L > c]$ to δ. The exact smallest δ at level c is the hockey-stick divergence, which can be written as an average over outputs, $\delta(c) = \mathbb{E}_P[(1 - e^{c-L})_+]$: factoring p out of $(p - e^c q)_+$ leaves $(1 - e^{c-L})_+$. So the exact δ charges an output with loss $L > c$ only the fraction $1 - e^{c-L}$ of its probability, not all of it. Step 3 then bounds the tail with a Chernoff bound, which overestimates it. From RDP to (ε, δ) and to tests removes much of both losses with sharper conversions.

The order trades two terms against each other. Small orders make the curve small but the tail term $\ln(1/\delta)/(\alpha - 1)$ large; large orders do the opposite (Figure 29.4, left). The optimum moves to smaller orders as the composed curve grows, because a steeper curve makes large orders more expensive. By Equation 29.18 with $\sqrt{2\ln(1/\delta)} = 4.7985$ at $\delta = 10^{-5}$, one Gaussian step with $\sigma = 20$ wants $\alpha \approx 1 + 20 \times 4.7985 \approx 97$, while 1000 steps, with composed noise multiplier $20/\sqrt{1000} = 0.6325$, want $\alpha \approx 1 + 0.6325 \times 4.7985 \approx 4$. That is why the grid runs from 1.1 to 512.

For many Gaussian steps the conversion reproduces the square-root growth of advanced composition. For k steps, Equation 29.18 with $\sigma/\sqrt{k}$ in place of σ gives $\varepsilon_\delta = \frac{k}{2\sigma^2} + \frac{\sqrt{2k\ln(1/\delta)}}{\sigma}$. The second term grows like $\sqrt{k}$, the same shape as advanced composition, but with constants derived from the Gaussian curve instead of from a worst-case $(\varepsilon_0, \delta_0)$ point.

29.8.5. Example: one Gaussian step, and many

One step, $\sigma = 1$, $\delta = 10^{-5}$. Here $\ln(1/\delta) = 11.5129$ and $\sqrt{2\ln(1/\delta)} = \sqrt{23.0259} = 4.7985$. The curve is $\alpha/2$, and Equation 29.17 adds $11.5129/(\alpha - 1)$. Three orders show the trade-off:

- $\alpha = 2$: $1.0000 + 11.5129 = 12.5129$;
- $\alpha = 5.8$: $2.9000 + 2.3985 = 5.2985$;
- $\alpha = 20$: $10.0000 + 0.6059 = 10.6059$.

At the small order the tail term dominates, at the large order the curve does, and in between they nearly balance. The grid's best order is 5.8, next to the continuous optimum $\alpha^* = 1 + 4.7985 = 5.7985$, and both give $\varepsilon = 5.2985$.

To see how good this is, compare it with the exact ε of the Gaussian mechanism at $\delta = 10^{-5}$. The exact privacy curve of a Gaussian pair whose means are $\mu = 1/\sigma$ standard deviations apart is

$$\delta(\varepsilon) = \Phi\Big(\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) - e^{\varepsilon}\Phi\Big(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) \tag{29.19}$$

(Balle & Wang 2018; Laplace and Gaussian mechanisms), where Φ is the standard normal cumulative distribution function, $\Phi(t)$ being the probability that a standard normal variable is below t. It is the hockey-stick divergence $P(S) - e^{\varepsilon}Q(S)$ evaluated on the set S of outputs whose privacy loss exceeds ε: since the loss is normal with mean $\mu^2/2$ and standard deviation μ under P (and mean $-\mu^2/2$ under Q), each of $P(S)$ and $Q(S)$ is a normal tail, which gives the two Φ terms. Solving $\delta(\varepsilon) = 10^{-5}$ for ε by bisection gives 4.3772. The conversion is 21% too large ($5.2985/4.3772 = 1.21$). Read the other way, the mechanism at $\varepsilon = 5.2985$ actually has $\delta = 1.300 \times 10^{-7}$, 76.9 times smaller than the conversion promises ($10^{-5}/(1.300 \times 10^{-7}) = 76.9$).

k steps, $\sigma = 20$, $\delta = 10^{-5}$. Table 29.7 compares four ways to account for k Gaussian steps. The exact value is available because k steps are one Gaussian with $\mu = \sqrt{k}/\sigma$. The two generic routes from Part 3 first turn each step into one $(\varepsilon_0, \delta_0)$ point of its exact curve, then compose the points. *Basic composition* adds the per-step guarantees, both the εs and the δs, so it spends δ/k per step and reports $k\varepsilon_0$. *Advanced composition* treats the total privacy loss as a sum of k independent bounded terms and bounds its tail. It spends a fraction s of δ on the k per-step slacks, $\delta_0 = s\delta/k$ each, and the rest, $\delta' = (1-s)\delta$, on the tail of the sum, and it gives

$$\varepsilon_0\sqrt{2k\ln(1/\delta')} + k\varepsilon_0\tanh(\varepsilon_0/2). \tag{29.20}$$

The first term is the size of a fluctuation of the summed loss that is exceeded with probability at most δ', from Azuma's inequality for a sum of k terms each between $-\varepsilon_0$ and ε_0. The second term is a bound on the mean of the summed loss: k times the largest mean loss of one step, $\varepsilon_0\tanh(\varepsilon_0/2)$. The script picks the best s on the grid Part 3 uses, the powers $10^{-1/4}, 10^{-2/4}, \ldots, 10^{-10}$; at every k in Table 29.7 it lands on $s = 10^{-1/4} \approx 0.56$.

The second term is the sharper form from Part 3. The textbook form, $k\varepsilon_0(e^{\varepsilon_0} - 1)$ (Dwork & Roth 2014, Theorem 3.20), would give 105.86 at $k = 1000$ instead of 68.01.

Table 29.7.: Total ε at $\delta = 10^{-5}$ for k Gaussian steps with $\sigma = 20$, four ways.

k	Basic	Advanced	RDP + Mironov (best order)	Exact	RDP / exact	Advanced / exact
1	0.160	0.847	0.251 (128)	0.160	1.566	5.29
10	1.892	3.270	0.771 (31)	0.561	1.374	5.83
100	21.510	13.423	2.524 (10.6)	1.993	1.267	6.73
1000	238.578	68.008	8.838 (4)	7.511	1.177	9.05

Advanced composition is loose, and it gets looser as k grows: it is 5 to 9 times the exact value, because each step's curve was collapsed to one point before composing. For one step it is even worse than basic composition, since the factor $\sqrt{2\ln(1/\delta')}$ is paid even when $k = 1$, when there is no sum to concentrate.

RDP is 18% to 57% above exact in this table, and it gets tighter as k grows. At $k = 1$ the best order on the continuous scale would be 97.0 (giving 0.241), but the grid jumps from 63 to 128, so the grid's answer 0.251 is a little worse. For $k \geq 10$ the grid optimum agrees with Equation 29.18 to within 0.001 (0.771 at 31.3, 2.524 at 10.6, and 8.838 on the grid against 8.837 at $\alpha^* = 4.03$). The remaining gap to the exact value is the conversion's slack, which the next chapter reduces.

That slack depends on the composed $\mu = \sqrt{k}/\sigma$, the distance between the two composed Gaussians in standard deviations. At the continuous optimum, Mironov's conversion is 1.07 times exact at $\mu = 10$, 1.21 at $\mu = 1$, 1.42 at $\mu = 0.1$ and 1.76 at $\mu = 0.01$. Weak composed mechanisms pay the most, because as $\mu \to 0$ the exact ε falls faster than the Chernoff bound does.

Figure 29.4 shows both halves: the trade-off over orders for $k = 1000$, and the three methods as k grows.

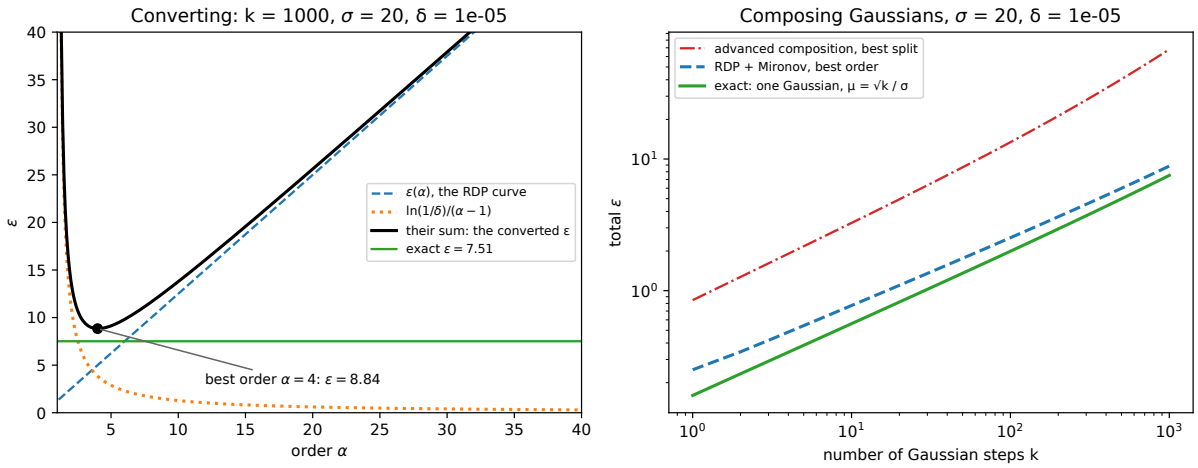

Figure 29.4.: Left: converting the curve of 1000 Gaussian steps with $\sigma = 20$ at $\delta = 10^{-5}$. The converted ε (black) is the sum of the RDP curve (dashed) and the tail term $\ln(1/\delta)/(\alpha - 1)$ (dotted). Its minimum over the grid, 8.84 at $\alpha = 4$, sits above the exact value 7.51 (green). Right: total ε against the number of steps k on log axes, for advanced composition, RDP with Mironov's conversion, and the exact value.

29.8.6. Check yourself

- A mechanism is $(10, 0.5)$-RDP. What $(\varepsilon, 10^{-5})$-DP does Equation 29.17 give at that order? *($0.5 + 11.5129/9 = 1.7792$.)*
- In Table 29.7, why is the best order 4 for $k = 1000$ steps but 128 for one step? *(The composed curve is 1000 times steeper, so large orders cost more. In Equation 29.18, replacing σ by $\sigma/\sqrt{k}$ shrinks $\alpha^* - 1$ by $\sqrt{k}$.)*

29.9. Code: check every curve and every conversion

The script code/renyi_dp.py computes every number in this chapter and draws every figure. The curves are small typed functions (`gaussian_rdp`, `laplace_rdp`, `randomized_response_rdp`). Composition is `compose_rdp`, a pointwise sum on the grid `ORDERS`. The conversion is `rdp_to_dp_mironov`, which returns the best ε and the order that attains it. The exact Gaussian privacy curve is `gaussian_delta_exact`, and `gaussian_eps_exact` inverts it by bisection. Later chapters import these functions. From the repository root:

```
uv run python code/part04-privacy-accounting/renyi_dp.py
```

Output (seed 0), summarized in Table 29.8:

Table 29.8.: The script's output with the default seed.

Experiment	Result
Randomized response, $p = 0.75$	$\varepsilon(2) = 0.8473$; KL 0.5493; $\varepsilon(\infty) = 1.0986$; curve in Table 29.3
Laplace curve against numerical integration	Largest difference 1.3×10^{-8} over $b \in \{0.5, 1, 4\}$ and four orders
Gaussian curve against numerical integration, $\sigma = 1$	1.0000 at $\alpha = 2$; 5.0000 at $\alpha = 10$
Adaptive randomized response, order 2	Exact 1.6766; bound 1.6946
Group privacy, Gaussian, two records, order 2	Exact 4.0000; weak triangle 4.5000; Proposition 2: 6.0000
Moments accountant, Gaussian $\mu = 1$	$K(1) = 1.0000$, $K(2) = 3.0000$; Monte Carlo 1.0000 and 3.0003
One Gaussian, $\sigma = 1$, $\delta = 10^{-5}$	RDP 5.2985 at $\alpha = 5.8$; exact 4.3772
1000 Gaussians, $\sigma = 20$, $\delta = 10^{-5}$	Advanced 68.01; RDP 8.84 at $\alpha = 4$; exact 7.51

tests/test_renyi_dp.py checks that the output still matches.

What to take from it. First, the closed forms are right. The Laplace and Gaussian curves agree with direct numerical integration, and the moments accountant's log-moments agree with the RDP curve and with simulation. Second, composition is exact where it should be. Non-adaptive randomized responses and Gaussian steps compose with equality, because their outputs are independent and the moments factorize; the adaptive example shows where the bound gives something away, on the branch where the second step is less revealing than its worst case. Third, the conversion costs 18% to 57% in Table 29.7, while advanced composition costs 5 to 9 times. Most of the gain of RDP comes from composing curves rather than points, so even a loose conversion done once at the end beats a good theorem applied to points.

29.11. Cheat sheet

$P = M(D)$, $Q = M(D')$ for neighbours; $L = \ln(p/q)$ the privacy loss; orders $\alpha > 1$. Table 29.9 collects the results.

Table 29.9.: Every result of this chapter.

Result	Statement	Tight?
(α, ε)-RDP	$D_\alpha(M(D)\|M(D')) \le \varepsilon$ for all $D \sim D'$	—
Limits	$\varepsilon(\alpha \to 1) \ge$ largest KL (equal for the mechanisms here); $\$\varepsilon(\infty) = \$$ pure DP ε; non-decreasing in α	—
Gaussian, noise multiplier σ	$\varepsilon(\alpha) = \alpha/(2\sigma^2)$	Exact
Laplace, scale b, sensitivity 1	$\frac{1}{\alpha-1}\ln\left(\frac{\alpha}{2\alpha-1}e^{(\alpha-1)/b} + \frac{\alpha-1}{2\alpha-1}e^{-\alpha/b}\right)$	Exact
Randomized response, keep p	$\frac{1}{\alpha-1}\ln\left(p^\alpha(1-p)^{1-\alpha} + (1-p)^\alpha p^{1-\alpha}\right)$	Exact
Composition	$\varepsilon_M(\alpha) \le \sum_i \varepsilon_i(\alpha)$, adaptively	Equality for products
Post-processing	$\varepsilon_{g\circ M}(\alpha) \le \varepsilon_M(\alpha)$	—
Weak triangle	$D_\alpha(P\|Q) \le \frac{\alpha-1/u}{\alpha-1} D_{u\alpha}(P\|R) + D_{v(\alpha-1)+1}(R\|Q)$, $\frac{1}{u}+\frac{1}{v}=1$	Equality for Gaussians at the best u (Exercise 4 in the exercise book)
Group of 2^c	order $\alpha/2^c$, $3^c\varepsilon(\alpha)$, if $\alpha \ge 2^{c+1}$	Loose: factor 1.5 per doubling on the Gaussian
Moments accountant	$K(\lambda) = \lambda\,\varepsilon(\lambda+1)$	Identity
Conversion	$(\varepsilon(\alpha) + \ln(1/\delta)/(\alpha-1), \delta)$-DP, best α	Loose: 18–57% above exact in Table 29.7; ×1.76 at composed $\mu = 0.01$

Result	Statement	Tight?
Gaussian optimum	$\alpha^* = 1 + \sigma\sqrt{2\ln(1/\delta)}$, $\varepsilon = \frac{1}{2\sigma^2} + \frac{\sqrt{2\ln(1/\delta)}}{\sigma}$	—

Rules of thumb

- Compose in RDP, convert once at the end. Never convert each step to $(\varepsilon_0, \delta_0)$ first.
- k Gaussian steps with noise multiplier σ are one Gaussian step with $\sigma/\sqrt{k}$.
- The best order shrinks as the composed curve grows; keep a grid from just above 1 to a few hundred.
- Mironov's conversion is loose by tens of percent at moderate μ, and by nearly a factor 2 for very weak composed mechanisms; for reporting, use the sharper conversions of the next chapter or a numerical accountant.
- Group privacy in RDP halves the order; for the Gaussian, use the curve with the group's sensitivity instead.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

30. From Rényi DP to (ε, δ) and to tests

30.1. Why this matters

Rényi differential privacy (RDP) is the quantity accountants track, because it composes by adding curves (previous chapter). Recall what the curve is. For two neighbouring datasets, which differ in one person's record, a mechanism produces two output distributions, P on the dataset without your record and Q on the one with it. For each **order** $\alpha > 1$, the Rényi divergence $D_\alpha(P\|Q)$ measures how far apart they are: it is a logarithmic average of the likelihood ratio P/Q raised to the power $\alpha - 1$, so larger orders weigh the outputs where P is much more likely than Q more heavily. The **RDP curve** $\varepsilon(\alpha)$ bounds that divergence, over all neighbouring pairs, at every order. When mechanisms run one after another, their curves add.

