5. **The cap.** D_α is non-decreasing in α with limit $D_\infty \le \varepsilon$ (Divergences). Larger orders weight the largest likelihood ratios more, and in the limit only the largest one, at most e^ε, counts. That gives the other term of the minimum.

The sharp constant, through randomized response. Hoeffding treats L as an arbitrary bounded variable, which wastes something. The sharper route shows that randomized response is the worst case, then computes its MGF exactly.

6. **Reduce to randomized response.** Every ε-DP pair is a post-processing of ε-randomized response. That is, if $P^\star$ and $Q^\star$ are the output distributions of randomized response on the bits 0 and 1, there is a single random map K from $\{0,1\}$ to outputs with $P = P^\star K$ and $Q = Q^\star K$. Composition (Section 21.4) gives the channel K explicitly (Equation 21.12). By the data-processing inequality for D_α (Fact 2), passing both distributions through K cannot increase their divergence, so $D_\alpha(P\|Q) \le D_\alpha(P^\star\|Q^\star)$ at every order. It is enough to bound the curve of randomized response.
7. **The MGF of randomized response.** Under $P^\star$ the truthful answer has probability $p = e^\varepsilon/(1+e^\varepsilon)$, and its likelihood ratio is $p/(1-p) = e^\varepsilon$. So the privacy loss is $+\varepsilon$ with probability p and $-\varepsilon$ otherwise. With $\lambda = \alpha - 1$, the MGF is $p\,e^{\lambda\varepsilon} + (1-p)\,e^{-\lambda\varepsilon}$, which is

$$\mathbb{E}[e^{\lambda L}] = \frac{e^{(\lambda+1)\varepsilon} + e^{-\lambda\varepsilon}}{1+e^\varepsilon} = \frac{\cosh\left((\lambda+\frac{1}{2})\varepsilon\right)}{\cosh(\varepsilon/2)}. \tag{31.8}$$

   For the second equality, factor $e^{\varepsilon/2}$ out of the numerator and the denominator: the numerator is $e^{\varepsilon/2}(e^{(\lambda+\frac{1}{2})\varepsilon} + e^{-(\lambda+\frac{1}{2})\varepsilon}) = 2e^{\varepsilon/2}\cosh\left((\lambda+\frac{1}{2})\varepsilon\right)$ and the denominator is $e^{\varepsilon/2}(e^{-\varepsilon/2}+e^{\varepsilon/2}) = 2e^{\varepsilon/2}\cosh(\varepsilon/2)$.
8. **A concavity bound.** You want the log of step 7 to be at most $\rho\,\lambda(\lambda+1)$. Write $x = (\lambda+\frac{1}{2})\varepsilon$ and $a = \varepsilon/2$. Then $x^2 - a^2 = \varepsilon^2((\lambda+\frac{1}{2})^2 - \frac{1}{4}) = \varepsilon^2(\lambda^2+\lambda)$ is exactly a multiple of $\lambda(\lambda+1)$, so a bound on $\ln\cosh x - \ln\cosh a$ that is linear in $x^2 - a^2$ gives the right shape. That suggests looking at $\ln\cosh$ as a function of x^2. Let $h(u) = \ln\cosh\sqrt{u}$ for $u > 0$. By the chain rule its derivative is $h'(u) = \tanh(\sqrt{u})/(2\sqrt{u})$, which is decreasing, because $\tanh(y)/y$ is decreasing for $y > 0$ (its derivative has the sign of $y - \sinh y\cosh y < 0$). A function with decreasing derivative is concave, and a concave function lies below its tangent line. The tangent at $u_0 = a^2$ has slope $h'(a^2) = \tanh(a)/(2a)$, so

$$\ln\cosh x - \ln\cosh a \le (x^2 - a^2)\frac{\tanh a}{2a}. \tag{31.9}$$

   With $x^2 - a^2 = \varepsilon^2(\lambda^2+\lambda)$ and $\tanh(a)/(2a) = \tanh(\varepsilon/2)/\varepsilon$, the right side is $\lambda(\lambda+1)\,\varepsilon\tanh(\varepsilon/2) = (\alpha-1)\alpha\,\varepsilon\tanh(\varepsilon/2)$. With step 7 that is Equation 31.3 with $\rho = \varepsilon\tanh(\varepsilon/2)$, and step 6 carries it to every ε-DP pair: Equation 31.7.
9. **No smaller ρ.** As $\alpha \to 1$, any RDP curve tends to the KL divergence, the mean privacy loss. For randomized response that mean is $\varepsilon p - \varepsilon(1-p) = \varepsilon(2p-1) = \varepsilon\frac{e^\varepsilon-1}{e^\varepsilon+1} = \varepsilon\tanh(\varepsilon/2)$. So $\varepsilon(\alpha)/\alpha$ tends to $\varepsilon\tanh(\varepsilon/2)$, and any smaller slope fails near $\alpha = 1$.

So the naive Hoeffding route already gives the constant $\frac{1}{2}$; the only care needed is to bound the mean with Hoeffding too, through $\mathbb{E}_P[e^{-L}] = 1$. Bun and Steinke prove the same result differently: they replace the likelihood ratio by a two-point variable on $\{e^{-\varepsilon}, e^\varepsilon\}$ with the same mean (Jensen's inequality, which says that for a convex function the average of the function is at least the function of the average, so spreading the ratio to the endpoints can only increase the moments), compute its moments in closed form with sinh, and finish with an inequality between hyperbolic sines. Earlier, Dwork and Rothblum bounded the mean by the slightly weaker $\frac{1}{2}\varepsilon(e^\varepsilon - 1)$. You might hope to get the sharp constant just by putting the sharp mean bound into step 4. That bound, Equation 21.14, says the KL divergence of any ε-DP pair is at most $\varepsilon\tanh(\varepsilon/2)$, by the same data-processing argument as step 6. It is not enough on its own: it gives $\varepsilon(\alpha) \le \varepsilon\tanh(\varepsilon/2) + (\alpha-1)\varepsilon^2/2$, a line with the same slope $\varepsilon^2/2$ that starts a little lower, and not of the form $\rho\alpha$. The slope comes from Hoeffding's variance term, which is what steps 6 to 8 avoid: they bound every exponential moment at once.

The exponential mechanism. Its privacy loss lies in an interval $[c-\varepsilon, c]$ of length ε, not 2ε, for some c that depends on the pair (the bounded-range property). Steps 2 to 4 go through with the shorter interval, and the constant $(b-a)^2/8$ in Hoeffding's lemma drops from $(2\varepsilon)^2/8$ to $\varepsilon^2/8$. Hoeffding with $\lambda = 1$ and $\mathbb{E}_P[e^{-L}] = 1$ give $0 \le -\mathbb{E}_P[L] + \varepsilon^2/8$, so $\mathbb{E}_P[L] \le \varepsilon^2/8$. (The same identity forces $c - \varepsilon \le 0 \le c$: if L were always positive, e^{-L} would always be below 1 and could not average to 1, and likewise if it were always negative. So the interval contains 0, the supports agree, and the mechanism is also ε-DP.) Step 3 with length ε gives $(\alpha-1)^2\varepsilon^2/8$, and the sum is $(\alpha-1)\varepsilon^2/8 + (\alpha-1)^2\varepsilon^2/8 = (\alpha-1)\alpha\,\varepsilon^2/8$: the mechanism is $(\varepsilon^2/8)$-zCDP. Cesar and Rogers bound the mean with a result of Dong, Durfee & Rogers (2020) instead. The bound is nearly tight. The script computes $D_\alpha/(\alpha\varepsilon^2/8)$, the fraction of the bound actually used, for the two-outcome bounded-range mechanisms of Cesar & Rogers's Definition 2.4, over $c \in (0, \varepsilon)$, $\alpha \in (1, 10^2]$ and both directions. The largest value is 0.9965 at $\varepsilon = 0.5$, 0.9864 at $\varepsilon = 1$ and 0.8348 at $\varepsilon = 4$, each at the smallest order checked: the worst case is the mean, as $\alpha \to 1$.

31.4.4. Interpretation

One curve covers every ε-DP mechanism. Step 6 says more than Equation 31.7. Since every ε-DP pair is a post-processing of randomized response, the exact RDP curve of ε-randomized response is a valid RDP curve for *every* ε-DP mechanism, at every order. An RDP accountant can charge each pure-DP step that curve, which is below both the cap ε and the line $\alpha\varepsilon\tanh(\varepsilon/2)$, instead of $\min(\varepsilon, \alpha\varepsilon^2/2)$. Randomized response is the worst ε-DP mechanism at every order.

$\varepsilon^2/2$ is sharp only as $\varepsilon \to 0$. For randomized response the smallest valid ρ is $\varepsilon\tanh(\varepsilon/2)$ (steps 8 and 9): 0.1225 against $\varepsilon^2/2 = 0.1250$ at $\varepsilon = 0.5$, and 0.4621 against 0.5000 at $\varepsilon = 1$. The script confirms it numerically: the largest $\varepsilon(\alpha)/\alpha$ on a fine grid of orders is the KL divergence. Since $\tanh(x) \approx x$ for small x, the ratio tends to 1. Mechanisms other than randomized response can need less: the Laplace mechanism needs 0.3679 at $\varepsilon = 1$ (Exercise 1 in the exercise book).