The curve is not the quantity anyone reports. A paper, a model card or a regulator asks for (ε, δ)-differential privacy (DP), or for a statement about attacks: how much better than guessing can a test tell whether your record was used? So every RDP analysis ends with a conversion, and the conversion decides the number you publish. This chapter answers three questions: how much the standard conversion loses, and where; what the best (ε, δ) is that you can claim from an RDP curve, and which order to use for it; and what an RDP curve says about tests, and what it can never say.

One idea organizes all three answers: **an RDP curve is a summary of the privacy loss distribution, and converting it asks for the largest δ consistent with that summary.** The privacy loss of an output is the logarithm of how much more likely that output is under P than under Q. Drawn at random from the mechanism, it is the privacy loss random variable (PRV), and δ is a particular average over it. The RDP curve records the moment generating function (MGF) of the PRV, the average of $e^{\lambda L}$ for a loss L, at the points $\lambda = \alpha - 1$, and nothing else. A conversion has to bound the average that defines δ using only those MGF values. Mironov's conversion does this with Markov's inequality and throws away most of what the summary says. The improved conversion, and the hypothesis-testing view behind it, recover almost all of it: for the Gaussian mechanism the improved conversion agrees to three decimals with the best any method could do with the curve alone. What remains, 5 to 10% of ε, is not a defect of any formula. A two-outcome mechanism has an RDP curve no larger than the Gaussian's and a larger δ, so no conversion that sees only the curve can do better. Table 30.1 lists the results.

Table 30.1.: The results in this chapter and where they are used.

Result	Where it is used
Mironov's conversion $\varepsilon(\alpha) + \ln(1/\delta)/(\alpha - 1)$	The original moments accountant; still in older code and papers

Result	Where it is used
Improved conversion (Balle et al.; Canonne, Kamath & Steinke)	Every modern RDP accountant: Opacus, Google's `dp_accounting`
RDP as a constraint on tests	Reading an RDP guarantee as a bound on attack power; comparing with f-DP
Choosing the order α	Designing the order grid of an accountant
The slack no conversion removes	Knowing when to switch to a numerical accountant
(ε, δ) does not imply RDP; ε-DP does	Mixing pure-DP and RDP components in one analysis

Conventions. $P = M(D)$ and $Q = M(D')$ are the output distributions of the mechanism M on neighbouring datasets D and D'. The same letters name their densities at an output y, $P(y)$ and $Q(y)$, because q is the sampling rate. As in Part 3, D' is the dataset that holds your record and D the one without it. A guarantee must hold for every ordered pair of neighbours, so every bound below holds just as well with the roles of P and Q swapped. The privacy loss at an output y is $L(y) = \ln(P(y)/Q(y))$: positive when y is more likely under D than under D', negative when it is less likely. With $Y \sim P$, the random number $L(Y)$ is the PRV (composition). Throughout, α **is the Rényi order and never an error rate.** A test of "the output came from P" against "it came from Q", that is, of "your record was not used" against "it was", looks at the output and either accepts or rejects. It has **type I error** FPR, its false positive rate, the probability that it rejects although the output came from P (for a membership test, saying D' when the data were D), and **type II error** FNR, its false negative rate, the probability that it accepts although the output came from Q, as in hypothesis testing. Its **power** $1 - \text{FNR}$ is the probability that it correctly rejects when the output came from Q.

The running example is the Gaussian mechanism. One step adds noise $\mathcal{N}(0, \sigma^2)$ to a query of sensitivity 1, where σ is the noise multiplier. After dividing the output by σ, the two worlds are $\mathcal{N}(0, 1)$ and $\mathcal{N}(1/\sigma, 1)$. With k independent steps the outputs form a vector, and only its component along the direction of the shift differs between the worlds; that shift has length $\sqrt{k}/\sigma$. So every quantity in this chapter depends only on $\mu = \sqrt{k}/\sigma$, and the composed mechanism is the pair $\mathcal{N}(0, 1)$, $\mathcal{N}(\mu, 1)$. Its RDP curve is $\varepsilon(\alpha) = \alpha\mu^2/2$: one step has curve $\alpha/(2\sigma^2)$ (previous chapter), and k steps add k copies, $k\alpha/(2\sigma^2) = \alpha\mu^2/2$. All numbers use $\delta = 10^{-5}$ and the part's grid of 154 orders: 1.1 to 10.9 in steps of 0.1, every integer from 12 to 63, and then 128, 256 and 512.

30.2. Toolkit: four facts every derivation uses

30.2.1. Fact 1 — δ is an expectation over the privacy loss

(ε, δ)-DP for the ordered pair (P, Q) says $P(S) \le e^{\varepsilon} Q(S) + \delta$ for every event S (definition): any set of outputs is at most e^{ε} times more likely under D than under D', up to an additive slack δ. The smallest δ that works is therefore the largest value of $P(S) - e^{\varepsilon} Q(S)$ over all events. That

largest value is reached by putting into S exactly the outputs with $P > e^{\varepsilon}Q$, because each such output adds a positive amount $P - e^{\varepsilon}Q$ and every other output would subtract. The result, $\int (P - e^{\varepsilon}Q)_+$, where $(x)_+ = \max(x, 0)$, is the hockey-stick divergence $E_{e^{\varepsilon}}(P\|Q)$ of divergences. Written in terms of the privacy loss, it is an average over the PRV:

$$\delta(\varepsilon) = E_{e^{\varepsilon}}(P\|Q) = \mathbb{E}_P\big[(1 - e^{\varepsilon - L})_+\big] = \Pr_P[L > \varepsilon] - e^{\varepsilon} \Pr_Q[L > \varepsilon]. \tag{30.1}$$

The second form comes from factoring P out of the integrand. Where $P > 0$, $(P - e^{\varepsilon}Q)_+ = P\,(1 - e^{\varepsilon}Q/P)_+$, and $Q/P = e^{-L}$, so this is $P\,(1 - e^{\varepsilon - L})_+$; integrating P times a function of the output is taking its average under P. The integrand is positive exactly where $L > \varepsilon$, and integrating $P - e^{\varepsilon}Q$ over that set gives the last form.

The second form is the one to remember. Each output contributes to δ only if its privacy loss exceeds ε, and then only the fraction $1 - e^{\varepsilon - L}$ of its probability. An output with loss $L = \varepsilon + \ln 2$ contributes half its probability, since $1 - e^{-\ln 2} = 1 - \frac{1}{2}$. An output with loss just above ε contributes almost nothing, and only an output with infinite loss contributes all of its probability.

30.2.2. Fact 2 — RDP is the MGF of the privacy loss

The Rényi divergence of order α is defined by $D_\alpha(P\|Q) = \frac{1}{\alpha - 1} \ln \int P^{\alpha} Q^{1-\alpha}$. Write $P^{\alpha}Q^{1-\alpha} = P\,(P/Q)^{\alpha - 1}$ and $(P/Q)^{\alpha - 1} = e^{(\alpha - 1)L}$: the integral is the average under P of $e^{(\alpha - 1)L}$, which is the MGF of the PRV at the point $\alpha - 1$. An RDP bound $D_\alpha(P\|Q) \le \varepsilon(\alpha)$ is therefore a bound on that MGF value:

$$\mathbb{E}_P\big[e^{(\alpha - 1)L}\big] = e^{(\alpha - 1)D_\alpha(P\|Q)} \le e^{(\alpha - 1)\varepsilon(\alpha)}. \tag{30.2}$$

This is Equation 3.12 of divergences, with the exponent multiplied out.

So knowing the RDP curve at the orders $\alpha_1, \alpha_2, \ldots$ is knowing (an upper bound on) the MGF of the PRV at $\alpha_1 - 1, \alpha_2 - 1, \ldots$. That is the whole summary. Every conversion is a way of bounding the average in Equation 30.1 using only the averages in Equation 30.2.

30.2.3. Fact 3 — Data processing on a test

A test ϕ maps the output to "reject" or "accept", so its outcome is a coin. Under P the coin shows "reject" with probability FPR; under Q it shows "reject" with probability $1 - \mathrm{FNR}$. Turning the output into this coin is post-processing, and post-processing cannot increase a Rényi divergence: this is the data processing inequality of divergences. The short reason is that merging outputs can only shrink the sum $\int P^{\alpha}Q^{1-\alpha}$. The function $x^{\alpha}y^{1-\alpha}$ is convex for $\alpha > 1$ and scales linearly when x and y are both multiplied by the same factor, and such a function satisfies $g(x_1 + x_2, y_1 + y_2) \le g(x_1, y_1) + g(x_2, y_2)$; merging two outputs replaces the right side by the left (Section F.5 in the appendices proves this). (A test that randomizes its decision is handled the same way; divergences gives the general proof.) So, writing $\mathrm{Bern}(x)$ for "reject with probability x",

$$D_\alpha\big(\mathrm{Bern}(\mathrm{FPR}) \,\|\, \mathrm{Bern}(1 - \mathrm{FNR})\big) \le D_\alpha(P\|Q). \tag{30.3}$$

In words: a test cannot tell the two worlds apart better, in Rényi divergence, than the full output does.

30.2.4. Fact 4 — The Gaussian pair, exactly

For the running example everything can be computed in closed form, which is what lets this chapter measure each conversion against the truth. Take $P = \mathcal{N}(0,1)$ and $Q = \mathcal{N}(\mu,1)$. The privacy loss is the difference of the two log densities, $L(y) = -\frac{y^2}{2} + \frac{(y-\mu)^2}{2} = \frac{\mu^2}{2} - \mu y$. It is a linear function of y, so under P, where y is standard normal, the PRV is normal with mean $\mu^2/2$ and standard deviation μ: $\mathcal{N}(\mu^2/2, \mu^2)$.

Now evaluate the last form of Equation 30.1. Write $\Phi(x) = \Pr[Z \le x]$ for the standard normal cumulative distribution function. Under P, $L > \varepsilon$ means $y < \mu/2 - \varepsilon/\mu$, which has probability $\Phi(\mu/2 - \varepsilon/\mu)$. Under Q, write $y = \mu + z$ with z standard normal; then $L = -\mu^2/2 - \mu z$, and $L > \varepsilon$ means $z < -\mu/2 - \varepsilon/\mu$. So

$$\delta(\varepsilon) = \Phi\Big(\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) - e^{\varepsilon}\,\Phi\Big(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big), \tag{30.4}$$

the closed form already derived in divergences. It falls as ε grows, because the integrand $(1-e^{\varepsilon-L})_+$ does, so inverting it by bisection gives the exact ε at any δ. The script evaluates the second term in logarithms so that it stays accurate when e^{ε} overflows. As a check, at $\mu = 1$ a Riemann sum of $\mathbb{E}_P[(1-e^{\varepsilon-L})_+]$ over the normal density gives 1.2694×10^{-1} at $\varepsilon = 1$ and 1.5372×10^{-3} at $\varepsilon = 3$, the same as the closed form to all printed digits.

30.3. Where Mironov's conversion loses

30.3.1. Context

Rényi DP derived Mironov's conversion: an $(\alpha, \varepsilon(\alpha))$-RDP mechanism, one whose Rényi divergence of order α is at most $\varepsilon(\alpha)$, is $(\varepsilon(\alpha) + \ln(1/\delta)/(\alpha-1), \delta)$-DP. It is easy to remember and easy to compute, and Section D.3 in the appendices derives it from scratch, with the Gaussian's best order in closed form. This section rewrites that proof as two inequalities on the privacy loss and measures what each one costs on the Gaussian, so that you can see where the excess comes from.

30.3.2. Statement

The proof first replaces δ by the probability that the loss exceeds ε, and then bounds that probability with the MGF. For every order $\alpha > 1$ and every ε,

$$\delta(\varepsilon) \overset{(1)}{\le} \Pr_P[L > \varepsilon] \overset{(2)}{\le} e^{(\alpha-1)(\varepsilon(\alpha)-\varepsilon)}, \tag{30.5}$$

and setting the right side equal to δ gives **Mironov's conversion**

$$\varepsilon' = \varepsilon(\alpha) + \frac{\ln(1/\delta)}{\alpha - 1}. \tag{30.6}$$

30.3.3. Derivation

The proof in Rényi DP has exactly these two steps. Written with Fact 1 and Fact 2:

1. **Drop the fraction.** Fact 1 says each output with $L > \varepsilon$ contributes the fraction $1 - e^{\varepsilon - L}$ of its probability. Step 1 rounds that fraction up to 1: $(1 - e^{\varepsilon - L})_+ \le \mathbf{1}[L > \varepsilon]$, because the left side is 0 when $L \le \varepsilon$ and below 1 otherwise. Averaging under P gives inequality (1). This is the step that charges the whole tail $\Pr_P[L > \varepsilon]$ to δ.
2. **Bound the tail by the MGF (Chernoff).** Markov's inequality says a nonnegative random variable exceeds a level t with probability at most its average divided by t. Apply it to $e^{(\alpha-1)L}$, which exceeds $e^{(\alpha-1)\varepsilon}$ exactly when $L > \varepsilon$: $\Pr_P[L > \varepsilon] \le \mathbb{E}_P[e^{(\alpha-1)L}]\, e^{-(\alpha-1)\varepsilon}$. Fact 2 bounds the average by $e^{(\alpha-1)\varepsilon(\alpha)}$, which gives inequality (2).
3. **Solve for ε.** Setting $e^{(\alpha-1)(\varepsilon(\alpha)-\varepsilon)} = \delta$ and taking logarithms gives $(\alpha - 1)(\varepsilon(\alpha) - \varepsilon) = -\ln(1/\delta)$, which is Equation 30.6. DP also needs the inequality with the roles of the two datasets swapped, the pair (Q, P). RDP bounds $D_\alpha(Q\|P)$ by the same curve, because swapping two neighbours gives two neighbours, so the same argument applies.

30.3.4. Interpretation

The two steps lose in different places. Table 30.2 measures them on the Gaussian, converting each inequality of Equation 30.5 into an ε at $\delta = 10^{-5}$. The first row is the exact ε from Equation 30.4. The second is the ε at which the tail $\Pr_P[L > \varepsilon] = \Phi(\mu/2 - \varepsilon/\mu)$ equals δ. Since $\Phi(x) = 10^{-5}$ at $x = -\Phi^{-1}(1 - 10^{-5}) = -4.2649$, where Φ^{-1} is the inverse of Φ, this is $\varepsilon = \mu^2/2 + 4.2649\,\mu$: $0.5 + 4.2649 \approx 4.765$ at $\mu = 1$ and $50 + 42.649 = 92.649$ at $\mu = 10$. The third row is Mironov's ε' minimized over the grid.

Table 30.2.: Mironov's conversion for the Gaussian at $\delta = 10^{-5}$, split into its two steps.

	$\mu = 1$ (one step, $\sigma = 1$)	$\mu = 10$ (100 steps, $\sigma = 1$)
Exact ε	4.377	91.817
After step 1, $\Pr_P[L > \varepsilon] = \delta$	4.765	92.649
After step 2, Mironov	5.299 at $\alpha = 5.8$	98.026 at $\alpha = 1.5$
Loss from step 1	0.388	0.832
Loss from step 2	0.534	5.377 (0.041 of it from the grid)

Step 1 ignores how far past ε the loss goes. An output with L slightly above ε counts fully toward the tail but almost nothing toward δ. The density of the Gaussian PRV is falling steeply at ε, which sits several standard deviations above its mean, so most of the tail sits just above ε, and step 1 overcounts it.

Step 2 replaces a tail by an MGF, and that costs more. Markov's inequality is tight only for a variable that puts all its mass on 0 and on the level t; the Gaussian PRV is nothing like that, so the bound is far above the true tail at 4.765. At $\mu = 10$ this step costs 5.377 of the $98.026 - 91.817 = 6.209$ total excess (Table 30.2). Of that, 0.041 is the grid's: over all real orders Mironov's conversion gives 97.985 at $\alpha = 1.480$, against 98.026 at the grid's 1.5.

On the δ side the losses are multiplicative. At Mironov's $\varepsilon = 5.299$ for $\mu = 1$, the exact δ is 1.300×10^{-7}. The tail is 7.992×10^{-7}, 6.1 times larger, and Mironov's bound is 1.000×10^{-5}, 12.5 times larger again. You pay for $\delta = 10^{-5}$ and get 1.3×10^{-7}.

30.3.5. Example: one release of a mean

You release the mean of a bounded statistic with the Gaussian mechanism at noise multiplier $\sigma = 1$, so $\mu = 1$ and $\varepsilon(\alpha) = \alpha/2$. Mironov's conversion gives $\alpha/2 + \ln(10^5)/(\alpha - 1)$ at each order. The first term grows with the order and the second shrinks, so there is a best order in between. Over the continuous range of orders the sum is smallest at $\alpha = 5.799$, with $\varepsilon' = 5.299$ (Section 30.6 derives both); the grid's best order, 5.8, gives the same 5.299. The exact answer is 4.377. Reporting Mironov's number overstates ε by 0.921, which means $e^{0.921}$ more "allowed" likelihood ratio for every output.

30.3.6. Check yourself

- Why does step 2 lose about ten times more at $\mu = 10$ than at $\mu = 1$? *(The PRV has mean $\mu^2/2$ and standard deviation μ. At the best order, Mironov's $\varepsilon^* = \mu^2/2 + 2\sqrt{(\mu^2/2)\ln(1/\delta)} = \mu^2/2 + \mu\sqrt{2\ln(1/\delta)}$ sits $\sqrt{2\ln(1/\delta)} \approx 4.799$ standard deviations above the mean, while the true tail point sits $\Phi^{-1}(1-\delta) = 4.2649$ standard deviations above it. The gap is a fixed number of standard deviations, about 0.534, so in ε it grows like μ: 0.534 at $\mu = 1$, about ten times that at $\mu = 10$.)*
- Is step 1 ever tight? *(Only when every output with $L > \varepsilon$ has $L = \infty$, where $1 - e^{\varepsilon - L} = 1$, such as a mechanism that sometimes reveals the record outright, with the pair ordered so that P is the output on the dataset that holds the record.)*

30.4. The improved conversion

30.4.1. Context

Both of Mironov's steps together replace the integrand $(1 - e^{\varepsilon - z})_+$ of Equation 30.1, as a function of the loss value z, by an exponential $c\, e^{(\alpha-1)z}$ that lies above it. An exponential is used because it is the only kind of function whose average Fact 2 tells you. Mironov's choice is $c = e^{-(\alpha-1)\varepsilon}$, the exponential that equals 1 at $z = \varepsilon$ and so passes through the corner of the indicator. That is not the smallest exponential above the integrand, because the integrand is well below 1 near $z = \varepsilon$. Using the smallest one is the whole improvement.

30.4.2. Statement

An $(\alpha, \varepsilon(\alpha))$-RDP mechanism is (ε', δ)-DP with

$$\varepsilon' = \varepsilon(\alpha) + \ln\frac{\alpha - 1}{\alpha} - \frac{\ln\delta + \ln\alpha}{\alpha - 1}, \tag{30.7}$$

or equivalently, at a given ε,

$$\delta = \frac{e^{(\alpha-1)(\varepsilon(\alpha)-\varepsilon)}}{\alpha}\Big(1-\frac{1}{\alpha}\Big)^{\alpha-1}. \tag{30.8}$$

This is Theorem 21 of Balle, Barthe, Gaboardi, Hsu & Sato (2020) and Proposition 12 of Canonne, Kamath & Steinke (2020), who also give the δ form; Asoodeh, Liao, Calmon, Kosut & Sankar proved it independently (2020, Lemma 1, Eq. 20). We call it the **improved conversion**. Compared with Equation 30.6, its δ is Mironov's $e^{(\alpha-1)(\varepsilon(\alpha)-\varepsilon)}$ multiplied by the factor $\frac{1}{\alpha}(1-\frac{1}{\alpha})^{\alpha-1}$, which is below 1.

30.4.3. Derivation

The plan: find the smallest constant c for which $c\,e^{(\alpha-1)z}$ stays above the integrand, then average.

1. **Bound the integrand by an exponential.** If $(1-e^{\varepsilon-z})_+ \le c\,e^{(\alpha-1)z}$ for every real z, then the same holds with z replaced by the random loss L, and averaging under P keeps the inequality. By Fact 1 the left side averages to $\delta(\varepsilon)$, and by Fact 2 the right side averages to at most $c\,e^{(\alpha-1)\varepsilon(\alpha)}$. So $\delta(\varepsilon) \le c\,\mathbb{E}_P[e^{(\alpha-1)L}] \le c\,e^{(\alpha-1)\varepsilon(\alpha)}$.
2. **The smallest c.** The condition of step 1 says $c \ge (1-e^{\varepsilon-z})_+\,e^{-(\alpha-1)z}$ for every z, so the smallest valid c is $c^* = \sup_z (1-e^{\varepsilon-z})_+\,e^{-(\alpha-1)z}$. For $z \le \varepsilon$ the expression is 0, so only $z > \varepsilon$ matters. There it is $g(z) = e^{-(\alpha-1)z} - e^{\varepsilon-\alpha z}$.
3. **Find the maximum.** Differentiate: $g'(z) = -(\alpha-1)e^{-(\alpha-1)z} + \alpha e^{\varepsilon-\alpha z} = e^{-\alpha z}(\alpha e^{\varepsilon} - (\alpha-1)e^{z})$. The bracket equals $e^{\varepsilon} > 0$ at $z = \varepsilon$ and decreases as z grows, so g first rises and then falls. Its maximum is where the bracket vanishes, at $e^{z^*} = \frac{\alpha}{\alpha-1}e^{\varepsilon}$, that is, $z^* = \varepsilon - \ln(1-1/\alpha)$.
4. **Evaluate it.** Factor $g(z^*) = e^{-\alpha z^*}(e^{z^*} - e^{\varepsilon})$. At z^*, $e^{z^*} - e^{\varepsilon} = e^{\varepsilon}(\frac{\alpha}{\alpha-1} - 1) = e^{\varepsilon}\cdot\frac{1}{\alpha-1}$, and $e^{-\alpha z^*} = e^{-\alpha\varepsilon}(1-1/\alpha)^{\alpha}$. Multiplying,

$$c^* = \frac{e^{-(\alpha-1)\varepsilon}}{\alpha-1}\Big(1-\frac{1}{\alpha}\Big)^{\alpha}. \tag{30.9}$$

5. **Collect.** Step 1 gives $\delta \le c^* e^{(\alpha-1)\varepsilon(\alpha)}$. Since $(1-1/\alpha)/(\alpha-1) = 1/\alpha$, the constant in front simplifies to $\frac{1}{\alpha}(1-\frac{1}{\alpha})^{\alpha-1}$, and this is Equation 30.8.
6. **Solve for ε.** Set the bound equal to δ and take logarithms: $\ln\delta = (\alpha-1)(\varepsilon(\alpha)-\varepsilon) - \ln\alpha + (\alpha-1)\ln(1-1/\alpha)$. Divide by $\alpha-1$ and solve for ε, using $\ln(1-1/\alpha) = \ln\frac{\alpha-1}{\alpha}$, to get Equation 30.7. As before, the reverse pair (Q, P) follows because RDP bounds $D_\alpha(Q\|P)$ by the same curve.

The script checks step 4 by brute force: at $\alpha = 6$ and $\varepsilon = 4$ the formula gives $c^* = 1.380552\times10^{-10}$ at $z^* = 4 - \ln(5/6) = 4.1823$, and the maximum of g over a grid of two million points is the same to all seven digits.

Figure 30.1 draws the two exponentials. Mironov's passes through the corner of the indicator at $z = \varepsilon$; the smallest one sits lower and touches the integrand at z^*, slightly to the right of ε.

30.4.4. Interpretation

The gain depends only on the order. Both conversions add something to the same $\varepsilon(\alpha)$, so when you subtract Equation 30.7 from Equation 30.6 at the same α, the $\varepsilon(\alpha)$ terms cancel, and so do

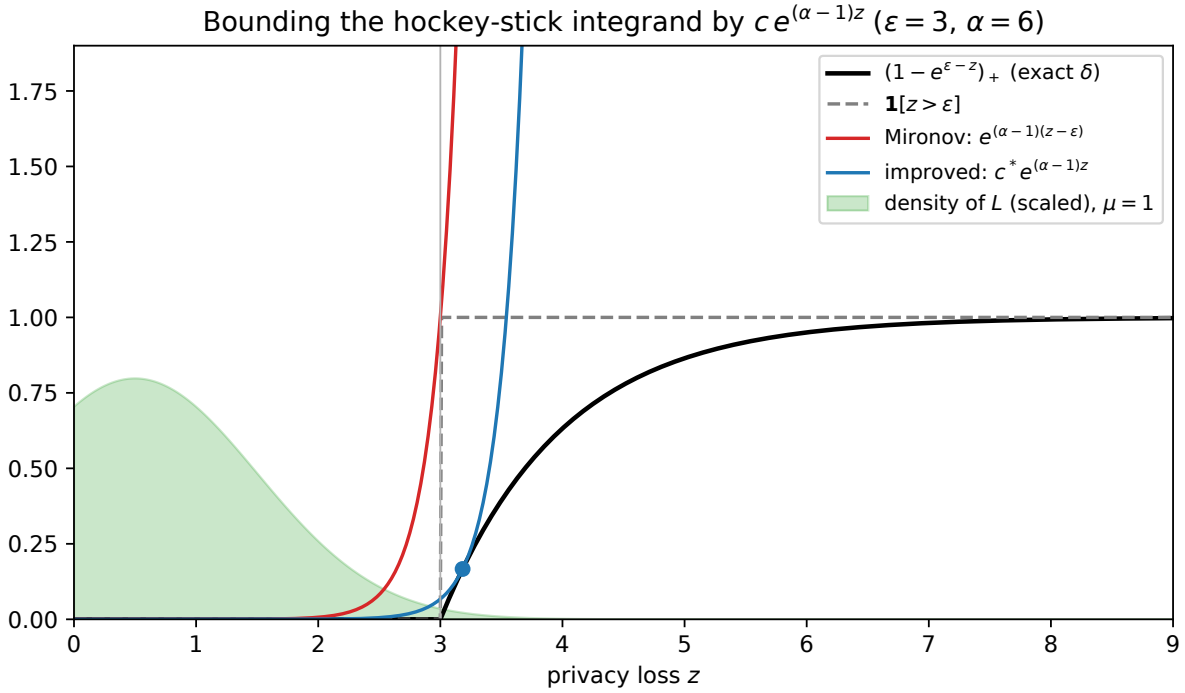

Figure 30.1.: The hockey-stick integrand $(1 - e^{\varepsilon - z})_+$ (black) at $\varepsilon = 3$, the indicator $\mathbf{1}[z > \varepsilon]$ that Mironov's step 1 replaces it with (dashed), and the two exponentials of order $\alpha = 6$ that bound it: Mironov's, through the corner of the indicator (red), and the smallest one, which touches the integrand at $z^* = \varepsilon - \ln(1 - 1/\alpha)$ (blue). The shaded curve is the density of the Gaussian privacy loss at $\mu = 1$: the conversions average the exponentials against it.

the $\ln(1/\delta)$ terms. What is left is how much smaller the improved ε' is:

$$\Delta(\alpha) = \frac{\ln \alpha}{\alpha - 1} + \ln \frac{\alpha}{\alpha - 1}, \tag{30.10}$$

whatever the mechanism and whatever δ. On the δ side, the improved δ is Mironov's times $\frac{1}{\alpha}(1-\frac{1}{\alpha})^{\alpha-1}$. Because $(1-1/\alpha)^{\alpha-1} \to 1/e$, that factor behaves like $1/(e\alpha)$ for large α. Table 30.3 gives values; at $\alpha = 2$, for instance, the factor is $\frac{1}{2} \cdot \frac{1}{2} = 0.25$ and the saving is $\ln 2 + \ln 2 = 1.3863$.

Table 30.3.: What the improved conversion gains over Mironov's at the same order.

α	δ factor	$1/(e\alpha)$	ε saving $\Delta(\alpha)$
2	0.2500	0.1839	1.3863
10	0.0387	0.0368	0.3612
100	0.0037	0.0037	0.0566

Over a grid, the saving is at least $\Delta(\alpha_M)$, where α_M is the order Mironov's conversion picks, for any RDP curve. The reason is that the improved conversion takes its own best order, so its minimum is at most its value at α_M, and that value is Mironov's minimum minus $\Delta(\alpha_M)$ by Equation 30.10. So you can read the saving of any accountant off Table 30.3 from its best order: about 1.39 at order 2, 0.36 at order 10, 0.06 at order 100. For the Gaussian at $\mu = 1$, Mironov picks order 5.8, $\Delta(5.8) = \frac{\ln 5.8}{4.8} + \ln \frac{5.8}{4.8} = 0.555$, and the actual saving is 0.570, a little more because the improved conversion moves to a better order. If two accountants report ε about 0.4 apart from the same curve at a best order near 10, one of them is using Mironov's conversion. Opacus and `dp_accounting` both use the improved one.

The improved conversion also beats both of Mironov's steps, not only the second. For the Gaussian at $\mu = 1$ it gives 4.729 (at $\alpha = 5.4$), below even the 4.765 of the tail $\Pr_P[L > \varepsilon] = \delta$ after step 1 in Table 30.2. That is possible because it never replaces the integrand by an indicator: its exponential is allowed to dip below 1 just above ε, where the integrand is small. At $\mu = 10$ it gives 96.116 against Mironov's 98.026 and the exact 91.817. At $\varepsilon = 4.729$ the exact Gaussian δ is 2.097×10^{-6}, so the guarantee still holds with room to spare.