The line is a poor fit far from $\alpha = 1$. Figure 31.2 draws the exact curve of randomized response, both zCDP lines and the cap. At $\varepsilon = 1$ the line $\alpha\varepsilon^2/2$ is close near $\alpha = 1$ but crosses the cap where $\alpha\varepsilon^2/2 = \varepsilon$, that is at $\alpha = 2/\varepsilon = 2$. Beyond that, the pure-DP cap ε is the better bound, and the true curve is below both. At $\varepsilon = 3$ the line $\alpha\varepsilon^2/2$ starts above the cap: its slope $\varepsilon^2/2 = 4.5$ already exceeds $\varepsilon = 3$ at $\alpha = 1$, so it is worse than ε at every order. The sharp line starts at the KL divergence, below the cap, but crosses it almost at once. An RDP accountant keeps the exact curve, or $\min(\varepsilon, \alpha\varepsilon^2/2)$; a zCDP accountant can keep only a line. For mechanisms with large ε, as in local DP, where each user randomizes their own data, describe them by their RDP curve or their ε, not by ρ.

31.4.5. Example: randomized response at $\varepsilon = 1$

The truthful-report probability is $e/(1+e) = 0.7311$. Table 31.3 compares the exact curve with the bounds. The second column is the Hoeffding bound with the sharp mean, $\varepsilon\tanh(\varepsilon/2) + (\alpha-1)\varepsilon^2/2$ with $\varepsilon\tanh(1/2) = 0.4621$; it sits $0.5 - 0.4621 = 0.0379$ below the zCDP line at every order, because both have slope $\varepsilon^2/2 = 0.5$.

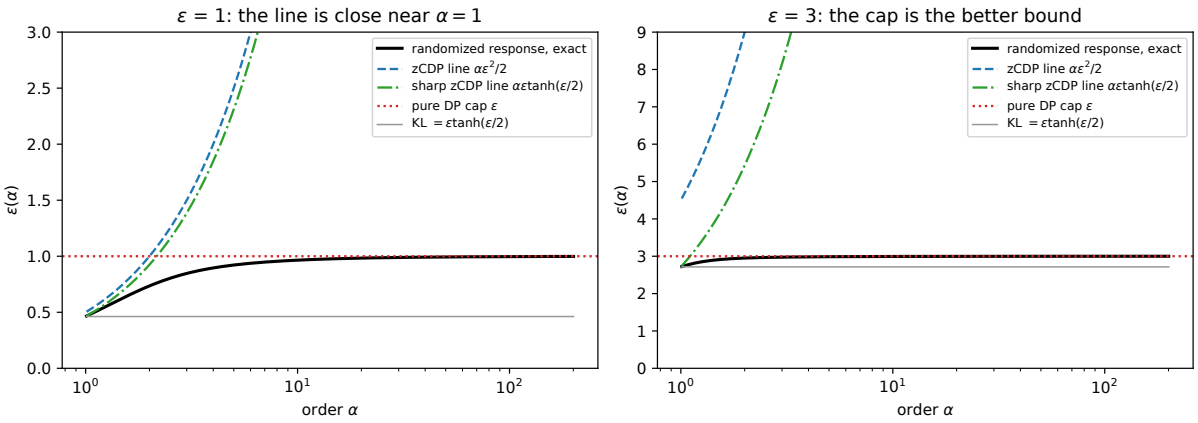

Figure 31.2.: The RDP curve of randomized response (black) against the zCDP line $\alpha\varepsilon^2/2$ (dashed), the sharp zCDP line $\alpha\varepsilon\tanh(\varepsilon/2)$ (dash-dotted) and the pure-DP cap ε (dotted), for $\varepsilon = 1$ (left) and $\varepsilon = 3$ (right). The grey line is the KL divergence $\varepsilon\tanh(\varepsilon/2)$, the curve's value at $\alpha \to 1$.

Table 31.3.: Randomized response at $\varepsilon = 1$: the exact RDP curve against the Hoeffding bound with the sharp mean, the zCDP line and the line capped at ε.

α	Exact $\varepsilon(\alpha)$	$\varepsilon\tanh(\varepsilon/2) + (\alpha-1)\varepsilon^2/2$	$\alpha\varepsilon^2/2$	$\min(\varepsilon, \alpha\varepsilon^2/2)$
1.5	0.6273	0.7121	0.7500	0.7500
2	0.7353	0.9621	1.0000	1.0000
5	0.9217	2.4621	2.5000	1.0000
10	0.9652	4.9621	5.0000	1.0000
50	0.9936	24.9621	25.0000	1.0000

Up to $\alpha = 2$ the line is within 36% of the exact value ($1.0000/0.7353 = 1.360$); at $\alpha = 50$ it is 25 times too large ($25.0000/0.9936 = 25.2$), while the cap is within 1% ($1.0000/0.9936 = 1.0064$).

31.4.6. Check yourself

- A Laplace mechanism is 0.1-DP. What ρ do you charge for it in a zCDP budget? *($\varepsilon^2/2 = 0.01/2 = 0.005$, or slightly less with the sharp $\varepsilon\tanh(\varepsilon/2)$.)*
- Why can't zCDP describe a 5-DP mechanism well? *(Charged $\varepsilon^2/2 = 12.5$, its line lies above the cap $\varepsilon = 5$ at every order $\alpha > 1$ (because $12.5\alpha > 5$). The sharp $\rho = 5\tanh(2.5) = 4.9331$ helps little: the line 4.9331α passes 5 at $\alpha = 5/4.9331 = 1.0136$. Converting either gives a worse ε than the 5 you started with.)*

31.5. From zCDP to (ε, δ)

31.5.1. Context

Whatever you account in, you report (ε, δ). Fact 3 turns an RDP curve into (ε, δ): each order α gives a valid $\varepsilon = \varepsilon(\alpha) + \ln(1/\delta)/(\alpha - 1)$, and you take the best order. For a ρ-zCDP mechanism the RDP curve is known in closed form, $\rho\alpha$, so that optimization over α can be done by hand. The result is the formula most papers quote. The improved conversion of Fact 3 has no closed form but is easy to minimize numerically.

31.5.2. Statement

Putting the line $\rho\alpha$ into Mironov's conversion and choosing the best order gives the simple conversion (Section D.4 in the appendices derives it from scratch, with worked numbers). A ρ-zCDP mechanism is (ε, δ)-DP for every $\delta \in (0, 1)$ with

$$\varepsilon = \rho + 2\sqrt{\rho \ln(1/\delta)}, \tag{31.10}$$

attained at $\alpha^* = 1 + \sqrt{\ln(1/\delta)/\rho}$ (Bun & Steinke 2016, Proposition 1.3). Putting the same line into the improved conversion (Canonne, Kamath & Steinke 2020, Proposition 12 and Corollary 13) gives a smaller ε, as a minimum over orders that has to be computed numerically:

$$\varepsilon = \min_{\alpha > 1} \left[\rho\alpha + \frac{\ln(1/\delta)}{\alpha - 1} + \ln\left(1 - \frac{1}{\alpha}\right) - \frac{\ln \alpha}{\alpha - 1} \right]. \tag{31.11}$$

For calibration you need the reverse: the largest ρ whose simple conversion stays within a target ε at δ. Solving Equation 31.10 for ρ, a target ε at δ is met by any

$$\rho \le \left(\sqrt{\varepsilon + \ln(1/\delta)} - \sqrt{\ln(1/\delta)} \right)^2. \tag{31.12}$$

31.5.3. Derivation

1. **Plug the line into Mironov's conversion.** By Fact 3 with $\varepsilon(\alpha) = \rho\alpha$, every $\alpha > 1$ gives a valid ε: $g(\alpha) = \rho\alpha + \ell/(\alpha - 1)$, where $\ell = \ln(1/\delta)$. The first term grows with the order and the second shrinks, so there is a best order in between.
2. **Minimize.** $g'(\alpha) = \rho - \ell/(\alpha - 1)^2$ is zero at $\alpha - 1 = \sqrt{\ell/\rho}$. Both terms of g are convex on $\alpha > 1$ (a line, and a positive multiple of $1/(\alpha - 1)$), so g is convex and this stationary point is the minimum.
3. **Evaluate.** At $\alpha^* = 1 + \sqrt{\ell/\rho}$, the first term is $\rho\alpha^* = \rho + \rho\sqrt{\ell/\rho} = \rho + \sqrt{\rho\ell}$ and the second is $\ell/\sqrt{\ell/\rho} = \ell\sqrt{\rho/\ell} = \sqrt{\rho\ell}$. Their sum is $\rho + 2\sqrt{\rho\ell}$, which is Equation 31.10. Bun and Steinke reach the same formula through the tail bound: by Equation 31.4 with $t = 2\sqrt{\rho\ell}$, $\Pr[L > \varepsilon] \le e^{-4\rho\ell/(4\rho)} = \delta$ for this ε, and a privacy loss that exceeds ε with probability at most δ gives (ε, δ)-DP (the argument of Fact 3; see also Composition).
4. **The improved form** is Fact 3's improved conversion with $\varepsilon(\alpha) = \rho\alpha$. Its derivation is in From Rényi DP to (ε, δ) and to tests. The script minimizes it over a fine continuous grid of 20,001 log-spaced orders from $1 + 10^{-4}$ to $1 + 10^4$, and, for comparison, over the part's grid `ORDERS`, the fixed list of orders on which this part's accountants store RDP curves.

5. **Inversion.** Write $x = \sqrt{\rho}$. Equation 31.10 reads $x^2 + 2x\sqrt{\ell} = \varepsilon$. Adding ℓ to both sides completes the square: $(x + \sqrt{\ell})^2 = \varepsilon + \ell$. Take the positive root, $x = \sqrt{\varepsilon + \ell} - \sqrt{\ell}$, and square it. Since the simple ε grows with ρ, any smaller ρ also meets the target.

31.5.4. Interpretation

For a Gaussian, every bit of slack is in the conversion. Dividing the output of a Gaussian mechanism by σ changes nothing about privacy, because the map can be undone. After the division the two output distributions are $\mathcal{N}(0,1)$ and $\mathcal{N}(\mu,1)$ with $\mu = \Delta/\sigma$, and $\rho = \Delta^2/(2\sigma^2) = \mu^2/2$. So a ρ-zCDP Gaussian mechanism is the pair $\mathcal{N}(0,1)$ vs $\mathcal{N}(\mu,1)$ with $\mu = \sqrt{2\rho}$, the μ of μ-Gaussian differential privacy (GDP) in f-DP and Gaussian differential privacy. For this pair the exact (ε,δ) trade-off is known. The **privacy profile** $\delta(\varepsilon)$ is the smallest δ for which the mechanism is (ε,δ)-DP, the largest value of $P(S) - e^{\varepsilon}Q(S)$ over sets of outputs S. The best set is the outputs where the privacy loss exceeds ε, so $\delta(\varepsilon) = \Pr_P[L > \varepsilon] - e^{\varepsilon}\Pr_Q[L > \varepsilon]$. The privacy loss is normal with mean $\mu^2/2$ and variance μ^2 under P (as in Section 31.3), and with mean $-\mu^2/2$ under Q, so each probability is a value of Φ (The Laplace and Gaussian mechanisms):

$$\delta(\varepsilon) = \Phi\Big(\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) - e^{\varepsilon}\,\Phi\Big(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big). \tag{31.13}$$

The zCDP line is exact for the Gaussian, so the gap between Equation 31.10 and the exact ε from Equation 31.13 is the price of the conversion alone. Figure 31.3 shows it. The simple formula is 21% too large at $\rho = 0.5$ (ratio $5.299/4.377 = 1.210$), the improved conversion 8% (ratio $4.728/4.377 = 1.080$). Both gaps shrink, in relative terms, as ρ grows.

The grid hardly matters here. On `ORDERS`, the improved conversion agrees with the fine grid to within 0.001 for $\rho \le 1$. At $\rho = 50$ the best order on the fine grid is 1.472, between the grid points 1.4 and 1.5, and `ORDERS` gives 96.116 against 96.035.

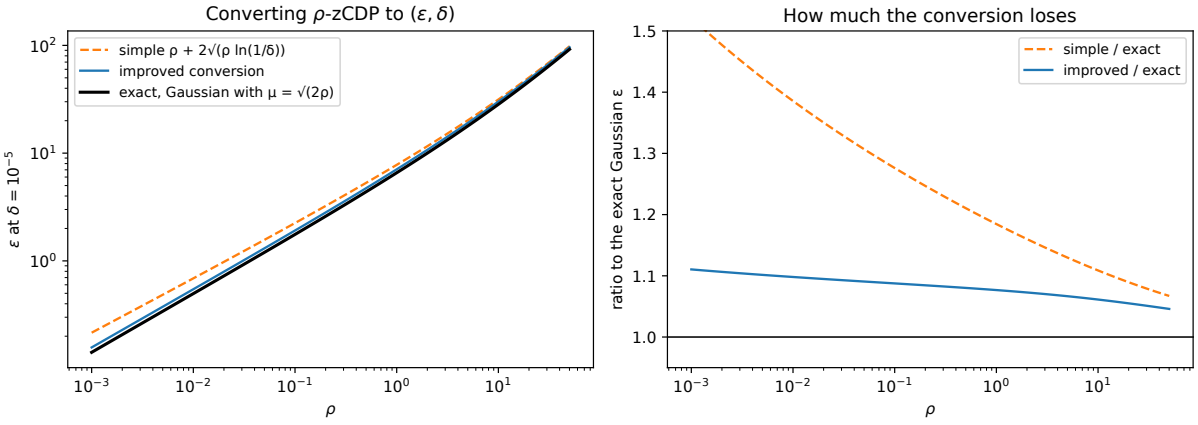

Figure 31.3.: Left: ε at $\delta = 10^{-5}$ for a ρ-zCDP mechanism, from the simple formula Equation 31.10, the improved conversion Equation 31.11, and the exact value for the Gaussian mechanism with $\mu = \sqrt{2\rho}$. Right: each conversion divided by the exact Gaussian value.

31.5.5. Example: ε for k Gaussian steps

k Gaussian steps with $\sigma = 1$ are $(k/2)$-zCDP, since each costs $1/2$ and composition adds. Table 31.4 converts a range of ρ at $\delta = 10^{-5}$, where $\ln(1/\delta) = 11.5129$. The row $\rho = 0.5$ is one step of the part's small example. For it the best order of the simple formula is $\alpha^* = 1 + \sqrt{11.5129/0.5} = 5.799$, and the simple ε is $0.5 + 2\sqrt{0.5 \times 11.5129} = 5.299$. The row $\rho = 5$ is ten steps, and $\rho = 50$ a hundred.

Table 31.4.: ε at $\delta = 10^{-5}$ for ρ-zCDP: simple formula, improved conversion on a fine grid of orders and on the part's `ORDERS`, and the exact ε of the Gaussian mechanism with the same ρ.

ρ	$\mu = \sqrt{2\rho}$	Simple Equation 31.10	Improved, fine grid	Improved, `ORDERS`	Exact Gaussian
0.01	0.1414	0.689	0.546	0.546	0.497
0.1	0.4472	2.246	1.914	1.914	1.760
0.5	1.0000	5.299	4.728	4.729	4.377
1	1.4142	7.786	7.077	7.077	6.573
5	3.1623	20.174	19.047	19.054	17.857
50	10.0000	97.985	96.035	96.116	91.817

Calibrating the noise. To make a single Gaussian step $(1, 10^{-5})$-DP through Equation 31.12, take $\rho = (\sqrt{12.5129} - \sqrt{11.5129})^2 = 0.02082$, that is $\sigma = 1/\sqrt{2\rho} = 4.901$.

31.5.6. Check yourself

- You have a budget of $\rho = 1$ and spend 0.5 on one query. How much ε at $\delta = 10^{-5}$ is left for the rest? *(The question has no clean answer: ε does not add, because the conversion is a square root of ρ, not a multiple of it. Budgets are kept in ρ, which adds, and converted once at the end. The whole run is 7.077-DP by the improved conversion whatever the split.)*
- Why does the simple formula's best order $\alpha^* = 1 + \sqrt{\ln(1/\delta)/\rho}$ grow as ρ shrinks? *(A small ρ makes the term $\rho\alpha$ cheap, so the conversion can afford a high order, which shrinks the $\ln(1/\delta)/(\alpha - 1)$ term.)*

31.6. Group privacy

31.6.1. Context

A household, a user with many records, or a hospital contributes several records. Group privacy asks how the guarantee degrades for datasets that differ in m records. (This section writes m for the group size, because k counts composed mechanisms in this part.) Two such datasets are joined by a chain of m neighbouring steps, each changing one record. For pure DP the answer is $m\varepsilon$: each step multiplies probabilities by at most e^{ε}, so m steps multiply them by at most $e^{m\varepsilon}$ (Properties of DP). For (ε, δ)-DP, δ blows up exponentially in m, because each step's δ is multiplied by the e^{ε} factors of the later steps. For RDP the chain argument works only if you

give up orders, because Rényi divergence has no triangle inequality: $D_\alpha(P\|Q)$ is not bounded by $D_\alpha(P\|R) + D_\alpha(R\|Q)$ at the same order. zCDP gets a clean answer because it constrains every order at once, so it can pay for the chain in higher orders.

31.6.2. Statement

The answer is that the slope grows with the square of the group size, exactly as it does for the Gaussian, where a group shifts the mean m times as far. If M is ρ-zCDP and D, D' are joined by a chain of m neighbouring steps, then for every $\alpha > 1$

$$D_\alpha(M(D) \,\|\, M(D')) \le m^2 \rho\, \alpha, \tag{31.14}$$

so M is $m^2\rho$-zCDP for groups of size m (Bun & Steinke 2016, Proposition 1.9). The Gaussian mechanism attains it. The tool is a **triangle-like inequality** for Rényi divergence (their Lemma 5.2). It lets you go from P to Q through an intermediate R, at the price of using higher orders on the two legs and a factor slightly above 1 on the first: for distributions P, Q, R and $m > 1$,

$$D_\alpha(P\|Q) \le \frac{m\alpha}{m\alpha - 1} D_{\frac{m\alpha-1}{m-1}}(P\|R) + D_{m\alpha}(R\|Q). \tag{31.15}$$

For comparison, Mironov's group bound for plain RDP gives up orders instead: an (α, ε)-RDP mechanism is $(\alpha/2^c, 3^c\varepsilon)$-RDP for groups of 2^c, when $\alpha \ge 2^{c+1}$ (Mironov 2017, Proposition 2; see Rényi DP).

31.6.3. Derivation

The triangle-like inequality, by Hölder. Write $P(y)$, $Q(y)$, $R(y)$ for the densities. The idea is to write the sum that defines $D_\alpha(P\|Q)$ as an average under R of a product of two ratios, P/R and R/Q, and then split the product with Hölder's inequality. Each factor then becomes a Rényi divergence of one leg of the chain.