For one order, it is close to optimal. The next section computes the best possible conversion from the RDP values on a whole grid, and a single order is the special case of a grid with one point. Take only the forward constraint $D_\alpha(P\|Q) \le \varepsilon(\alpha)$ at one order, as the improved conversion does, at $\mu = 1$. At order 2, where $\varepsilon(2) = 1$, Mironov gives $1 + \ln(10^5) = 12.513$, the improved conversion $1 + \ln \frac{1}{2} + \ln(10^5) - \ln 2 = 11.127$, and the optimum 10.668. At orders 8 and 32 the improved conversion and the optimum agree to three decimals (5.214 and 16.228). Exercise 6 in the exercise book explains why the gap appears only at small orders.

Balle et al. derive the same formula geometrically, as a tangent line. In the plane of test errors $(\mathrm{FPR}, \mathrm{FNR})$, the (ε, δ) constraint $1 - \mathrm{FPR} \le e^\varepsilon \mathrm{FNR} + \delta$ is a straight line, and the best line that keeps a relaxed version of the region RDP allows (Section 30.5) on its feasible side touches the region's boundary. Figure 30.1 shows the same tangency in the privacy-loss variable: the blue exponential touches the integrand at z^*.

30.4.5. Example: the same release, converted better

For the mean released with $\sigma = 1$, the improved conversion over the grid gives $(4.729, 10^{-5})$-DP at order 5.4. Mironov's gave 5.299 at order 5.8, and the exact value is 4.377. The improved conversion removes 0.570 of the 0.921 excess, at no cost: it uses the same RDP curve and one extra line of code.

30.4.6. Check yourself

- Why must the bounding function be an exponential in z, rather than, say, a polynomial that hugs the integrand more closely? *(Fact 2 only tells you $\mathbb{E}_P[e^{(\alpha-1)L}]$. To bound $\mathbb{E}_P[g(L)]$ you need $g \le c\, e^{(\alpha-1)z}$; any other g has an expectation the RDP curve does not determine.)*
- The improved conversion can return a negative ε' when $\varepsilon(\alpha)$ is tiny. What should you report? *($\varepsilon' = 0$. $\delta(\varepsilon)$ can only fall as ε grows, so a bound at some $\varepsilon' < 0$ also holds at 0. The script clips at 0, as Canonne et al. do.)*

30.5. RDP as a constraint on tests

30.5.1. Context

An (ε, δ) statement is one straight line in the plane of test errors: every test has $1 - \mathrm{FPR} \le e^{\varepsilon}\mathrm{FNR} + \delta$. An RDP curve says more. By Fact 3, each order constrains the pair $(\mathrm{FPR}, \mathrm{FNR})$ of every test, and the constraints for different orders bend differently. This section draws the region an RDP curve allows, following Balle et al. (2020), compares it with the Gaussian's true trade-off curve, and uses it to compute the best possible conversion. The **trade-off function** $T(P, Q)(\mathrm{FPR})$ of hypothesis testing is the smallest type II error any test can have at type I error FPR; it describes the most powerful possible attack at each false-positive rate.

30.5.2. Statement

The statement turns Fact 3 into an explicit inequality on $(\mathrm{FPR}, \mathrm{FNR})$ for each order, in both directions. Let M have RDP curve $\varepsilon(\cdot)$ at the orders of a grid. Every test between $P = M(D)$ and $Q = M(D')$, with type I error FPR and type II error FNR, satisfies for every order α in the grid

$$\mathrm{FPR}^{\alpha}(1-\mathrm{FNR})^{1-\alpha} + (1-\mathrm{FPR})^{\alpha}\mathrm{FNR}^{1-\alpha} \le e^{(\alpha-1)\varepsilon(\alpha)}, \qquad (1-\mathrm{FNR})^{\alpha}\mathrm{FPR}^{1-\alpha} + \mathrm{FNR}^{\alpha}(1-\mathrm{FPR})^{1-\alpha} \le e^{(\alpha-} \tag{30.11}$$

Call the set of $(\mathrm{FPR}, \mathrm{FNR})$ satisfying all of these the **RDP privacy region**, and let $f_{\mathrm{RDP}}(\mathrm{FPR})$ be the smallest FNR in it at type I error FPR. Two claims follow.

1. **Trade-off bound.** $T(P, Q)(\mathrm{FPR}) \ge f_{\mathrm{RDP}}(\mathrm{FPR})$ for every FPR: no test is more powerful than the region allows.

2. **Optimal conversion.** Every pair consistent with the curve has

$$\delta(\varepsilon) \le \delta_{\text{opt}}(\varepsilon) = \max_{\text{FPR}} \left[1 - \text{FPR} - e^{\varepsilon} f_{\text{RDP}}(\text{FPR})\right], \tag{30.12}$$

and some two-outcome pair consistent with the curve attains it. So δ_{opt} is the best δ that any conversion using only these RDP values can certify.

30.5.3. Derivation

The first three steps compute the Rényi divergence of a test's outcome and apply the RDP curve to it. The last two rewrite δ as a statement about tests, so that the region bounds it.

1. **The outcome of a test is a coin (Fact 3).** Table 30.4 lists the outcome's distribution under each hypothesis.

Table 30.4.: The outcome of a test with errors (FPR, FNR), as a two-point distribution under each hypothesis.

Outcome	Probability under P	Probability under Q
reject	FPR	$1 - \text{FNR}$
accept	$1 - \text{FPR}$	FNR

2. **Compute its Rényi divergence.** The definition $D_\alpha = \frac{1}{\alpha-1} \ln \sum P^\alpha Q^{1-\alpha}$ for a two-point distribution is a sum of two terms, one per row of Table 30.4: $D_\alpha(\text{outcome under } P \,\|\, \text{outcome under } Q) = \frac{1}{\alpha-1} \ln \left[\text{FPR}^\alpha (1 - \text{FNR})^{1-\alpha} + (1 - \text{FPR})^\alpha \text{FNR}^{1-\alpha}\right]$.
3. **Apply the RDP curve.** Data processing (Fact 3) gives this divergence $\le D_\alpha(P\|Q) \le \varepsilon(\alpha)$. Multiply by $\alpha - 1 > 0$ and exponentiate to get the first inequality of Equation 30.11. The second comes the same way from $D_\alpha(Q\|P) \le \varepsilon(\alpha)$, which RDP also guarantees because swapping two neighbours gives two neighbours; it is the same sum with the columns of the table swapped. Since every test's (FPR, FNR) lies in the region, its FNR is at least the smallest FNR the region allows at its FPR. This proves claim 1.
4. **Write δ as a best test.** Let S be the acceptance region of a test, the outputs on which it accepts P, so $P(S) = 1 - \text{FPR}$ and $Q(S) = \text{FNR}$. Fact 1 says $\delta(\varepsilon)$ is the largest $P(S) - e^\varepsilon Q(S)$ over all events, so $\delta(\varepsilon) = \max_S [P(S) - e^\varepsilon Q(S)] = \max_\phi [1 - \text{FPR} - e^\varepsilon \text{FNR}]$. Every test's (FPR, FNR) is in the region, so $\text{FNR} \ge f_{\text{RDP}}(\text{FPR})$, and replacing FNR by $f_{\text{RDP}}(\text{FPR})$ can only increase the expression. That gives the bound in Equation 30.12.
5. **Show that the bound is attained.** Let $(\text{FPR}^*, \text{FNR}^*)$ maximize Equation 30.12, with $\text{FNR}^* = f_{\text{RDP}}(\text{FPR}^*)$. Build a mechanism whose output is just the coin of Table 30.4 with these errors: $M(D) = \text{Bern}(1 - \text{FPR}^*)$ and $M(D') = \text{Bern}(\text{FNR}^*)$, where the outcome 1 is "accept". By step 2 its Rényi divergences in both directions are exactly the left sides of Equation 30.11 at $(\text{FPR}^*, \text{FNR}^*)$, which lie in the region, so the mechanism satisfies the curve. The test "accept on outcome 1" has errors $(\text{FPR}^*, \text{FNR}^*)$, so this mechanism's $\delta(\varepsilon)$ is at least $1 - \text{FPR}^* - e^\varepsilon \text{FNR}^*$, which is $\delta_{\text{opt}}(\varepsilon)$.

Computing it. For fixed FPR, both left sides of Equation 30.11 equal 1 at $\text{FNR} = 1 - \text{FPR}$: the first becomes $\text{FPR}^\alpha \text{FPR}^{1-\alpha} + (1 - \text{FPR})^\alpha (1 - \text{FPR})^{1-\alpha} = \text{FPR} + (1 - \text{FPR})$, the second

likewise. That is where the test ignores the output and the two coins are identical. Both are convex in FNR (each term has the form $x^\alpha y^{1-\alpha}$, which is jointly convex in (x, y) for $\alpha > 1$, by Section F.5), and their smallest value is at FNR $= 1 - \text{FPR}$, so they decrease on $[0, 1 - \text{FPR}]$. The constraints therefore hold for FNR above some cut-off and fail below it, and $f_{\text{RDP}}(\text{FPR})$ is that cut-off, found by bisection. The script works with logarithms of FPR, $1 - \text{FPR}$, FNR and $1 - \text{FNR}$, because the interesting tests have errors like 10^{-6}. The objective in Equation 30.12 is concave in FPR, because f_{RDP} is convex: the region is an intersection of convex sets, one per constraint, and the lower boundary of a convex set is a convex function. So a grid search refined by a one-dimensional bracketing search finds the maximum. The ε at a given δ is the maximum over FPR of $\ln\left((1 - \text{FPR} - \delta)/f_{\text{RDP}}(\text{FPR})\right)$, the ε at which the line through the point $(\text{FPR}, f_{\text{RDP}}(\text{FPR}))$ just reaches δ.

30.5.4. Interpretation

To see how loose the region is, compare it with the truth for the Gaussian. The best test between $\mathcal{N}(0, 1)$ and $\mathcal{N}(1, 1)$ rejects when the output exceeds a threshold τ (the Neyman–Pearson lemma: the best test thresholds the likelihood ratio, which here increases with the output). Its type I error is $\text{FPR} = 1 - \Phi(\tau)$, so $\tau = \Phi^{-1}(1 - \text{FPR})$, and its type II error is the probability that an output from $\mathcal{N}(1, 1)$ falls below τ, which is $G_1(\text{FPR}) = \Phi(\Phi^{-1}(1 - \text{FPR}) - 1)$. At FPR $= 0.1$, $\Phi^{-1}(0.9) = 1.2816$, so $G_1 = \Phi(0.2816) = 0.6109$ and the true power is 0.3891. Figure 30.2 plots, for the Gaussian at $\mu = 1$, the largest power $1 - f_{\text{RDP}}(\text{FPR})$ that its RDP curve allows, against this true power $1 - G_1(\text{FPR})$.

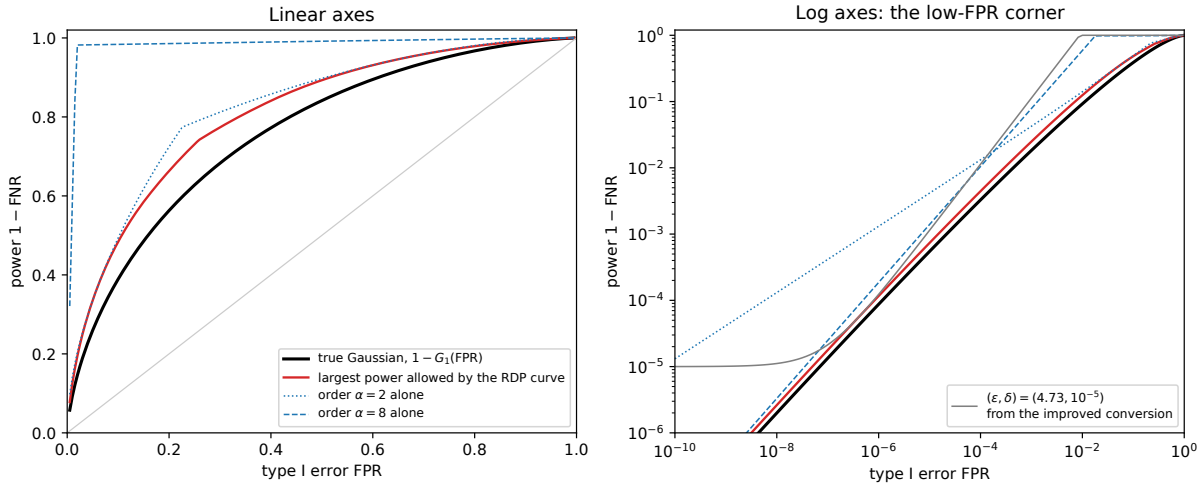

Figure 30.2.: Largest power $1 - \text{FNR}$ at type I error FPR allowed by the Gaussian's RDP curve at $\mu = 1$ (red, all orders of the grid together), by the single orders 2 and 8 (blue), and achieved by the Gaussian itself (black). Left: linear axes. Right: log axes, with the (ε, δ) line $1 - \text{FNR} \le e^\varepsilon \text{FPR} + \delta$ from the improved conversion (grey), which touches the red curve.

Each order guards a different range of FPR. For small FPR and FNR near 1, the term $(1 - \text{FNR})^\alpha \text{FPR}^{1-\alpha}$ of the second inequality of Equation 30.11 is by far the larger, because $\text{FPR}^{1-\alpha}$ blows up as FPR $\to 0$. Keeping only that term and solving for $1 - \text{FNR}$ gives $1 - \text{FNR} \lesssim$

$e^{(\alpha-1)\varepsilon(\alpha)/\alpha}\,\mathrm{FPR}^{(\alpha-1)/\alpha}$. On log axes this is a line of slope $(\alpha-1)/\alpha$, with intercept $(\alpha-1)\varepsilon(\alpha)/\alpha = (\alpha-1)/2$ when $\varepsilon(\alpha) = \alpha/2$. Order 2 has slope $\frac{1}{2}$ and is weak at small FPR: at $\mathrm{FPR} = 10^{-6}$ it allows power 1.3118×10^{-3}, while order 8 (slope $\frac{7}{8}$) allows 1.8622×10^{-4}. In the bulk the roles swap: at $\mathrm{FPR} = 0.1$, order 2 allows 0.4932 and order 8 allows 0.9838. The two lines meet where $\frac{1}{2} + \frac{1}{2}\ln\mathrm{FPR} = \frac{7}{2} + \frac{7}{8}\ln\mathrm{FPR}$, that is $-3 = \frac{3}{8}\ln\mathrm{FPR}$, at $\mathrm{FPR} = e^{-8} \approx 3.35 \times 10^{-4}$. The lines are bounds on the boundaries, not the boundaries themselves, because they drop a term. Order 8's line is exact at small FPR, but order 2's overstates its power: at $\mathrm{FPR} = 10^{-6}$ it gives $e^{1/2} \cdot 10^{-3} \approx 1.6487 \times 10^{-3}$ against the exact 1.3118×10^{-3}. So the exact boundaries of the two orders cross a little lower, at $\mathrm{FPR} \approx 1.87 \times 10^{-4}$, the value the script finds by solving for equal power. At $\mathrm{FPR} = 10^{-3}$ neither is binding: the binding order is 3.7, which alone allows 2.4910×10^{-2}, the grid's value. Large orders guard small FPR, small orders the bulk.

The RDP region is a good but loose summary of the trade-off curve. Table 30.5 compares powers. The curve allows 1.24 to 1.36 times the power the Gaussian has, at every FPR shown; at $\mathrm{FPR} = 0.1$, for instance, $0.48376/0.38914 = 1.24$.

Table 30.5.: Power of the best test against the Gaussian mechanism at $\mu = 1$, true and allowed by its RDP curve.

Type I error FPR	True power $1 - G_1(\mathrm{FPR})$	Largest power allowed by the RDP curve	Ratio
0.1	3.8914×10^{-1}	4.8376×10^{-1}	1.24
10^{-3}	1.8298×10^{-2}	2.4910×10^{-2}	1.36
10^{-6}	8.7218×10^{-5}	1.1636×10^{-4}	1.33

The RDP region is not an (ε, δ) region. The grey line in Figure 30.2 is the improved conversion's guarantee. It touches the red curve at one small FPR and lies far above it elsewhere, because an (ε, δ) pair is a single straight line, and the best it can do is be tangent to the curved region at one point. A whole trade-off curve is the envelope of such lines, one for each ε, which is the duality that Gaussian DP develops.

Nor does the region characterize RDP. A test squeezes the output into a single bit, and the Rényi divergence of a pair is in general larger than the largest Rényi divergence of any single test's outcome: information spread over many outputs is lost when they are merged into "accept" and "reject". So a pair can have every test inside the region and still violate the RDP curve. The region is what RDP implies about tests, not an equivalent definition.

30.5.5. Example: a membership test against a released statistic

An auditor runs a membership test against the mean released with $\sigma = 1$ and wants a false-positive rate of $\mathrm{FPR} = 10^{-3}$. The RDP curve alone guarantees that no test detects membership with probability above 2.4910×10^{-2}. The Gaussian's exact trade-off curve says the best test reaches 1.8298×10^{-2}. The $(4.729, 10^{-5})$ guarantee from the improved conversion only says power $\leq e^{\varepsilon}\mathrm{FPR} + \delta$, which is $e^{4.729} \times 10^{-3} + 10^{-5} = 0.1131$, more than four times the region's bound. Reading an RDP result through one (ε, δ) pair throws away most of what it says about low false-positive rates.

30.5.6. Check yourself

- Why are there two inequalities per order in Equation 30.11? *(One for $D_\alpha(P\|Q)$ and one for $D_\alpha(Q\|P)$. RDP bounds both, because the neighbouring relation is symmetric; the first matters for tests with* FPR *near 1, the second for* FPR *near 0.)*
- Why is the optimum in Equation 30.12 attained by a two-outcome mechanism, rather than needing a richer one? *(Any mechanism's δ is the best value of* $1 - \text{FPR} - e^\varepsilon \text{FNR}$ *over its tests, and each test only sees a coin. The coin with the extreme errors is itself a mechanism with the same constraints.)*

30.6. Choosing the order

30.6.1. Context

Both conversions hold at every order, so you take the best one. Each converted ε' is the RDP curve, which grows with the order, plus a term in $\ln(1/\delta)/(\alpha-1)$, which shrinks with it, so the best order balances the two. For the Gaussian the curve is linear in α, and the best order has a closed form or nearly so. The formulas show how the best order moves with the number of steps and with δ, and that tells you what an accountant's grid of orders must contain.

30.6.2. Statement

Let $\varepsilon(\alpha) = \rho\alpha$, with slope $\rho = \mu^2/2 = k/(2\sigma^2)$ for the composed Gaussian. Over continuous $\alpha > 1$, the best orders are as follows. For **Mironov's conversion**, the best order is $\alpha^* = 1 + \sqrt{\ln(1/\delta)/\rho}$, and $\varepsilon^* = \rho + 2\sqrt{\rho \ln(1/\delta)}$. For the **improved conversion**, the best order solves

$$\rho(\alpha - 1)^2 = \ln \frac{1}{\alpha\delta}, \tag{30.13}$$

which the script solves by iterating $\alpha \leftarrow 1 + \sqrt{\ln(1/(\alpha\delta))/\rho}$ from Mironov's α^*. The only difference from Mironov's condition is the extra α inside the logarithm, which pulls the best order slightly lower.

30.6.3. Derivation

Each step sets a derivative to zero, as for any smooth minimum.

1. **Mironov.** The derivative of $\rho\alpha + \ln(1/\delta)/(\alpha-1)$ is $\rho - \ln(1/\delta)/(\alpha-1)^2$. Setting it to zero gives $(\alpha-1)^2 = \ln(1/\delta)/\rho$, which is α^*. Substitute back: $\rho\alpha^* = \rho + \rho\sqrt{\ln(1/\delta)/\rho} = \rho + \sqrt{\rho \ln(1/\delta)}$, and the second term is $\ln(1/\delta)/\sqrt{\ln(1/\delta)/\rho} = \sqrt{\rho \ln(1/\delta)}$ too. At the optimum the two terms contribute equally beyond ρ.
2. **Improved, derivative.** Write Equation 30.7 as $\rho\alpha + \ln(1 - \frac{1}{\alpha}) + \frac{\ln(1/\delta) - \ln\alpha}{\alpha - 1}$ and differentiate term by term: $\frac{\mathrm{d}}{\mathrm{d}\alpha}\ln(1 - \frac{1}{\alpha}) = \frac{1}{\alpha(\alpha-1)}$, and $\frac{\mathrm{d}}{\mathrm{d}\alpha}\frac{\ln(1/\delta) - \ln\alpha}{\alpha-1} = -\frac{1}{\alpha(\alpha-1)} - \frac{\ln(1/\delta) - \ln\alpha}{(\alpha-1)^2}$ by the quotient rule. The $\frac{1}{\alpha(\alpha-1)}$ terms cancel, leaving $\rho - \frac{\ln(1/(\alpha\delta))}{(\alpha-1)^2}$. Setting it to zero gives Equation 30.13.

3. **It is a minimum.** The derivative of that expression is $\frac{1}{\alpha(\alpha-1)^2} + \frac{2\ln(1/(\alpha\delta))}{(\alpha-1)^3}$, which is positive whenever $\alpha < 1/\delta$, so the objective is convex there and the stationary point is its minimum.
4. **Scaling.** Ignoring the slowly varying $\ln\alpha$, $\alpha^* - 1 \approx \sqrt{\ln(1/\delta)/\rho} = \sigma\sqrt{2\ln(1/\delta)/k}$. More steps or less noise push the best order toward 1; smaller δ pushes it up, but only through $\sqrt{\ln(1/\delta)}$.

30.6.4. Interpretation

Figure 30.3 shows the two converted $\varepsilon'(\alpha)$ for $\mu = 1$. Both are U-shaped: at small α the $\ln(1/\delta)/(\alpha-1)$ term explodes, at large α the curve $\varepsilon(\alpha)$ itself does. The improved curve sits below Mironov's everywhere by $\Delta(\alpha)$ of Equation 30.10, and its minimum is at a slightly smaller order.

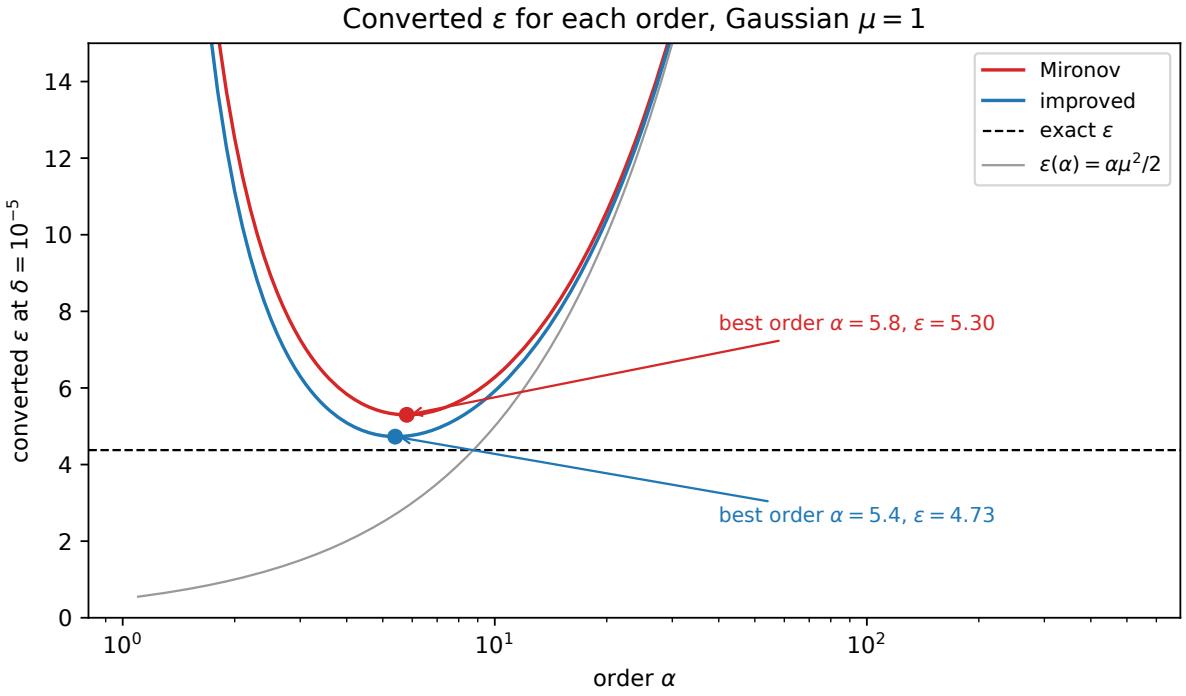

Figure 30.3.: Converted ε at $\delta = 10^{-5}$ for each order of the grid, for the Gaussian at $\mu = 1$, with Mironov's conversion (red) and the improved one (blue). Dots mark the best order of each. The dashed line is the exact ε, and the grey curve is the RDP curve $\varepsilon(\alpha) = \alpha/2$ that both conversions add to.

Table 30.6 shows how the best order moves over four settings. In the first row, for instance, $\rho = 1/(2\cdot 100) = 0.005$, and Mironov's best order is $1 + \sqrt{\ln(10^5)/0.005} = 1 + \sqrt{2302.6} = 48.985$; the improved conversion's extra $\ln\alpha$ brings it down to 40.525.

Table 30.6.: Best orders for the composed Gaussian at $\delta = 10^{-5}$.

σ	k	ρ	Best order, improved (continuous / grid)	ε continuous / grid	Mironov's best order
10	1	0.005	40.525 / 41	0.375 / 0.375	48.985
1	1	0.5	5.432 / 5.4	4.728 / 4.729	5.799
1	100	50	1.472 / 1.5	96.035 / 96.116	1.480
1	10,000	5000	1.048 / 1.1	5475.791 / 5611.778	1.048

The grid needs orders near 1 for long runs with little noise. At $\rho = 5000$ the best order is 1.048, below the grid's smallest order 1.1, and the grid's answer is $5611.778 - 5475.791 = 135.987$ larger than the continuous optimum. (That setting is a huge ε anyway; Exercise 5 in the exercise book measures the relative loss.)

The grid also needs large orders, for small total ρ. One step at $\sigma = 10$ already wants order 40.525, and at $\rho = 5 \times 10^{-5}$ the best order is 338.312 (Exercise 5 in the exercise book). Subsampled mechanisms (subsampling), which use each record only in a random fraction of the steps, have tiny curves at small orders, which is why the grid ends at 128, 256 and 512.

The value of δ matters little, because it enters only through $\sqrt{\ln(1/\delta)}$. At $\mu = 1$, moving from $\delta = 10^{-5}$ to 10^{-10} doubles $\ln(1/\delta)$ but moves the improved best order only from 5.432 to 7.483.

30.6.5. Example: tuning a grid for a training run

You plan $k = 100$ full-batch noisy gradient steps at $\sigma = 1$, so $\rho = 100/2 = 50$. Equation 30.13 puts the best order at 1.472, and the grid's 1.5 costs $96.116 - 96.035 = 0.081$ in ε. If you instead plan a single release at $\sigma = 10$, the best order is 40.525, and the grid's integer orders match it to three decimals of ε. One grid serves both because it is dense near 1 and runs from 1.1 to 512.

30.6.6. Check yourself

- Why does the best order go to 1 as $k \to \infty$? *(The curve's slope ρ grows with k, so the $\rho\alpha$ term punishes large orders more, while the $\ln(1/\delta)/(\alpha - 1)$ term does not change. The balance point $\alpha - 1 \approx \sqrt{\ln(1/\delta)/\rho}$ shrinks like $1/\sqrt{k}$.)*
- If an accountant reports the best order at the edge of its grid, what should you do? *(Extend the grid in that direction: the true optimum lies outside, and the reported ε is larger than necessary.)*

30.7. The slack no conversion removes

30.7.1. Context

The improved conversion is better than Mironov's, and the optimal conversion of Equation 30.12 is better still, in principle. Yet both stay above the exact ε of the Gaussian. Is that a weakness of the formulas, or of the summary? This section shows it is the summary: a different mechanism satisfies the same RDP curve and has a larger δ, and a conversion that sees only the curve must cover both. It also looks at the opposite direction, from (ε, δ) to RDP.

30.7.2. Statement

The three claims are about what the RDP curve can and cannot carry.

1. **The curve does not determine δ.** For the Gaussian, the optimal conversion from the RDP values on the grid agrees with the improved conversion to three decimals, and both exceed the exact ε by 5 to 10% (Table 30.8). The excess is real: a two-outcome mechanism satisfies the Gaussian's RDP curve $\alpha/2$ at every order $\alpha > 1$ and has $\delta(\varepsilon) = 4.4698 \times 10^{-5}$ at the Gaussian's exact $\varepsilon = 4.377$.
2. **(ε, δ)-DP with $\delta > 0$ implies no RDP bound at any order.**
3. **ε-DP implies $(\alpha, \min(\varepsilon, \alpha\varepsilon^2/2))$-RDP for every $\alpha > 1$** (Bun & Steinke 2016, Proposition 3.3). The constant $\frac{1}{2}\varepsilon^2$ can be sharpened to $\varepsilon \tanh(\varepsilon/2)$ (Equation 31.7 in concentrated DP).

30.7.3. Derivation

Claim 1. The idea is to build the worst mechanism the curve allows and compute its δ. By Equation 30.12, the largest δ consistent with a set of orders is attained by the two-outcome pair at the maximizer. On the part's grid, at $\mu = 1$ and $\varepsilon = 4.377$, that pair has $\delta = 4.4700 \times 10^{-5}$. But it satisfies the curve only at the grid's orders: its Rényi divergence is a smooth function of the order, and between two grid orders it can poke above $\alpha/2$. To get a pair that satisfies the curve at every real order, the script maximizes over a dense set of orders (steps of 0.002 from 1.01 to 30, and every integer up to 512) and then raises $Q(\text{accept})$ by a relative 10^{-5}, which pushes the pair strictly inside the curve. Table 30.7 shows the result. The privacy loss column is $\ln(P/Q)$ for each outcome: $\ln(2.2779 \times 10^{-4}/2.2998 \times 10^{-6}) = 4.5956$ for "accept", and for "reject" a tiny negative number, because P puts slightly less mass there than Q.

Table 30.7.: A two-outcome mechanism that satisfies the Gaussian's RDP curve at $\mu = 1$ at every order and has nearly the largest δ at $\varepsilon = 4.377$ that any such mechanism can have.