1. **Insert R.** $e^{(\alpha-1)D_\alpha(P\|Q)} = \sum_y P(y)^\alpha Q(y)^{1-\alpha} = \mathbb{E}_R\big[(P/R)^\alpha\,(R/Q)^{\alpha-1}\big]$, where the ratios are evaluated at $Y \sim R$. To check it, multiply out one term: $R \cdot P^\alpha R^{-\alpha} \cdot R^{\alpha-1}Q^{1-\alpha} = P^\alpha Q^{1-\alpha}$. Rewriting a sum under one distribution as an average under another like this is a change of measure (Fact 1 of Divergences).
2. **Hölder's inequality.** For positive random variables X, Y and exponents $u, v > 1$ with $\frac{1}{u} + \frac{1}{v} = 1$, $\mathbb{E}[XY] \le (\mathbb{E}[X^u])^{1/u}(\mathbb{E}[Y^v])^{1/v}$. Choose v so that the second factor becomes a divergence of order $m\alpha$, the order the induction below can afford, and u to match: $u = \frac{m\alpha-1}{\alpha(m-1)}$ and $v = \frac{m\alpha-1}{\alpha-1}$, which satisfy $\frac{1}{u} + \frac{1}{v} = \frac{\alpha(m-1)+\alpha-1}{m\alpha-1} = 1$. Then

$$\mathbb{E}_R\big[(P/R)^\alpha (R/Q)^{\alpha-1}\big] \le \big(\mathbb{E}_R[(P/R)^{u\alpha}]\big)^{1/u} \big(\mathbb{E}_R[(R/Q)^{v(\alpha-1)}]\big)^{1/v}. \tag{31.16}$$

3. **Recognize two Rényi divergences.** By Fact 1 in its sum form, an average under R of a power of P/R is a Rényi divergence of P from R: $\mathbb{E}_R[(P/R)^\beta] = \sum_y R(y)^{1-\beta}P(y)^\beta = e^{(\beta-1)D_\beta(P\|R)}$ with $\beta = u\alpha = \frac{m\alpha-1}{m-1}$. In the same way $\mathbb{E}_R[(R/Q)^{\gamma-1}] = \sum_y R(y)^\gamma Q(y)^{1-\gamma} = e^{(\gamma-1)D_\gamma(R\|Q)}$ with $\gamma = v(\alpha-1)+1 = m\alpha$.

4. **Take logarithms and divide by $\alpha - 1$.** The left side becomes $D_\alpha(P\|Q)$. The second factor contributes $\frac{1}{v} \cdot v(\alpha-1)D_{m\alpha}(R\|Q)/(\alpha-1) = D_{m\alpha}(R\|Q)$. The first contributes $\frac{1}{u}(u\alpha-1)D_\beta(P\|R)/(\alpha-1)$, a coefficient $\frac{u\alpha-1}{u(\alpha-1)}$. Here $u\alpha - 1 = \frac{m\alpha-1-(m-1)}{m-1} = \frac{m(\alpha-1)}{m-1}$, so the coefficient is $\frac{m(\alpha-1)}{m-1} \cdot \frac{\alpha(m-1)}{(m\alpha-1)(\alpha-1)} = \frac{m\alpha}{m\alpha-1}$. This is Equation 31.15.

Group privacy, by induction on m. Now walk along the chain one record at a time, using the triangle-like inequality to add one step to a group of $m-1$.

5. **Base case.** $m = 1$ is the definition.
6. **Step.** Let $D \sim_{m-1} \hat{D} \sim D'$: $\hat{D}$ is $m-1$ steps from D and one step from D'. Apply Equation 31.15 with $P = M(D)$, $R = M(\hat{D})$, $Q = M(D')$. The first term involves the group of $m-1$, so by the induction hypothesis at order $\beta = \frac{m\alpha-1}{m-1}$ it is at most $\frac{m\alpha}{m\alpha-1}(m-1)^2\rho\frac{m\alpha-1}{m-1} = m(m-1)\rho\alpha$; the factor $\frac{m\alpha-1}{m-1}$ from the order cancels the coefficient's denominator. The second term is a single neighbouring step, so by ρ-zCDP at order $m\alpha$ it is at most $m\rho\alpha$. The sum is $(m^2 - m + m)\rho\alpha = m^2\rho\alpha$, which is Equation 31.14.
7. **Tightness.** For the Gaussian mechanism a group of m shifts the mean by $m\Delta$, and the Gaussian Rényi divergence $\alpha s^2/(2\sigma^2)$ with $s = m\Delta$ (Equation 3.15) gives exactly $\alpha m^2\Delta^2/(2\sigma^2) = m^2\rho\alpha$. Along the chain $\mathcal{N}(0,1)$, $\mathcal{N}(1,1)$, $\mathcal{N}(2,1)$, Equation 31.15 holds with equality: at $\alpha = 3$, $m = 2$, the left side is D_3 for a shift of 2, $3 \cdot 4/2 = 6$; on the right, the first leg has order $(6-1)/1 = 5$ and coefficient $6/5$, giving $\frac{6}{5} \cdot \frac{5}{2} = 3$, and the second leg has order 6, giving $6/2 = 3$. Both sides are 6.

31.6.4. Interpretation

Quadratic in m, and that is right. With $\rho \approx \varepsilon^2/2$ for pure DP, $m^2\rho \approx (m\varepsilon)^2/2$: zCDP's group privacy matches pure DP's $m\varepsilon$ after the translation from ε to ρ. The RDP route is weaker on two counts. It halves the order at each doubling of the group, so a curve known on all orders becomes a curve known only on orders up to $\alpha/2^c$. And it multiplies ε by 3 per doubling, so the value $\rho\alpha$ at order α becomes $3^c\rho\alpha$ at order $\alpha' = \alpha/2^c$. In terms of the new order that is $3^c 2^c \rho\alpha' = 6^c\rho\alpha'$: a slope of $6^c\rho$, against zCDP's $m^2\rho = 4^c\rho$.

Strong group privacy is also a weakness. Bun and Steinke use exactly this property to prove lower bounds for zCDP that are as strong as those for pure DP. For example, stability-based algorithms, which are (ε, δ)-DP with sample sizes independent of the domain size, cannot be zCDP. That is the motivation for the next two sections: approximate zCDP and truncated CDP both weaken group privacy for large groups to escape these bounds.

31.6.5. Example: households under the Gaussian mechanism

Table 31.5 takes the Gaussian mechanism with $\sigma = 1$ ($\rho = 0.5$) and groups of size m. The RDP route starts from the curve at order 64, where $\varepsilon(64) = 0.5 \times 64 = 32$. For a group of $m = 2^c$ it gives order $64/2^c$, $\varepsilon = 3^c \times 32$, and slope $6^c \times 0.5$: for $m = 2$ that is order 32, $\varepsilon = 96$ and slope 3.

Table 31.5.: Group privacy of the Gaussian mechanism with $\sigma = 1$. zCDP gives slope $m^2\rho$ at every order, and its conversion is within about 8% of the exact value. Mironov's RDP group bound, started from order 64, gives slope $6^c\rho$ and only on orders up to $64/m$.

Group size m	zCDP $m^2\rho$	ε at 10^{-5} (improved)	Exact Gaussian, shift m	RDP route: order, ε, slope
1	0.5	4.728	4.377	—
2	2	10.725	9.997	32, 96, 3
4	8	25.919	24.382	16, 288, 18
8	32	68.616	65.319	8, 864, 108

For comparison, a 1-DP mechanism gives 8-DP for groups of 8.

31.6.6. Check yourself

- A user contributes up to 4 records to a 0.1-zCDP release. What ρ protects the user? *($4^2 \times 0.1 = 1.6$.)*
- Why does the induction in step 6 need ρ-zCDP at order $m\alpha$, larger than α? *(Hölder trades one divergence of order α for two of higher orders. zCDP controls every order, so the trade is free; a bound known only up to some order would run out after a few steps, which is what happens to truncated CDP.)*

31.7. Approximate zCDP

31.7.1. Context

Some useful mechanisms are (ε, δ)-DP but not zCDP at all. Propose-test-release and stability-based histograms check, privately, that the data are far from any dataset where the answer would change, release an exact answer when they are, and fail only with probability about δ. The group-privacy lower bound above shows they cannot be zCDP. You still want to compose them with Gaussian steps in one budget. Bun and Steinke's answer is to allow zCDP to fail on an event of probability δ.

31.7.2. Statement

M is **δ-approximately ρ-zCDP** if, after throwing away a bad event of probability at most δ in each world, the rest is ρ-zCDP. Precisely: for all neighbours $D \sim D'$ there are events E (for $M(D)$) and E' (for $M(D')$), each of probability at least $1 - \delta$, such that for every $\alpha > 1$

$$D_\alpha(M(D)|_E \,\|\, M(D')|_{E'}) \le \rho\alpha \quad \text{and} \quad D_\alpha(M(D')|_{E'} \,\|\, M(D)|_E) \le \rho\alpha, \tag{31.17}$$

where $M(D)|_E$ is the output distribution conditioned on E (Bun & Steinke 2016, Definition 1.12). The events may depend on the mechanism's internal randomness, not only on its output. With $\delta = 0$ the events are certain and this is ρ-zCDP.

Three more properties make it a usable ledger. First, it absorbs (ε, δ)-DP: an (ε, δ)-DP mechanism is δ-approximately $(\varepsilon^2/2)$-zCDP (their Proposition 1.13 and Corollary 8.7). Second, it composes column by column: δ_1-approximate ρ_1-zCDP followed by δ_2-approximate ρ_2-zCDP is $(\delta_1 + \delta_2 - \delta_1\delta_2)$-approximately $(\rho_1 + \rho_2)$-zCDP (their Lemma 8.2). For many steps the failure probability is $1 - \prod_i (1 - \delta_i) \le \sum_i \delta_i$. Third, it converts to (ε, δ) by adding the failure probability to the conversion's δ: a δ_a-approximately ρ-zCDP mechanism is $(\varepsilon, \delta_a + (1 - \delta_a)\delta')$-DP, where ε is any conversion of ρ-zCDP at δ' (their Lemma 8.8, stated there with their own refinement of the conversion; the argument below works with any of them).