Outcome	$P = M(D)$	$Q = M(D')$	Privacy loss L
accept	2.2779×10^{-4}	2.2998×10^{-6}	4.5956
reject	rest	rest	-2.255×10^{-4}

1. **Check that it satisfies the curve.** On a scan of α from $1 + 10^{-8}$ to 10^6 (steps of 10^{-4} between 2 and 30), refined around the maximum, the largest value of $D_\alpha(P\|Q) - \alpha/2$ is -9.97×10^{-6}, at $\alpha = 5.0955$; it is negative, so the curve holds everywhere scanned. The reverse divergences $D_\alpha(Q\|P)$ stay about 0.5 below the curve, closest as $\alpha \to 1$. The limits are safe too: as $\alpha \to \infty$, $D_\alpha(P\|Q)$ tends to the largest privacy loss, 4.5956, while $\alpha/2$ grows without bound. The rounded values in the table also satisfy the curve, with largest excess -1.93×10^{-5}.
2. **Compute its δ.** By Equation 30.1 only outcomes with $L > \varepsilon$ contribute, and here that is only "accept". So $\delta(4.377) = P(\text{accept}) - e^{4.377}\,Q(\text{accept})$; with $e^{4.377} \approx 79.6$ this is 2.2779×10^{-4} minus about 1.831×10^{-4}, which is 4.4698×10^{-5} with unrounded values, against the Gaussian's 10^{-5}.
3. **Conclude.** So no curve-based method can certify $(4.377, 10^{-5})$ for the Gaussian, because the same certificate would have to cover this mechanism, which has the same curve and about 4.5 times the δ. The improved conversion's δ at that ε is 4.4701×10^{-5}, within 10^{-8} of this pair's.

The pair puts almost all its mass at $L \approx 0$ and a sliver at $L = 4.5956$, near the touching point z^* of Figure 30.1. That is the distribution for which the improved conversion's exponential bound is nearly an equality, since the exponential and the integrand meet there. It is very unlike the Gaussian PRV, which spreads its tail smoothly over all large losses. The RDP curve cannot tell them apart: it only sees MGF values (Fact 2).

Claim 2. A single example suffices. Take the mechanism that outputs nothing, except that with probability δ it publishes your record. Order the pair with the dataset that holds you first, $P = M(D')$ and $Q = M(D)$, which a guarantee must also cover. Then P puts mass δ on an output that Q never produces, and otherwise matches Q. Moving mass δ can change the probability of any event by at most δ, so $P(S) \le Q(S) + \delta$ for every event, and the mechanism is $(0, \delta)$-DP. But the sum $\sum P^\alpha Q^{1-\alpha}$ in the Rényi divergence contains the term $\delta^\alpha \cdot 0^{1-\alpha}$ for the published record, and $0^{1-\alpha} = \infty$ for $\alpha > 1$, so $D_\alpha(P\|Q) = \infty$ at every order. RDP, like pure DP, rules out catastrophic events however rare; (ε, δ)-DP allows them with probability δ.

Claim 3. The first bound, $\varepsilon(\alpha) \le \varepsilon$, follows directly from Fact 2. ε-DP says the privacy loss never exceeds ε, so $e^{(\alpha-1)L} \le e^{(\alpha-1)\varepsilon}$ for every output, and its average under P is at most $e^{(\alpha-1)\varepsilon}$; taking logarithms and dividing by $\alpha - 1$ gives $D_\alpha \le \varepsilon$. (Equivalently, Rényi divergence is non-decreasing in α and tends to the max-divergence, the largest privacy loss, which ε-DP bounds by ε; see divergences.) The second bound, $\alpha\varepsilon^2/2$, says an ε-DP mechanism is $\varepsilon^2/2$-zero-concentrated: the logarithm of the MGF of its privacy loss grows at most quadratically. Bun & Steinke (2016, Proposition 3.3) prove it through a two-point variable and an inequality between hyperbolic sines; concentrated DP gives a shorter proof with Hoeffding's lemma, and also proves the sharper line $\alpha\varepsilon\tanh(\varepsilon/2)$ of Equation 31.7, which randomized response attains as $\alpha \to 1$. This section uses both without proof. For randomized response at $\varepsilon = 0.5$, the bound at order 2 is $\min(0.5,\ 2 \cdot 0.25/2) = 0.2500$, at order 4 it is $\min(0.5,\ 4 \cdot 0.25/2) = 0.5000$, and at order 10 it is $\min(0.5,\ 1.25) = 0.5000$; the script gives $D_2 = 0.2273$ against the bound 0.2500, and $D_4 = 0.3519$ and $D_{10} = 0.4473$ against 0.5000.

30.7.4. Interpretation

Table 30.8 and Figure 30.4 compare all four answers for the Gaussian with $\sigma = 10$ per step. The per-step noise is chosen so that $\mu = \sqrt{k}/10$ runs from 0.1 to 10 over $k = 1$ to 10,000, and the exact ε from 0.341 to 91.817: the range where accounting choices matter. Because everything depends only on μ, the row $k = 100$, where $\mu = 1$, repeats the single release at $\sigma = 1$ of the earlier sections.

Table 30.8.: ε at $\delta = 10^{-5}$ for the Gaussian with $\sigma = 10$ composed k times: exact, the best any conversion from the RDP grid can give, the improved conversion and Mironov's.

k	μ	Exact	Optimal from the curve	Improved	Mironov	Ratios to exact (opt. / impr. / Mir.)
1	0.100	0.341	0.375	0.375	0.485	1.10 / 1.10 / 1.42
10	0.316	1.199	1.308	1.308	1.568	1.09 / 1.09 / 1.31
100	1.000	4.377	4.729	4.729	5.299	1.08 / 1.08 / 1.21
1000	3.162	17.857	19.054	19.054	20.175	1.07 / 1.07 / 1.13
10,000	10.000	91.817	96.116	96.116	98.026	1.05 / 1.05 / 1.07

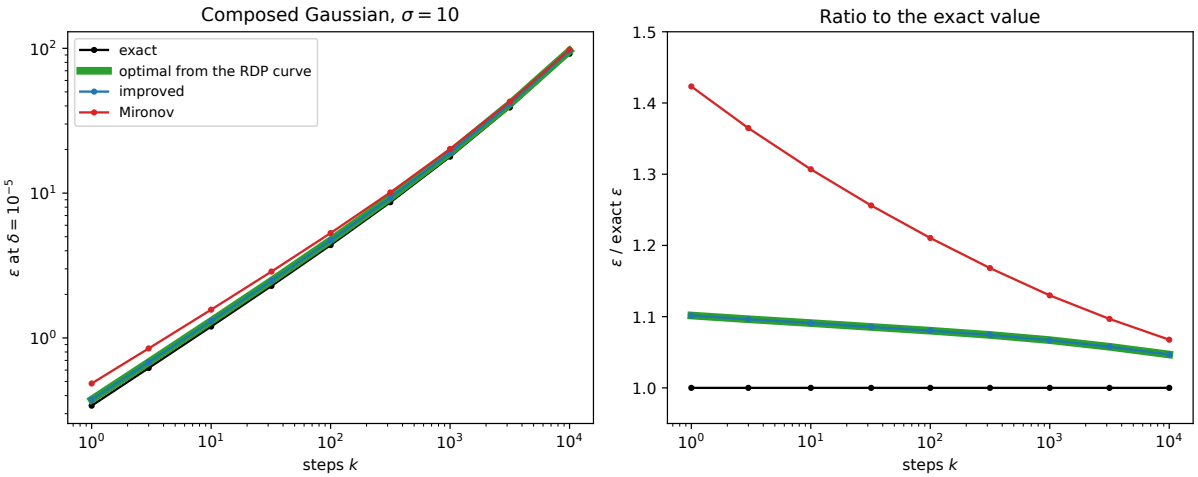

Figure 30.4.: Left: ε at $\delta = 10^{-5}$ for the Gaussian with $\sigma = 10$ composed k times, exact (black), optimal from the RDP curve (wide green), improved (blue, on top of the green) and Mironov (red). Right: each divided by the exact value. The improved conversion is optimal for the curve; the remaining 5 to 10% belongs to the RDP summary itself.

The optimal and improved conversions coincide. At $\mu = 1$ they are 4.728505 and 4.728507, a difference of 2×10^{-6}. The optimal conversion can use all orders at once, but that helps only if

more than one order constrains the worst mechanism. Here it buys nothing measurable over the best single order: at $\varepsilon = 4.377$ the grid's worst pair is held back only by the constraint at order 5.1, and every other order of the grid leaves at least 0.0011 of room.

Mironov's excess shrinks fast with k, the unavoidable excess slowly. Mironov is 42% above the exact value at $k = 1$ and 7% at $k = 10{,}000$; the RDP summary costs 10% and 5%. Both shrink in relative terms because for large μ the $\rho\alpha$ part, which every method shares, dominates.

When the slack matters, change the summary, not the formula. To get the exact 4.377 you must track more than an MGF: the trade-off function (Gaussian DP) or the full privacy loss distribution (numerical accounting).

The 5 to 10% is for the plain Gaussian. The differentially private version of stochastic gradient descent (SGD), DP-SGD, composes subsampled Gaussian steps, in which each step uses a random fraction q of the records, and their RDP curve is not a line. Subsampling applies the same conversions to the part's running example ($q = 0.01$, $\sigma = 1$): 7.43 with Mironov's conversion and 6.71 with the improved one after $T = 10{,}000$ steps. There the gap to the exact value can be much larger, and choosing an accountant measures it.

30.7.5. Example: what to tell a reviewer

Your paper reports $(4.729, 10^{-5})$-DP from an RDP accountant for a mechanism that is in fact a Gaussian with $\mu = 1$. A reviewer asks whether a better conversion would lower it. The answer is no. The two-outcome mechanism of Table 30.7 satisfies the same RDP curve and has $\delta = 4.4698 \times 10^{-5}$ at $\varepsilon = 4.377$, so any certificate computed from the curve alone must also hold for it. The same construction at $\delta = 10^{-5}$ gives a pair inside the curve at every order whose ε is 4.728376, and the improved conversion at the best real order, 5.4318, gives 4.728387. The first is a mechanism that a certificate must cover, so the best certificate is at least 4.728376; the second is a valid certificate, so the best is at most 4.728387. So the best value any method can certify from the curve at every real order lies between 4.728376 and 4.728387, which is 4.7284 to four decimals; a method that sees only the grid's orders must report at least 4.728505. A lower number needs an accountant that sees the mechanism, and for the Gaussian that number is 4.377.

30.7.6. Check yourself

- Does the two-outcome mechanism contradict the Gaussian's $\delta = 10^{-5}$ at $\varepsilon = 4.377$? *(No. It is a different mechanism that satisfies the same RDP curve. The conversion must cover both, so it cannot certify the smaller δ for either.)*
- A mechanism is $(1, 10^{-8})$-DP. What RDP curve does that give you? *(None: $\delta > 0$ allows a rare event with infinite privacy loss, and claim 2 shows that makes every D_α infinite. You need to know how the δ arises, for example from Gaussian noise, to get an RDP curve.)*

30.8. Code: check every conversion by computation

The script code/rdp_conversions.py computes every number in this chapter and draws its figures. The conversions are small typed functions: `rdp_to_dp_mironov` and `rdp_to_dp_improved`

return the best ε and order over a grid, `rdp_to_delta_improved` goes the other way, `rdp_tradeoff_lower_bound` computes f_{RDP} by bisection in logarithms, `rdp_to_dp_tradeoff` maximizes Equation 30.12, `continuous_worst_pair` builds the two-outcome pair of Table 30.7 and `max_gaussian_curve_excess` checks it against the curve at every real order, and `gaussian_delta_exact` and `gaussian_eps_exact` give the exact Gaussian answers. From the repository root:

```
uv run python code/part04-privacy-accounting/rdp_conversions.py
```

Output (seed 0; nothing is random):

Table 30.9.: Results printed by the script.

Experiment	Result
Fact 1, Gaussian $\mu = 1$, $\varepsilon = 1$	closed form 1.2694×10^{-1}; Riemann sum 1.2694×10^{-1}
Mironov at $\mu = 1$	5.299 at order 5.8; continuous optimum 5.299 at 5.799
Optimal constant at $\alpha = 6$, $\varepsilon = 4$	formula 1.380552×10^{-10}; grid 1.380552×10^{-10}
Improved at $\mu = 1$	4.729 at order 5.4; exact 4.377
Single order 2, $\varepsilon(2) = 1$	Mironov 12.513, improved 11.127, optimal 10.668
Power at FPR $= 10^{-3}$, $\mu = 1$	true 1.8298×10^{-2}; RDP allows 2.4910×10^{-2}
Best order, $\rho = 5000$	continuous 1.048; grid 1.1
Optimal from the curve vs improved, $\mu = 1$	4.728505 and 4.728507
Worst two-outcome pair at $\varepsilon = 4.377$	grid orders only: $\delta = 4.4700 \times 10^{-5}$; every real order: $\delta = 4.4698 \times 10^{-5}$, largest excess over $\alpha/2$ is -9.97×10^{-6}
Worst pair at $\delta = 10^{-5}$, every real order	$\varepsilon = 4.728376$; improved at order 5.4318: 4.728387
Randomized response $\varepsilon = 0.5$, order 2	$D_2 = 0.2273 \leq 0.2500$

tests/test_rdp_conversions.py checks that the output still matches Table 30.9 and every other number in the text.

What to take from it. The improved conversion is free and nearly optimal: it agrees with the optimal conversion from the curve to three decimals at every k of Table 30.8, and at $\mu = 1$ the two differ by 2×10^{-6}. The gap that remains to the exact value is real, because a concrete two-outcome mechanism with the same curve realizes it, so no formula can close it. What still matters is the grid, where it is sparse or ends: very long runs push the best order below 1.1, and very short ones push it into the sparse stretch between 63 and 512, or beyond 512.

30.10. Cheat sheet

Table 30.10 collects every result in the chapter.

Table 30.10.: Every result in this chapter.