31.7.3. Derivation

This derives the conversion, which is what you use at the end. The idea: on the good event the mechanism is ρ-zCDP and the usual conversion applies; the bad event can add at most its probability. Let $\Pr[E], \Pr[E'] \ge 1 - \delta_a$ and fix a set of outputs S.

1. **Split on the event.** $\Pr[M(D) \in S] \le \Pr[M(D) \in S \mid E] \Pr[E] + (1 - \Pr[E])$, because the probability of S on the complement of E is at most 1. Write $a = \Pr[M(D) \in S \mid E]$; the right side is $a \Pr[E] + 1 - \Pr[E] = 1 - \Pr[E](1 - a)$, which can only shrink as $\Pr[E]$ grows. So its value at the smallest allowed $\Pr[E]$ bounds it: it is at most $a(1 - \delta_a) + \delta_a$.
2. **Use the conditional zCDP.** The conditioned pair is ρ-zCDP, so by any conversion, $\Pr[M(D) \in S \mid E] \le e^{\varepsilon} \Pr[M(D') \in S \mid E'] + \delta'$.
3. **Remove the conditioning on D'.** Dropping the outputs outside E' can only lower a probability: $\Pr[M(D') \in S] \ge \Pr[M(D') \in S \mid E'] \Pr[E'] \ge \Pr[M(D') \in S \mid E'](1 - \delta_a)$.
4. **Combine.** Put step 2 into step 1 and use step 3 for the term with e^{ε}: $\Pr[M(D) \in S] \le (1 - \delta_a)(e^{\varepsilon} \Pr[M(D') \in S \mid E'] + \delta') + \delta_a \le e^{\varepsilon} \Pr[M(D') \in S] + (1 - \delta_a)\delta' + \delta_a$.

The other two properties have shorter reasons. The conversion from (ε, δ)-DP comes from a decomposition of any (ε, δ)-DP pair: with probability $1 - \delta$ it behaves like an ε-DP pair, and Section 31.4 turns that into $\varepsilon^2/2$. Section J.2 in the appendices derives the decomposition and this conversion, and proves composition for pipelines that mix (ε, δ)-DP and zCDP steps. Composition holds because the conditioned mechanisms compose as zCDP (Fact 2), and the good events of both steps hold together with probability at least $(1 - \delta_1)(1 - \delta_2) = 1 - (\delta_1 + \delta_2 - \delta_1\delta_2)$.

31.7.4. Interpretation

Approximate zCDP is a way to keep one ledger with two columns, ρ and δ_a. The ρ column composes like zCDP, with its $\sqrt{k}$ behaviour after conversion; the δ_a column adds up, like δ in basic composition. It is only worth using when some steps are genuinely (ε, δ) and not zCDP. For a step that is zCDP, putting it in the δ_a column wastes δ.

31.7.5. Example: a pipeline with stability-based steps

A pipeline runs 10 stability-based steps, each $(0.5, 10^{-7})$-DP, and 10 Gaussian steps with $\sigma = 1$. Each stability step enters the ρ column as $0.5^2/2 = 0.125$ and the δ_a column as 10^{-7}. The total is $\rho = 10 \times 0.125 + 10 \times 0.5 = 6.25$ and $\delta_a = 1 - (1 - 10^{-7})^{10} = 1.0000 \times 10^{-6}$. Converting with the improved conversion at $\delta' = 10^{-5} - \delta_a$ gives $\varepsilon = 22.100$ at total $\delta = 10^{-5}$. Without approximate

zCDP you would convert the Gaussians alone ($\varepsilon = 19.119$ at $\delta = 9 \times 10^{-6}$) and add the stability steps by basic composition ($\varepsilon = 10 \times 0.5 = 5$, $\delta = 10^{-6}$), for $19.119 + 5 = 24.119$. The unified ledger saves about 2 because the $\varepsilon = 0.5$ steps compose in ρ as $\varepsilon^2/2$ each, not as ε.

31.7.6. Check yourself

- Is $(\varepsilon, 0)$-DP the same as 0-approximate $(\varepsilon^2/2)$-zCDP? *(No. ε-DP implies $(\varepsilon^2/2)$-zCDP, but zCDP does not imply pure DP: the Gaussian is zCDP and not ε-DP for any finite ε, because its privacy loss is normal and so unbounded.)*
- Why do the δ_a add while the ρ add only under a square root in ε? *(The δ_a are failure probabilities of events and combine by the union bound. The ρ add, and the conversion turns ρ into $\varepsilon \approx 2\sqrt{\rho \ln(1/\delta)}$.)*

31.8. Subsampling, and truncated CDP

31.8.1. Context

DP-SGD, the running example of this part, runs each step on a Poisson sample of the data: each record is used independently with probability q. Subsampling makes a step much more private than the Gaussian it contains, because a record is usually not in the batch. Does zCDP see this? In this section q is the sampling rate, never a density.

Take add/remove neighbours (two datasets differ by one record being present or absent), sensitivity 1 and noise multiplier σ, and reduce to one dimension. Without the record the step outputs $Q = \mathcal{N}(0, \sigma^2)$. With it, the record is in the sample with probability q, shifting the output's mean by 1, and absent otherwise, so the output is the mixture $P = (1-q)\mathcal{N}(0, \sigma^2) + q\,\mathcal{N}(1, \sigma^2)$. The RDP curve compares P against Q; the other order, Q against P, is never larger (the first fact is derived in Amplification by subsampling, Equation 33.9; the second is cited there to Mironov, Talwar & Zhang (2019) and derived in Section L.1 in the appendices). For integer orders the curve has a closed form, a binomial sum over how many of α copies of the record's contribution are present:

$$\varepsilon(\alpha) = \frac{1}{\alpha - 1} \ln A_\alpha, \qquad A_\alpha = \sum_{j=0}^{\alpha} \binom{\alpha}{j} (1-q)^{\alpha-j} q^j \exp\left(\frac{j^2 - j}{2\sigma^2}\right) \tag{31.18}$$

(Mironov, Talwar & Zhang 2019). To see where it comes from, let r be the likelihood ratio of $\mathcal{N}(1, \sigma^2)$ to Q. Then $P/Q = 1 - q + q\,r$, and by Fact 1, $A_\alpha = e^{(\alpha-1)D_\alpha(P\|Q)} = \mathbb{E}_Q[(P/Q)^\alpha] = \mathbb{E}_Q[(1 - q + q\,r)^\alpha]$. Expand the power binomially. Each term needs $\mathbb{E}_Q[r^j]$, which by Fact 1 is $e^{(j-1)D_j}$ for the pair $\mathcal{N}(1, \sigma^2)$, $\mathcal{N}(0, \sigma^2)$; with $D_j = j/(2\sigma^2)$ (Equation 3.15 at order j) that is $e^{(j^2-j)/(2\sigma^2)}$.

31.8.2. Statement

No amplification for zCDP. For the Poisson-subsampled Gaussian with any $q \in (0, 1]$, the smallest ρ with $\varepsilon(\alpha) \le \rho\alpha$ for all α is $1/(2\sigma^2)$, the same as without subsampling.

Truncated CDP. Since the problem comes from large orders, ask for the line only on orders below a cut-off ω. A mechanism is (ρ, ω)**-tCDP** if for all neighbours and all $\alpha \in (1, \omega)$

$$D_\alpha(M(D) \,\|\, M(D')) \le \rho\alpha \tag{31.19}$$

(Bun, Dwork, Rothblum & Steinke 2018, Definition 1). ρ-zCDP is the case $\omega = \infty$, that is (ρ, ∞)-tCDP. Composition works as for zCDP on the orders both steps cover: (ρ_1, ω_1) and (ρ_2, ω_2) compose to $(\rho_1 + \rho_2, \min(\omega_1, \omega_2))$ (their Lemma 2). The conversion to (ε, δ) is the simple zCDP conversion when its best order is below ω, and uses the order ω itself otherwise (their Lemma 6):

$$\varepsilon = \begin{cases} \rho + 2\sqrt{\rho \ln(1/\delta)} & \text{if } \ln(1/\delta) \le (\omega - 1)^2 \rho, \\ \rho\omega + \dfrac{\ln(1/\delta)}{\omega - 1} & \text{otherwise.} \end{cases} \tag{31.20}$$

And, unlike zCDP, tCDP is amplified by subsampling (their Theorem 11): let $\rho, q \in (0, 0.1]$ with $\ln(1/q) \ge 3\rho(2 + \log_2(1/\rho))$, and let M be (ρ, ω')-tCDP with $\omega' \ge \ln(1/q)/(2\rho) \ge 3$. Running M on a uniformly random subset of a fraction q of the records (fixed size, without replacement) is $(13q^2\rho,\ \omega)$-tCDP with $\omega = \ln(1/q)/(4\rho)$.

31.8.3. Derivation

No amplification for zCDP. Write $\rho_0 = 1/(2\sigma^2)$, the slope of the Gaussian without subsampling. The plan is to show that ρ_0 is enough (subsampling never hurts) and that nothing smaller is enough (at large orders, subsampling stops helping).

1. **Upper bound, by convexity.** $1 - q + q\,r$ is an average of the values 1 and r with weights $1 - q$ and q. Since $x \mapsto x^\alpha$ is convex, the power of an average is at most the average of the powers: $(1 - q + q\,r)^\alpha \le (1 - q) + q\,r^\alpha$. Take $\mathbb{E}_Q$; with $\mathbb{E}_Q[r^\alpha] = e^{(\alpha-1)\alpha\rho_0}$ from the Gaussian curve, $A_\alpha \le 1 - q + q\,e^{(\alpha-1)\alpha\rho_0} \le e^{(\alpha-1)\alpha\rho_0}$, the last step because an average of 1 and a number at least 1 is at most that number. So $D_\alpha(P\|Q) \le \rho_0\alpha$. The other order obeys the same bound, by a convexity argument on pairs. For any pair (A, B), $e^{(\alpha-1)D_\alpha(A\|B)} = \sum_y B(y)\,(A(y)/B(y))^\alpha$ is the perspective of the convex function x^α, which makes it jointly convex in (A, B) (Section F.5): the value at an average of pairs is at most the average of the values. Writing the pair (Q, P) as the mixture $(1-q)\,(Q, Q) + q\,(Q, \mathcal{N}(1, \sigma^2))$ gives $e^{(\alpha-1)D_\alpha(Q\|P)} \le (1 - q) + q\,e^{(\alpha-1)\alpha\rho_0}$, the same bound. Subsampling never hurts.
2. **Lower bound, by one term.** Every term of Equation 31.18 is positive, so dropping terms gives a lower bound. Keep only $j = \alpha$, the event that the record is present in all α copies: $A_\alpha \ge q^\alpha e^{(\alpha^2-\alpha)\rho_0}$. Taking logs and dividing by $\alpha - 1$,
$$\varepsilon(\alpha) \ge \rho_0\alpha + \frac{\alpha \ln q}{\alpha - 1}. \tag{31.21}$$
3. **Divide by α and let $\alpha \to \infty$.** $\varepsilon(\alpha)/\alpha \ge \rho_0 + \ln q/(\alpha - 1) \to \rho_0$: the penalty $\ln q$ for the record being rarely sampled is fixed, while the Gaussian part grows with the order, so the penalty's share of the slope vanishes. A line $\rho\alpha$ above the whole curve needs $\rho \ge \rho_0$, and by step 1, ρ_0 suffices.

The tCDP conversion. This is the zCDP conversion of Section 31.5 with the orders restricted to $(1, \omega]$.

4. **Restrict Mironov's conversion.** As in Section 31.5, every $\alpha \in (1, \omega]$ gives a valid $g(\alpha) = \rho\alpha + \ell/(\alpha - 1)$ with $\ell = \ln(1/\delta)$. (The endpoint ω is allowed: D_α is non-decreasing in α and lower semicontinuous, as a supremum over finite partitions of functions continuous in α, so $D_\omega \le \lim_{\alpha \uparrow \omega} D_\alpha \le \rho\omega$.)
5. **Constrained minimum of a convex function.** The unconstrained minimizer is $\alpha^* = 1 + \sqrt{\ell/\rho}$. If $\alpha^* \le \omega$, that is $\ell \le (\omega - 1)^2\rho$, use it and get Equation 31.10. Otherwise α^* lies beyond ω; a convex function is decreasing to the left of its minimizer, so g is decreasing on $(1, \omega]$, the best allowed order is ω, and it gives $\rho\omega + \ell/(\omega - 1)$.

The subsampling theorem has a longer proof (their Section 3): write the subsampled pair as mixtures $qP + (1-q)R$ and $qQ + (1-q)R$, expand $(1 + qZ)^\alpha$ with $Z = (P - Q)/(qQ + (1-q)R)$, and bound the second moment of Z through D_2 and the higher moments through the tCDP bound at orders up to ω'. The second-moment term carries the factor q^2 that gives the amplification. The truncation is essential: the higher-order terms are controlled only for α up to about $\ln(1/q)/\rho$.

31.8.4. Interpretation

The curve bends, and a line cannot. Figure 31.4 shows the curve of one DP-SGD step, $q = 0.01$, $\sigma = 1$, on integer orders. Up to $\alpha = 8$ it is tiny and almost linear. Its slope there is close to $q^2(e^{1/\sigma^2} - 1)/2 = 10^{-4} \times 1.71828/2 = 8.5914 \times 10^{-5}$. That value comes from the first terms of Equation 31.18. If every exponential in the sum were 1, the sum would be $((1-q) + q)^\alpha = 1$; the $j = 0$ and $j = 1$ exponentials are exactly 1, so the excess over 1 starts at $j = 2$, and for small q it is $A_\alpha \approx 1 + \binom{\alpha}{2} q^2(e^{1/\sigma^2} - 1)$. Then $\ln A_\alpha/(\alpha - 1) \approx \alpha q^2(e^{1/\sigma^2} - 1)/2$. Between $\alpha = 8$ and $\alpha = 16$ the curve jumps by more than three orders of magnitude, from 8.9364×10^{-4} to 3.0879 (Table 31.6). Beyond that it follows the lower bound Equation 31.21, which turns positive where $\rho_0(\alpha - 1) = \ln(1/q)$, at $\alpha = 1 + 2\sigma^2 \ln(1/q) = 1 + 2\ln 100 = 10.21$. At large orders the term $j = \alpha$ dominates: it is the event that the record is in every one of α imagined samples, rare but with the full Gaussian loss. A line through the origin above the whole curve must have the slope at infinity, $\rho_0 = 0.5$. A line that only has to stay above the curve up to $\omega = 8$ can have slope 1.1171×10^{-4}, $0.5/(1.1171 \times 10^{-4}) = 4476$ times smaller.

Small orders are what matter for DP-SGD. After $T = 10{,}000$ steps the RDP curve is $T\varepsilon(\alpha)$, and the conversion picks the order where $T\varepsilon(\alpha) + \ln(1/\delta)/(\alpha - 1)$ is smallest. With per-step values around 10^{-4}, the first term is small at small orders (from $10^4 \times 1.7181 \times 10^{-4} = 1.7181$ at order 2 to 8.9364 at order 8), and the order is pushed up only until the curve's jump makes the first term expensive. That is a small order: on the integer orders of `ORDERS` the best is $\alpha = 4$, for Mironov's conversion and for the improved one. The large orders that set the zCDP slope are never used. So the right one-number summary of DP-SGD keeps ρ only on small orders, which is what (ρ, ω)-tCDP does. RDP accounting keeps the whole curve and does at least as well.

tCDP's theorem is loose in its constant. Theorem 11 holds for every tCDP mechanism, so its constant 13 is generous. With $\sigma = \sqrt{5}$ ($\rho = 1/(2 \cdot 5) = 0.1$, so the theorem applies) and $q = 0.01$, the side condition reads $3\rho(2 + \log_2(1/\rho)) = 1.597 \le \ln(1/q) = 4.605$, and the theorem gives $(13 \times 0.01^2 \times 0.1,\ 4.605/0.4) = (1.300 \times 10^{-4},\ 11.51)$-tCDP. The Poisson-subsampled Gaussian curve on integer orders up to 11.51 needs only $\rho = 1.128 \times 10^{-5}$, about 11 times less. After 10,000

steps the theorem's parameters convert to $\varepsilon = 9.037$ by Equation 31.20, while RDP accounting of the Poisson curve on the integer orders of `ORDERS`, with the improved conversion, gives 2.046.

This comparison is only indicative. The theorem is for fixed-size sampling and replace-one neighbours, the curve for Poisson sampling and add/remove neighbours, and Amplification by subsampling explains why the two must not be mixed in an accountant.

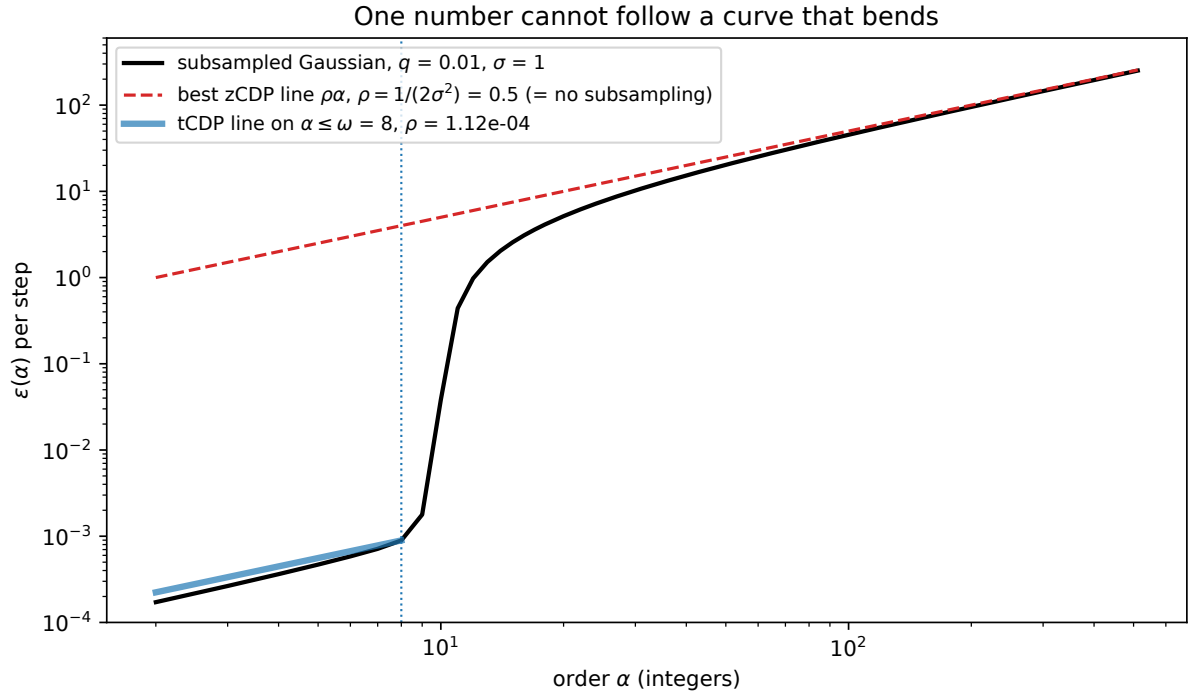

Figure 31.4.: The RDP curve of one Poisson-subsampled Gaussian step with $q = 0.01$, $\sigma = 1$, on integer orders (black), against the best zCDP line $\rho\alpha$ with $\rho = 1/(2\sigma^2) = 0.5$ (red dashed), which is the unsubsampled Gaussian's line $\alpha/2$, and the tCDP line on orders up to $\omega = 8$ (blue). Both axes are logarithmic.