Result	Statement	Where it comes from
δ as an expectation	$\delta(\varepsilon) = \mathbb{E}_P[(1 - e^{\varepsilon - L})_+]$	Hockey-stick divergence
RDP as an MGF	$\mathbb{E}_P[e^{(\alpha-1)L}] = e^{(\alpha-1)D_\alpha(P\|Q)}$	Definition of D_α
Mironov	$\varepsilon' = \varepsilon(\alpha) + \ln(1/\delta)/(\alpha - 1)$	Indicator, then Markov
Improved	$\varepsilon' = \varepsilon(\alpha) + \ln\frac{\alpha-1}{\alpha} - \frac{\ln\delta + \ln\alpha}{\alpha-1}$; $\delta = \frac{e^{(\alpha-1)(\varepsilon(\alpha)-\varepsilon)}}{\alpha}(1 - \frac{1}{\alpha})^{\alpha-1}$	Smallest exponential above the integrand
Gain at a fixed order	$\Delta(\alpha) = \frac{\ln\alpha}{\alpha-1} + \ln\frac{\alpha}{\alpha-1}$ in ε; factor $\approx 1/(e\alpha)$ in δ	Subtracting the two

Result	Statement	Where it comes from
Test region	$\mathrm{FPR}^{\alpha}(1-\mathrm{FNR})^{1-\alpha}+(1-\mathrm{FPR})^{\alpha}\mathrm{FNR}^{1-\alpha}\le e^{(\alpha-1)\varepsilon(\alpha)}$, and with FPR, FNR swapped	Data processing on the test's outcome
Optimal conversion	$\delta_{\mathrm{opt}}=\max_{\mathrm{FPR}}[1-\mathrm{FPR}-e^{\varepsilon}f_{\mathrm{RDP}}(\mathrm{FPR})]$, attained by a two-outcome pair	Region plus attainment
Best order, linear curve	Mironov $\alpha^*=1+\sqrt{\ln(1/\delta)/\rho}$; improved $\rho(\alpha-1)^2=\ln(1/(\alpha\delta))$	Calculus
Unavoidable slack (Gaussian)	5 to 10% of ε at $\delta=10^{-5}$	A two-outcome pair inside the same curve
$(\varepsilon,\delta)\Rightarrow$ RDP	False for any $\delta>0$	An atom of P that Q lacks
ε-DP $\Rightarrow$ RDP	$\varepsilon(\alpha)\le\min(\varepsilon,\alpha\varepsilon^2/2)$; sharply $\alpha\varepsilon\tanh(\varepsilon/2)$ in place of $\alpha\varepsilon^2/2$	Monotonicity; Bun & Steinke, proved in concentrated DP

Rules of thumb

- Always use the improved conversion. It saves $\Delta(\alpha)$, about 0.36 at order 10, and on the Gaussian it matches the best any method can do with the curve to three decimals.
- Check the best order. If it sits at either end of the grid, extend the grid.
- Expect an RDP accountant to overstate the plain Gaussian's ε by 5 to 10%, and subsampled DP-SGD's by more. If that matters, use a privacy loss distribution accountant.
- Read an RDP guarantee as a bound on tests with the whole region, not with one (ε,δ) line: at low false-positive rates the region is much tighter.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

31. Concentrated differential privacy

31.1. Why this matters

The first chapter of this part describes a mechanism by a whole curve. For two neighbouring datasets D and D', which differ in one person's record, the mechanism's outputs $M(D)$ and $M(D')$ are two probability distributions, and the **Rényi divergence** D_α of order $\alpha > 1$ measures how far apart they are; larger orders put more weight on the outputs where one distribution is much more likely than the other. The **Rényi differential privacy (RDP) curve** $\varepsilon(\alpha)$ is the largest D_α over all neighbouring pairs, one value per order. That is a lot to carry around. For the Gaussian mechanism, which adds normal noise of standard deviation σ to a query whose value moves by at most 1 between neighbours, the curve is a straight line through the origin, $\varepsilon(\alpha) = \alpha/(2\sigma^2)$, and a line through the origin is fixed by its slope. So for the Gaussian you could keep one number instead of a curve. The question of this chapter is: **when does one number describe the whole RDP curve, and what does that number buy you?**

The answer is **zero-concentrated differential privacy (zCDP)**, the most widely used form of concentrated differential privacy (CDP). A mechanism is ρ-zCDP when its RDP curve lies under the line $\rho\alpha$. Three things follow at once, and each comes from a property of the RDP curve that the line inherits. First, composition is addition. When you run several mechanisms one after another, their RDP curves add, so lines through the origin add to a line whose slope is the sum of the slopes: k steps of ρ-zCDP are $k\rho$-zCDP. Second, the privacy loss is "concentrated", which gives the definition its name. The privacy loss is the log of how much more likely an output is under D than under D', and a bound on every Rényi divergence turns out to be a bound on its moment generating function (MGF), the function $\lambda \mapsto \mathbb{E}[e^{\lambda L}]$ that controls how heavy the tails of a random variable L can be. The line $\rho\alpha$ says that the privacy loss has a tail no heavier than a normal variable with mean ρ and variance 2ρ. Third, the conversion to the usual (ε, δ) guarantee has a closed form, $\varepsilon = \rho + 2\sqrt{\rho \ln(1/\delta)}$, because the optimization over orders that the conversion requires can be done by hand for a line.

31.1.1. The one idea: a line under the curve

Everything in this chapter is about **how well a line $\rho\alpha$ fits a mechanism's RDP curve**. For the Gaussian the line is the curve, and nothing is lost. A pure differential privacy (DP) mechanism, one whose output probabilities change by at most a factor e^ε between neighbours, has a curve that bends over and flattens at ε, because no Rényi divergence can exceed the largest log-ratio of probabilities. A line through the origin fits such a curve only near $\alpha = 1$; the fit costs a little there and a lot at large orders. For the subsampled Gaussian of differentially private stochastic gradient descent (SGD), DP-SGD for short, where each step runs on a small random sample of the data, the curve is tiny at small orders and then bends sharply upwards. Any line that stays above it everywhere is as steep as the line of the Gaussian without subsampling, so

zCDP throws away all of the privacy that subsampling gained. **Truncated CDP** fixes this by asking for the line only on orders up to a cut-off ω.

Table 31.1 lists the results and where each is used.

Table 31.1.: The results of this chapter and where each is used.

Result	Where it is used
Definition of ρ-zCDP; Gaussian is $\Delta^2/(2\sigma^2)$-zCDP; composition adds ρ	Accounting for any pipeline of Gaussian mechanisms with one number, as in the 2020 US Census TopDown algorithm
ε-DP implies $(\varepsilon^2/2)$-zCDP, sharply $(\varepsilon\tanh(\varepsilon/2))$-zCDP; exponential mechanism is $(\varepsilon^2/8)$-zCDP	Mixing Laplace, randomized response and selection steps with Gaussian steps in one budget
ρ-zCDP to (ε, δ): simple and improved conversions	Reporting the final guarantee; calibrating σ to a target ε
Group privacy $m^2\rho$ for groups of m	Protecting households or users with several records; lower bounds
Approximate zCDP	Pipelines that include mechanisms that are only (ε, δ)-DP, such as stability-based ones
No amplification by subsampling; truncated CDP	Why DP-SGD is accounted in RDP, not zCDP; a one-number summary that does amplify

How to read this chapter. The definition and the conversion sections are the core; read them first. The pure-DP section shows how other mechanisms enter a zCDP budget. The subsampling section explains why the rest of this part works with RDP curves and privacy loss distributions instead of a single ρ.

31.2. Toolkit: four facts used below

Each fact is stated here once, with the short reason it holds and a link to where it is derived in full. Throughout, $P = M(D)$ and $Q = M(D')$ are the output distributions on two neighbouring datasets, and $P(y)$, $Q(y)$ are their probabilities (or densities) at an output y.

31.2.1. Fact 1 — Rényi divergence is a log-MGF of the privacy loss

The **privacy loss** at an output y is $\ln(P(y)/Q(y))$: how much more likely y is when the data are D than when they are D', on a log scale. Drawing the output from P makes it a random variable, the **privacy loss random variable** $L = L_{D,D'}(Y)$ with $Y \sim P$. The Rényi divergence of order α is defined as $D_\alpha(P\|Q) = \frac{1}{\alpha-1}\ln\sum_y P(y)^\alpha Q(y)^{1-\alpha}$. Write $P(y)^\alpha Q(y)^{1-\alpha} = P(y)\,(P(y)/Q(y))^{\alpha-1} =$

$P(y)\,e^{(\alpha-1)L(y)}$: the sum is then an average over $Y \sim P$ of $e^{(\alpha-1)L}$. So the Rényi divergence, times $\alpha - 1$, is the log of the MGF of the privacy loss at the point $\alpha - 1$:

$$(\alpha-1)D_\alpha(P\|Q) = \ln \mathbb{E}_P[e^{(\alpha-1)L}]. \tag{31.1}$$

This is Equation 3.12 in Divergences, with the log-likelihood ratio renamed the privacy loss.

31.2.2. Fact 2 — RDP composes by adding curves, and survives post-processing

If M_1 has RDP curve $\varepsilon_1(\alpha)$ and M_2, possibly chosen after seeing the output of M_1, has curve $\varepsilon_2(\alpha)$, the pair has curve at most $\varepsilon_1(\alpha)+\varepsilon_2(\alpha)$. The reason is that the sum $\sum P^\alpha Q^{1-\alpha}$ over pairs of outputs (y_1, y_2) factors: for each first output y_1, the inner sum over y_2 is at most $e^{(\alpha-1)\varepsilon_2(\alpha)}$, whatever M_2 was chosen, and the remaining sum over y_1 is at most $e^{(\alpha-1)\varepsilon_1(\alpha)}$. Exponents multiply, so the divergences add. Also, any function of the output has curve at most $\varepsilon(\alpha)$: this is the data-processing inequality, which says that passing two distributions through the same random map can only make them harder to tell apart. Both are derived in Rényi DP, from additivity and the data-processing inequality for D_α.

31.2.3. Fact 3 — Mironov's conversion from RDP to (ε, δ)

A mechanism is (ε, δ)-DP when, for every set S of outputs, $P(S) \le e^\varepsilon Q(S) + \delta$. One way to get there is to show that the privacy loss exceeds ε with probability at most δ: on outputs where $L \le \varepsilon$ you have $P(y) \le e^\varepsilon Q(y)$, and the rest of S has P-probability at most δ. Markov's inequality applied to $e^{(\alpha-1)L}$ bounds that probability, $\Pr[L > \varepsilon] \le \mathbb{E}[e^{(\alpha-1)L}]e^{-(\alpha-1)\varepsilon} \le e^{(\alpha-1)(\varepsilon(\alpha)-\varepsilon)}$ by Fact 1, and setting the right side equal to δ and solving for ε gives the conversion. A mechanism with $\varepsilon(\alpha)$ at order α is $(\varepsilon(\alpha) + \ln(1/\delta)/(\alpha-1), \delta)$-DP, for every $\delta \in (0, 1)$. Every order gives a valid guarantee, and you pick the order that makes ε smallest. An improved conversion, which avoids the slack of Markov's inequality, subtracts $\ln(\alpha)/(\alpha-1) - \ln(1-1/\alpha)$ from this. Both are derived in From Rényi DP to (ε, δ) and to tests.

31.2.4. Fact 4 — Hoeffding's lemma

A random variable confined to an interval cannot have heavy tails, so its MGF is no larger than that of a normal variable with the same mean and a variance set by the interval's length. Precisely: if $X \in [a, b]$, then $\ln \mathbb{E}[e^{\lambda X}] \le \lambda\mathbb{E}[X] + \lambda^2(b-a)^2/8$ for every real λ. (A normal variable with variance v has $\ln \mathbb{E}[e^{\lambda X}] = \lambda\mathbb{E}[X] + \lambda^2 v/2$, so this is the normal bound with $v = (b-a)^2/4$.) Derived in Concentration.

31.3. The definition of zCDP

31.3.1. Context

You add Gaussian noise to a gradient, a count or a mean, again and again, and you want one number that says how much privacy you have spent so far. The RDP curve of the Gaussian is a line through the origin, and lines add. Bun and Steinke turned this observation into a definition:

describe a mechanism by the slope of a line that lies above its RDP curve. The definition also has a reading in terms of the privacy loss itself, and that reading gives the name.

31.3.2. Statement

A mechanism M is **ρ-zero-concentrated differentially private** (ρ-zCDP) if its RDP curve lies below the line of slope ρ: for all neighbouring $D \sim D'$ and all orders $\alpha > 1$,

$$D_\alpha(M(D) \,\|\, M(D')) \le \rho\alpha. \tag{31.2}$$

Multiplying both sides by $\alpha - 1$ and using Fact 1 turns this into a statement about the privacy loss random variable L: its MGF at every point $\alpha - 1 > 0$ is bounded,

$$\ln \mathbb{E}\big[e^{(\alpha-1)L}\big] \le (\alpha-1)\alpha\rho \quad \text{for all } \alpha > 1. \tag{31.3}$$

A bounded MGF limits how often L can be large, so the privacy loss has a Gaussian-type upper tail: the chance that it exceeds its mean ρ by more than t falls off like a normal tail, as $e^{-t^2/(4\rho)}$,

$$\Pr[L > \rho + t] \le e^{-t^2/(4\rho)} \quad \text{for all } t > 0. \tag{31.4}$$

Three properties make the definition useful. The Gaussian mechanism, which adds $\mathcal{N}(0, \sigma^2)$ to a query with ℓ_2 sensitivity $\Delta = \Delta_2 f$ (the largest Euclidean distance between the query's values on neighbouring datasets), is $\Delta^2/(2\sigma^2)$-zCDP. With the part's noise multiplier convention, which measures σ in units of the sensitivity ($\Delta = 1$), $\rho = 1/(2\sigma^2)$. Composition adds the parameters: if M_1 is ρ_1-zCDP and M_2 is ρ_2-zCDP, possibly chosen adaptively, the pair is $(\rho_1 + \rho_2)$-zCDP. And post-processing is free: any function of a ρ-zCDP output is ρ-zCDP.

31.3.3. Derivation

The first three steps show that the three displays say the same thing at increasing strength; the last two prove the three properties.

1. **The two forms agree.** Multiply Equation 31.2 by $\alpha - 1$, which is positive, so the inequality keeps its direction. By Fact 1 the left side becomes $\ln \mathbb{E}[e^{(\alpha-1)L}]$, and the right side is $(\alpha-1)\alpha\rho$.
2. **The tail bound is a Chernoff bound.** To bound the chance that L is large, apply Markov's inequality to the positive variable $e^{(\alpha-1)L}$, which is large exactly when L is. For any level c, $\Pr[L > c] = \Pr[e^{(\alpha-1)L} > e^{(\alpha-1)c}] \le \mathbb{E}[e^{(\alpha-1)L}]\, e^{-(\alpha-1)c}$. By Equation 31.3 this is at most $\exp\big((\alpha-1)(\alpha\rho - c)\big)$.
3. **Optimize the order.** Step 2 holds for every order, so use the one that gives the smallest bound. Put $c = \rho + t$ and write $\lambda = \alpha - 1$. The exponent is $\lambda(\rho + \lambda\rho - \rho - t) = \lambda^2\rho - \lambda t$, a parabola in λ that is smallest at $\lambda = t/(2\rho)$, where it equals $t^2/(4\rho) - t^2/(2\rho) = -t^2/(4\rho)$. This is Equation 31.4.
4. **Gaussian mechanism.** The output distributions are $\mathcal{N}(f(D), \sigma^2)$ and $\mathcal{N}(f(D'), \sigma^2)$ with $|f(D) - f(D')| \le \Delta$. Two normal distributions with the same variance σ^2 and means s apart have Rényi divergence $D_\alpha = \alpha s^2/(2\sigma^2)$ (Equation 3.15 in Divergences; the sum in Fact 1 becomes a Gaussian integral that you evaluate by completing the square). So $D_\alpha = \alpha(f(D) - f(D'))^2/(2\sigma^2) \le \alpha\Delta^2/(2\sigma^2)$. The same holds in d dimensions with ℓ_2

sensitivity, because the Rényi divergence of two isotropic Gaussians depends only on the distance between their means: rotate the coordinates so the means differ along one axis, and the other axes contribute nothing.

5. **Composition and post-processing.** By Fact 2, the composed curve is at most $\rho_1\alpha+\rho_2\alpha = (\rho_1+\rho_2)\alpha$, a line of slope $\rho_1+\rho_2$, and post-processing does not raise the curve.

Why "concentrated": the Gaussian case by hand. The tail bound says the privacy loss behaves no worse than a normal variable. For the Gaussian mechanism it *is* a normal variable, and the bound holds with equality in every exponential moment. To see this, take $\Delta = 1$, $P = \mathcal{N}(0,\sigma^2)$, $Q = \mathcal{N}(1,\sigma^2)$. The privacy loss at output y is the log of the ratio of the two normal densities; the normalizing constants cancel and only the exponents remain:

$$L(y) = \frac{(y-1)^2 - y^2}{2\sigma^2} = \frac{1-2y}{2\sigma^2}. \tag{31.5}$$

With $Y \sim \mathcal{N}(0,\sigma^2)$, L is a linear function of a normal variable, so it is normal. Its mean is the constant term, $1/(2\sigma^2) = \rho$, and its variance is the square of the coefficient of y times σ^2, that is $4\sigma^2/(4\sigma^4) = 1/\sigma^2 = 2\rho$. A normal variable with mean m and variance v has MGF $e^{\lambda m+\lambda^2 v/2}$, so the MGF of $\mathcal{N}(\rho,2\rho)$ at λ is $e^{\lambda\rho+\lambda^2\rho}$; at $\lambda = \alpha-1$ it is $e^{(\alpha-1)(1+\alpha-1)\rho} = e^{(\alpha-1)\alpha\rho}$. So Equation 31.3 holds **with equality** for every α. A ρ-zCDP mechanism is one whose privacy loss is, in every exponential moment, no worse than a normal with mean ρ and variance 2ρ.

Where the definition came from. Dwork and Rothblum (2016) introduced **concentrated differential privacy** with two parameters (μ,τ). The mean of the privacy loss is at most μ, and the privacy loss minus its mean is **sub-Gaussian** with parameter τ, which means its MGF is no larger than that of a centred normal with variance τ^2: $\mathbb{E}[e^{\lambda(L-\mathbb{E}L)}] \le e^{\lambda^2\tau^2/2}$ for every real λ. Bun and Steinke (2016) call this mean-concentrated DP and replaced it with Equation 31.2, for two reasons. First, the Rényi form follows from properties of D_α (data processing, additivity), so post-processing and composition are immediate; their Appendix A shows that the mean-concentrated definition is *not* closed under post-processing. Second, zCDP is a relaxation of mean-concentrated DP, so nothing that was mean-concentrated is lost. To see this, write $L = \mathbb{E}L + (L-\mathbb{E}L)$ and apply the sub-Gaussian bound with $\lambda = \alpha-1$: this gives $\ln\mathbb{E}[e^{(\alpha-1)L}] \le (\alpha-1)\mu + (\alpha-1)^2\tau^2/2$. Dividing by $\alpha-1$ and using Fact 1 gives $D_\alpha \le \mu + (\alpha-1)\tau^2/2 = (\mu-\tau^2/2) + (\tau^2/2)\alpha$, with equality for the Gaussian mechanism (their Lemma 4.2), where $\mu = \rho$ and $\tau^2 = 2\rho$ make the constant term vanish. In general that is a line with an intercept; Bun and Steinke allow one in a two-parameter (ξ,ρ)-zCDP, but mostly use $\xi = 0$, the one-parameter ρ-zCDP that this book follows. (This μ is unrelated to the μ of Gaussian differential privacy later in this part.)

31.3.4. Interpretation

zCDP is "RDP restricted to lines". Every ρ-zCDP mechanism has an RDP curve, and the curve is at most $\rho\alpha$. Going from a curve to ρ loses information: the smallest valid ρ is the largest ratio $\varepsilon(\alpha)/\alpha$, wherever it occurs, and the rest of the curve is forgotten. The rest of the chapter is about how much that costs.

The tail bound is loose by a polynomial factor. Figure 31.1 shows, for $\sigma = 1$ ($\rho = 0.5$), the simulated privacy loss against $\mathcal{N}(\rho,2\rho)$ and the exact tail against Equation 31.4. Since the loss is exactly $\mathcal{N}(\rho,2\rho)$, the event $L > \rho + t$ is the event that a standard normal exceeds $z = t/\sqrt{2\rho}$, so the exact tail is $\Phi(-t/\sqrt{2\rho})$, where Φ is the standard normal cumulative distribution function.

Both tails fall off like $e^{-t^2/(4\rho)} = e^{-z^2/2}$; the bound misses only the Gaussian tail's polynomial factor. For large z the Mills ratio approximation $\Phi(-z) \approx e^{-z^2/2}/(z\sqrt{2\pi})$ says the exact tail is the bound divided by $z\sqrt{2\pi} = t\sqrt{\pi/\rho}$, so the ratio of the exact tail to the bound is about $\sqrt{\rho/\pi}/t$. At $t = 4$, $z = 4$, the exact tail is $\Phi(-4) = 3.167 \times 10^{-5}$ and the bound $e^{-16/2} = 3.355 \times 10^{-4}$: their ratio is 0.094, against $\sqrt{0.5/\pi}/4 = 0.100$ from the Mills ratio. That gap is one reason the simple conversion of the conversion section (Section 31.5) is loose.

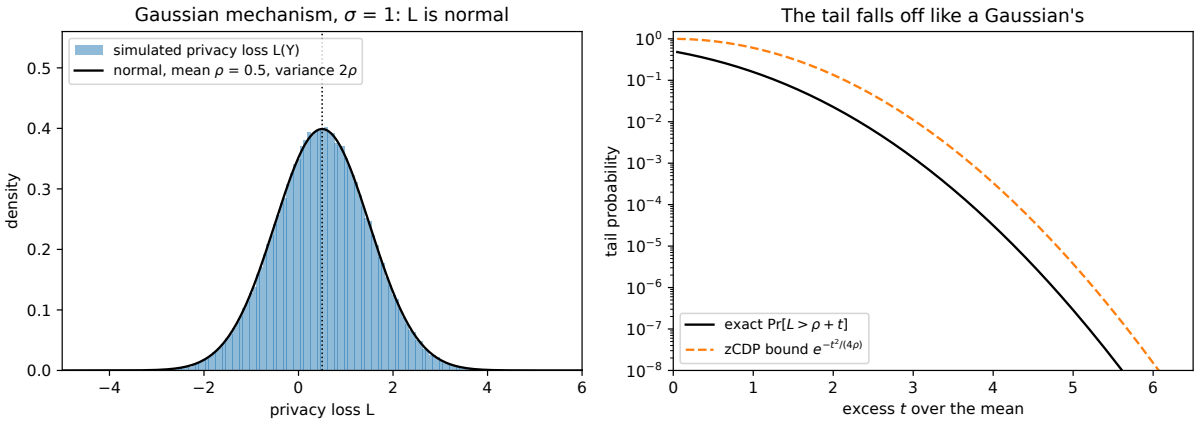

Figure 31.1.: The privacy loss of the Gaussian mechanism with $\sigma = 1$. Left: a histogram of $L(Y)$ from simulation against the normal density with mean $\rho = 0.5$ and variance $2\rho = 1$. Right: the exact upper tail $\Pr[L > \rho + t]$ against the zCDP bound $e^{-t^2/(4\rho)}$, on a log scale.

Where zCDP is used. zCDP is the accounting of choice when a system is built from Gaussian mechanisms on exact, non-subsampled data: statistical releases, query systems and synthetic data from noisy marginals. It is not the accounting of choice for DP-SGD, for the reason of Section 31.8. An example is the 2020 US Census TopDown algorithm, which protects the redistricting data (Abowd et al., 2022). It measures noisy versions of a set of queries ("measurements") under zCDP, using the discrete Gaussian mechanism, which adds integer-valued noise shaped like a normal density so that counts stay integers. It then post-processes the measurements together with **invariants**, statistics that the Census Bureau excluded from the privacy accounting as a matter of policy, into a microdata file. The discrete Gaussian and its zCDP guarantee are from Canonne, Kamath and Steinke (2020), the same paper as the improved conversion; Discrete mechanisms covers it. zCDP suits this setting for three reasons. The budget is split over many queries and geographic levels, and zCDP makes the split a sum of ρ's. The Gaussian's RDP curve is a line, so zCDP loses nothing before the final conversion. And the final conversion to (ε, δ) can be done once, at whatever δ the publisher chooses to report. The invariants are a reminder that the accounted ρ covers only the noisy measurements: anything released exactly, without noise, sits outside the guarantee.

31.3.5. Example: the Gaussian with $\sigma = 1$

With $\rho = 1/(2\sigma^2)$, one Gaussian step with $\sigma = 1$ is 0.5-zCDP; ten of them are $10 \times 0.5 = 5$-zCDP; one step with $\sigma = 2$ is $1/8 = 0.125$-zCDP. A million simulated privacy losses (seed 0) have mean 0.4990 and variance 1.0013, against $\rho = 0.5$ and $2\rho = 1$, and $\ln \mathbb{E}[e^L]$ is 1.0000, against

$(\alpha-1)\alpha\rho = 1$ at $\alpha = 2$. Table 31.2 compares the tail with its bound. With $\rho = 0.5$ the exact column is $\Phi(-t)$ and the bound is $e^{-t^2/2}$: at $t = 1$, $\Phi(-1) = 0.1587$ against $e^{-1/2} = 0.6065$.

Table 31.2.: Upper tail of the Gaussian mechanism's privacy loss, $\sigma = 1$, $\rho = 0.5$: exact, simulated with 10^6 draws, and the zCDP bound Equation 31.4.

t	Exact $\Pr[L > \rho + t]$	Simulated	zCDP bound $e^{-t^2/(4\rho)}$
1	1.587×10^{-1}	1.586×10^{-1}	6.065×10^{-1}
2	2.275×10^{-2}	2.261×10^{-2}	1.353×10^{-1}
4	3.167×10^{-5}	2.700×10^{-5}	3.355×10^{-4}

31.3.6. Check yourself

- A mechanism adds $\mathcal{N}(0, 4)$ noise to a count with sensitivity 1, and then a second mechanism adds $\mathcal{N}(0, 1)$ noise to another count. What is the total ρ? *($1/8 + 1/2 = 0.625$. The first has variance 4, so $\sigma = 2$ and $\rho = 1/(2 \cdot 4)$; the second has $\sigma = 1$ and $\rho = 1/2$; composition adds them.)*
- Does ρ-zCDP bound the lower tail of the privacy loss, $\Pr[L < -t]$? *(Yes, through the other order of the pair. Equation 31.3 only uses positive exponents, so it says nothing directly about large negative values. But the definition also holds with D and D' swapped, and a change of measure connects the two: for $\alpha > 1$, $\mathbb{E}_P[e^{-\alpha L}] = \sum_y P(y)(Q(y)/P(y))^\alpha = \sum_y P(y)^{1-\alpha}Q(y)^\alpha = e^{(\alpha-1)D_\alpha(Q\|P)} \le e^{(\alpha-1)\alpha\rho}$. Chernoff, as in steps 2 and 3, applied to $-L$ then gives $\Pr[L < -t] \le e^{-(t+\rho)^2/(4\rho)}$ for $t \ge \rho$. A weaker bound holds for every pair, zCDP or not: $\Pr_P[L < -t] \le e^{-t}$, because $P(y) < e^{-t}Q(y)$ on that event, and the Q-probabilities sum to at most 1.)*

31.4. Pure DP implies zCDP

31.4.1. Context

A real pipeline mixes mechanisms. A Laplace count, a randomized-response survey bit and an exponential-mechanism selection are ε-DP, not Gaussian: for neighbouring datasets, the probability of any output changes by at most a factor e^ε. To put them in the same budget as Gaussian steps, you need their ρ. A pure ε-DP mechanism has a bounded privacy loss, $|L| \le \varepsilon$, because the log of a ratio between $e^{-\varepsilon}$ and e^ε lies between $-\varepsilon$ and ε. A bounded variable has light, Gaussian-like tails (Hoeffding's lemma, Fact 4). So it should be zCDP with ρ of order ε^2. The question is the constant.

31.4.2. Statement

If M is ε-DP, then M is $(\varepsilon^2/2)$-zCDP (Bun & Steinke 2016, Proposition 1.4). The RDP curve of an ε-DP mechanism is also capped at ε, because every Rényi divergence is at most the max-divergence

D_∞, the largest log-ratio $\ln(P(y)/Q(y))$, which is at most ε: $D_\alpha \le D_\infty \le \varepsilon$. Together, its RDP curve lies under both the line and the cap:

$$\varepsilon(\alpha) \le \min\left(\varepsilon,\ \frac{\alpha\varepsilon^2}{2}\right). \tag{31.6}$$

The constant can be sharpened. The worst ε-DP mechanism turns out to be randomized response, which reports a bit truthfully with probability $e^\varepsilon/(1+e^\varepsilon)$ and flips it otherwise, and its slope gives the sharp constant. Every ε-DP mechanism is $(\varepsilon\tanh(\varepsilon/2))$-zCDP,

$$\varepsilon(\alpha) \le \alpha\,\varepsilon\tanh(\varepsilon/2), \tag{31.7}$$

and randomized response shows that no smaller ρ holds for every ε-DP mechanism. Since $\tanh x \le x$ for $x \ge 0$, $\varepsilon\tanh(\varepsilon/2) \le \varepsilon\cdot\varepsilon/2 = \varepsilon^2/2$, with ratio tending to 1 as $\varepsilon \to 0$, where $\tanh x \approx x$.

For the exponential mechanism, which selects one candidate from a list and favours candidates with higher scores, the constant is four times smaller: an ε-DP exponential mechanism is $(\varepsilon^2/8)$-zCDP (Cesar & Rogers 2021, the remark after Lemma 3.4). The reason is the bounded-range property of Durfee & Rogers (2019): its privacy loss lies in an interval of length ε, not 2ε.

31.4.3. Derivation

Fix neighbours, write $P = M(D)$, $Q = M(D')$, and $L = \ln(P(y)/Q(y))$ under P, where $P(y)$ and $Q(y)$ are the densities (capital letters, because q is the sampling rate later in this chapter).

The constant $\frac{1}{2}$, by Hoeffding. The plan is to bound the MGF of L with Hoeffding's lemma. Hoeffding needs the mean of L, so the first job is to bound that mean, and Hoeffding does that too.

1. **The privacy loss is bounded.** ε-DP for both orders of the pair means $e^{-\varepsilon} \le P(y)/Q(y) \le e^\varepsilon$ wherever either density is positive. So $L \in [-\varepsilon, \varepsilon]$, and P, Q have the same support: neither can be positive where the other is zero.
2. **The mean is at most $\varepsilon^2/2$.** Apply Hoeffding's lemma (Fact 4) to $X = -L$, which lies in an interval of length 2ε, with $\lambda = 1$: $\ln \mathbb{E}_P[e^{-L}] \le -\mathbb{E}_P[L] + (2\varepsilon)^2/8$. The left side is known exactly. $e^{-L} = Q(Y)/P(Y)$, and its average under P is $\sum_y P(y)\,Q(y)/P(y) = \sum_y Q(y) = 1$, because the supports agree (Fact 1 of Divergences). So $0 \le -\mathbb{E}_P[L] + \varepsilon^2/2$: the Kullback–Leibler (KL) divergence $\mathbb{E}_P[L]$, the average privacy loss, is at most $\varepsilon^2/2$.
3. **The MGF is sub-Gaussian.** Hoeffding's lemma again, now for L itself with $\lambda = \alpha - 1$: $\ln \mathbb{E}_P[e^{(\alpha-1)L}] \le (\alpha-1)\mathbb{E}_P[L] + (\alpha-1)^2(2\varepsilon)^2/8 = (\alpha-1)\mathbb{E}_P[L] + (\alpha-1)^2\varepsilon^2/2$.
4. **Combine.** Put the mean bound of step 2 into step 3: the right side is at most $(\alpha-1)\varepsilon^2/2 + (\alpha-1)^2\varepsilon^2/2 = (\alpha-1)(1+\alpha-1)\,\varepsilon^2/2 = (\alpha-1)\alpha\,\varepsilon^2/2$. That is Equation 31.3 with $\rho = \varepsilon^2/2$.