31.8.5. Example: the running DP-SGD example in zCDP and tCDP

Table 31.6 lists the per-step curve. All values are on integer orders, which is what Equation 31.18 computes; a guarantee between grid points needs the fractional-order formula of Amplification by subsampling.

Table 31.6.: The RDP curve of one DP-SGD step ($q = 0.01$, $\sigma = 1$) on integer orders: its value, its slope from the origin, the lower bound Equation 31.21, and the Gaussian without subsampling.

α	$\varepsilon(\alpha)$	$\varepsilon(\alpha)/\alpha$	Lower bound Equation 31.21	No subsampling, $\alpha/2$
2	1.7181×10^{-4}	8.5907×10^{-5}	-8.2103	1
4	3.6315×10^{-4}	9.0789×10^{-5}	-4.1402	2

α	$\varepsilon(\alpha)$	$\varepsilon(\alpha)/\alpha$	Lower bound Equation 31.21	No subsampling, $\alpha/2$
8	8.9364×10^{-4}	1.1171×10^{-4}	-1.2631	4
10	3.8270×10^{-2}	3.8270×10^{-3}	-0.1169	5
12	9.7801×10^{-1}	8.1501×10^{-2}	0.9762	6
16	3.0879	1.9299×10^{-1}	3.0878	8
64	2.7322×10^{1}	4.2690×10^{-1}	27.3217	32
512	2.5139×10^{2}	4.9099×10^{-1}	251.3858	256

zCDP. The steepest ratio on the integer orders of `ORDERS` is 0.4910, at $\alpha = 512$, but that is not a valid zCDP parameter: zCDP needs the line at every order, and the ratio tends to 0.5 as $\alpha \to \infty$. So zCDP must charge $\rho = 0.5$ per step, the same as without subsampling. After 10,000 steps, $\rho = 5000$, and $\varepsilon = 5000 + 2\sqrt{5000 \times 11.5129} = 5479.9$ at $\delta = 10^{-5}$ by Equation 31.10, or 5475.8 with the improved conversion. That is the number zCDP reports for a training run that RDP accounting, on the integer orders of `ORDERS`, puts at $\varepsilon = 7.469$ with Mironov's conversion and 6.719 with the improved one. Amplification by subsampling also uses the fractional orders of `ORDERS` and gets slightly lower values (Table 33.9).

tCDP. Table 31.7 takes the per-step slope on orders up to ω, composes 10,000 steps by adding the slopes, and converts with Equation 31.20.

Table 31.7.: tCDP accounting of the running example, $q = 0.01$, $\sigma = 1$, $T = 10{,}000$, $\delta = 10^{-5}$, for several truncation points ω. Slopes are taken on integer orders up to ω.

ω	ρ per step	ρ after 10^4 steps	ε at 10^{-5}
2	8.5907×10^{-5}	0.8591	13.231
3	8.8213×10^{-5}	0.8821	8.403
4	9.0789×10^{-5}	0.9079	7.469
5	9.3733×10^{-5}	0.9373	7.507
6	9.7250×10^{-5}	0.9725	7.665
8	1.1171×10^{-4}	1.1171	8.289
10	3.8270×10^{-3}	38.2704	80.252
16	1.9299×10^{-1}	1929.9067	2228.027

The best integer choice, $\omega = 4$, reproduces RDP with Mironov's conversion, 7.469. A smaller ω lowers the slope only a little but forbids the orders the conversion needs. With $\omega = 4$, $\ln(1/\delta) = 11.51 > (\omega - 1)^2\rho = 9 \times 0.9079 = 8.17$, so the second branch of Equation 31.20 applies: $4 \times 0.9079 + 11.5129/3 = 7.469$, which is Mironov's conversion at order 4. Using the first branch anyway would give 7.374, but that needs order $\alpha^* = 1 + \sqrt{11.5129/0.9079} = 4.561 > \omega$, where the tCDP bound says nothing. Once ω passes the bend near $\alpha = 10$, tCDP collapses towards zCDP.

31.8.6. Check yourself

- Why do the largest orders decide zCDP's ρ for a subsampled Gaussian, when no conversion ever uses them? *(zCDP requires the line at every order. The ratio $\varepsilon(\alpha)/\alpha$ keeps growing*

towards $1/(2\sigma^2)$ *as* $\alpha \to \infty$*, so the limit sets the slope, and* $\rho = 1/(2\sigma^2)$*.)*

- Two DP-SGD runs, one $(10^{-4}, 4)$-tCDP per step and one $(10^{-5}, 20)$-tCDP per step, are composed. What is the result? *(*$(\rho, \omega) = (1.1 \times 10^{-4}, 4)$ *per pair of steps:* ρ *adds and* ω *is the minimum, because the line is guaranteed for both steps only on the orders both cover.)*

31.9. Code: check every number

The script code/concentrated_dp.py computes every number in this chapter and draws every figure. The Gaussian privacy loss is checked against simulation, randomized response and the binary bounded-range mechanisms are evaluated exactly in log space, the conversions are minimized on a fine grid and on `ORDERS` and compared with the exact Gaussian $\delta(\varepsilon)$, and the subsampled-Gaussian curve is computed with Equation 31.18 by a log-sum-exp over the binomial terms. From the repository root:

```
uv run python code/part04-privacy-accounting/concentrated_dp.py
```

Output (seed 0), summarized in Table 31.8:

Table 31.8.: The script's output with the default seed.

Experiment	Result
Gaussian privacy loss, $\sigma = 1$	Simulated mean 0.4990, variance 1.0013, $\ln \mathbb{E}[e^L] = 1.0000$; tails in Table 31.2; exact/bound 0.094 at $t = 4$
Pure DP to zCDP	Smallest ρ of randomized response on a fine grid of orders $= \varepsilon \tanh(\varepsilon/2)$ (Equation 31.7): 0.1225 ($\varepsilon = 0.5$), 0.4621 ($\varepsilon = 1$), against $\varepsilon^2/2$ = 0.1250, 0.5000; curve in Table 31.3
Bounded range, $\varepsilon^2/8$	Largest $D_\alpha/(\alpha\varepsilon^2/8)$: 0.9965, 0.9864, 0.8348 at $\varepsilon = 0.5$, 1, 4
zCDP to $(\varepsilon, 10^{-5})$	Table 31.4; at $\rho = 0.5$ the simple formula is 1.210 and the improved 1.080 times the exact 4.377
Group privacy, $\sigma = 1$	Table 31.5; triangle-like inequality on Gaussians: both sides 6
Approximate zCDP pipeline	$\rho = 6.25$, $\delta_a = 1.0000 \times 10^{-6}$, $\varepsilon = 22.100$; without it 24.119
DP-SGD, $q = 0.01$, $\sigma = 1$, $T = 10^4$	zCDP: $\rho = 5000$, $\varepsilon = 5479.9$ (simple), 5475.8 (improved). tCDP, $\omega = 4$: $\varepsilon = 7.469$. RDP on integer orders: 7.469 (Mironov), 6.719 (improved), both at $\alpha = 4$

tests/test_concentrated_dp.py checks that the output still matches.

What to take from it. For Gaussian mechanisms zCDP is exact, and all the slack is in the conversion: 8% with the improved conversion at $\rho = 0.5$. For pure DP mechanisms the sharp constant is $\varepsilon \tanh(\varepsilon/2)$, and $\varepsilon^2/2$ is close to it for small ε, but any line ignores the cap ε; for large ε keep the RDP curve, for instance that of randomized response. For subsampled mechanisms zCDP is useless: it reports ε in the thousands for a run that is $\varepsilon \approx 7$, because its slope is set by orders the conversion never uses. tCDP, or the full RDP curve, recovers the amplification.

31.11. Cheat sheet

Table 31.9 collects the results. $\ell = \ln(1/\delta)$.

Table 31.9.: Every result of this chapter.

Result	Formula	Tight?
ρ-zCDP	$D_\alpha \le \rho\alpha$ for all $\alpha > 1$; $\ln \mathbb{E}[e^{(\alpha-1)L}] \le (\alpha-1)\alpha\rho$	Equality for the Gaussian
Privacy-loss tail	$\Pr[L > \rho + t] \le e^{-t^2/(4\rho)}$	Off by the Mills-ratio factor $\sqrt{\rho/\pi}/t$ for the Gaussian
Gaussian mechanism	$\rho = \Delta^2/(2\sigma^2)$; privacy loss $\sim \mathcal{N}(\rho, 2\rho)$	Exact
Composition, post-processing	ρ's add; functions of the output keep ρ	Exact for Gaussians
Pure DP	ε-DP $\Rightarrow$ $(\varepsilon^2/2)$-zCDP; curve $\le \min(\varepsilon, \alpha\varepsilon^2/2)$	Sharp only as $\varepsilon \to 0$
Pure DP, sharp	ε-DP $\Rightarrow$ $(\varepsilon\tanh(\varepsilon/2))$-zCDP; curve $\le$ that of ε-randomized response	Attained by randomized response
Exponential mechanism	$(\varepsilon^2/8)$-zCDP, by Hoeffding on an interval of length ε	Within 0.4% at $\varepsilon = 0.5$ on binary pairs
To (ε, δ), simple	$\varepsilon = \rho + 2\sqrt{\rho\ell}$ at $\alpha^* = 1 + \sqrt{\ell/\rho}$	21% above exact at $\rho = 0.5$
To (ε, δ), improved	$\min_\alpha[\rho\alpha + \ell/(\alpha-1) + \ln(1 - 1/\alpha) - \ln\alpha/(\alpha-1)]$	8% above exact at $\rho = 0.5$
Calibration	$\rho = (\sqrt{\varepsilon + \ell} - \sqrt{\ell})^2$, $\sigma = 1/\sqrt{2\rho}$	Via the simple conversion
Group of m	$m^2\rho$	Exact for Gaussians
Approximate zCDP	ρ adds, δ_a adds; $(\varepsilon(\rho, \delta'), \delta_a + \delta')$-DP	—
Subsampled Gaussian	Smallest $\rho = 1/(2\sigma^2)$: no amplification	Exact
(ρ, ω)-tCDP	$D_\alpha \le \rho\alpha$ for $\alpha \in (1, \omega)$; compose to $(\sum \rho_i, \min \omega_i)$; convert by Equation 31.20	Matches RDP-Mironov on the running example

Rules of thumb

- Keep budgets in ρ, which adds; convert to (ε, δ) once, at the end, with the improved conversion.
- One Gaussian step with σ costs $\rho = 1/(2\sigma^2)$: $\sigma = 1$ is $\rho = 0.5$, about $\varepsilon = 4.7$ at $\delta = 10^{-5}$.
- A pure ε-DP step costs $\varepsilon^2/2$, or $\varepsilon\tanh(\varepsilon/2)$ with the sharp bound; an exponential-mechanism step costs $\varepsilon^2/8$. For $\varepsilon \ge 2$ the line $\alpha\varepsilon^2/2$ is above the plain ε at every order, and the sharp line crosses it soon after $\alpha = 1$; keep the RDP curve or the plain ε.
- Never account a subsampled mechanism in zCDP. Use RDP, tCDP with a small ω, or a privacy loss distribution.

- zCDP's group privacy is quadratic in the group size, exactly as for the Gaussian.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

32. f-DP and Gaussian differential privacy

32.1. Why this matters

Every privacy definition in this part answers the same question: how well can an adversary who sees the output of a mechanism M tell whether it ran on a dataset D or on a neighbour D' that differs from it in one record? Differential privacy (DP) in its (ε, δ) form answers with two numbers. Rényi differential privacy (RDP) answers with a curve over orders α (Rényi DP), and concentrated DP with one number ρ (concentrated DP). But Part 1 already gave the complete answer to "how well can anyone tell P from Q". It is the **trade-off function** $T(P, Q)$: for each rate at which a test may wrongly reject P (its type I error), the smallest rate at which it can wrongly accept P when the truth is Q (its type II error) (Hypothesis testing, Section 4.5). This chapter makes that curve the privacy guarantee itself.

The organizing idea: **the most informative description of a mechanism's privacy is its whole trade-off curve between $M(D)$ and $M(D')$, and every other notion is a lossy summary of it.** An (ε, δ) pair is one straight line lying under the curve, an RDP curve is a set of moments of it, and both throw information away. Two facts make the curve practical rather than just complete. First, Gaussian mechanisms give a one-parameter family of curves G_μ that is closed under composition: running a mechanism with curve G_{μ_1} and then one with curve G_{μ_2} gives the curve $G_{\sqrt{\mu_1^2+\mu_2^2}}$. Second, a central limit theorem (CLT) says that composing many mechanisms, each of which leaks little, gives a curve close to some G_μ, whatever the mechanisms were. Table 32.1 lists the results.

Table 32.1.: The results in this chapter and where they are used.

Result	Where it is used
f-DP and the curve $f_{\varepsilon,\delta}$	Reading any (ε, δ) guarantee as a bound on every attacker's errors
μ-Gaussian differential privacy (GDP); the Gaussian mechanism is $1/\sigma$-GDP	A one-number guarantee that is exact for Gaussian noise
Duality: $\delta(\varepsilon) = 1 + f^*(-e^\varepsilon)$; the GDP privacy profile	Reporting a GDP guarantee as (ε, δ) without loss
Composition: $G_{\mu_1} \otimes G_{\mu_2} = G_{\sqrt{\mu_1^2+\mu_2^2}}$; the tensor product	Exact accounting for full-batch noisy gradient descent; what numerical accountants compute
CLT for composition	Approximating many small mechanisms by one G_μ

Result	Where it is used
Subsampled Gaussian CLT, $\mu = q\sqrt{T(e^{1/\sigma^2} - 1)}$	A quick, approximate ε for differentially private stochastic gradient descent (SGD), DP-SGD for short
RDP as a lossy summary of the curve	Why RDP accounting leaves slack, and how much

A clash of letters. The f-DP papers write α for the type I error and β for the type II error. In this book α is also the Rényi order, which this chapter needs. So this chapter writes the two errors of a test as its **false positive rate** FPR and its **false negative rate** FNR, and keeps α for Rényi orders only.

Notation. Throughout, $P = M(D)$ and $Q = M(D')$ are the two output distributions. Because q is the sampling rate in Section 32.8, their densities are written with the same letters, $P(y)$ and $Q(y)$. A test ϕ looks at the output y and "fires", deciding that the data was D', with probability $\phi(y)$. Its type I error is how often it fires when the data was D, $\text{FPR} = \mathbb{E}_P[\phi]$, and its type II error is how often it stays silent when the data was D', $\text{FNR} = 1 - \mathbb{E}_Q[\phi]$. The **privacy loss** of an output y is the log of how much more likely y is under D than under D', $L(y) = \ln \frac{P(y)}{Q(y)}$. Drawing the output from P makes it random: $L(Y)$ with $Y \sim P$ is the **privacy loss random variable (PRV)** (composition).

32.2. Toolkit: three facts every derivation uses

32.2.1. Fact 1 — The curve is fixed by the law of the privacy loss

The trade-off curve is about the best tests, and the best tests only ever look at the privacy loss. The Neyman–Pearson lemma of Part 1 says that, at any type I error, the test with the smallest type II error fires on the outputs that are most typical of Q relative to P, that is, where the likelihood ratio Q/P is largest. Since $Q/P = e^{-L}$, these are the outputs where the privacy loss L is smallest. So every optimal test has the form "fire when $L < l$" (with a coin flip at $L = l$ when L has an atom there), and its errors are the probabilities of the event $\{L < l\}$ under P and under Q. The curve $T(P, Q)$ therefore depends on the pair only through the law of L under P and under Q.

Those two laws are not independent of each other. To get a probability under Q from one under P, weight each output by $Q/P = e^{-L}$. This is Part 1's change of measure (Fact 2 of Hypothesis testing, where L names the ratio Q/P; here that ratio is e^{-L}): for any event A defined through L,

$$Q(A) = \mathbb{E}_P[e^{-L}\mathbf{1}[A]], \tag{32.1}$$

when Q puts no mass where $P = 0$. The reason is one line: $\mathbb{E}_P[e^{-L}\mathbf{1}[A]] = \int_A P \cdot \frac{Q}{P} = \int_A Q$. So the law of the PRV under P alone fixes the curve.

The Gaussian pair shows this at work. Take $P = \mathcal{N}(0,1)$ and $Q = \mathcal{N}(\mu,1)$, a unit-variance normal and the same normal shifted by μ. Taking the log of the ratio of the two densities, the y^2 terms cancel and

$$L(y) = \ln \frac{P(y)}{Q(y)} = -\frac{y^2}{2} + \frac{(y-\mu)^2}{2} = \frac{\mu^2}{2} - \mu y. \tag{32.2}$$

The loss is a linear function of a normal output, so it is normal. Under P, y has mean 0 and variance 1, so $L \sim \mathcal{N}(\frac{\mu^2}{2}, \mu^2)$. Under Q, y has mean μ, so $L \sim \mathcal{N}(\frac{\mu^2}{2} - \mu^2, \mu^2) = \mathcal{N}(-\frac{\mu^2}{2}, \mu^2)$. The change of measure with $A =$ everything says $\mathbb{E}_P[e^{-L}]$ should be $Q(\text{everything}) = 1$. The moment generating function of a normal, $\mathbb{E}[e^{\lambda X}] = e^{\lambda m + \lambda^2 v/2}$ for $X \sim \mathcal{N}(m,v)$, with $\lambda = -1$, gives $\mathbb{E}_P[e^{-L}] = e^{-\mu^2/2 + \mu^2/2} = 1$, as it must.

One consequence is used several times below: the slope of the curve is set by the loss at the threshold. Part 1 showed $T'(\text{FPR}) = -Q/P$ at the threshold of the test of size FPR. The reason is that moving the threshold to include one more sliver of outputs near y raises the type I error by $P(y)\,\mathrm{d}y$ and lowers the type II error by $Q(y)\,\mathrm{d}y$, so FNR changes by $-Q/P$ per unit of FPR. In terms of the loss, this is the **slope rule**

$$|T'(\text{FPR})| = e^{-l(\text{FPR})}, \tag{32.3}$$

where $l(\text{FPR})$ is the threshold of the size-FPR test, the FPR-quantile of L under P (the test fires when $L < l(\text{FPR})$, which happens with probability FPR under P).

32.2.2. Fact 2 — The best "gain" of a test is a hockey-stick divergence

Suppose each correct detection of D' earns one unit and each false alarm costs γ units. A test's net gain is then its power $1 - \text{FNR}$ minus γFPR. The best gain over all tests is a divergence between P and Q that the book has already met: the **hockey-stick divergence** $E_\gamma(Q\|P) = \sup_S \left(Q(S) - \gamma P(S)\right)$, the largest amount by which some event is more likely under Q than γ times its probability under P (Divergences). For any pair and any $\gamma \geq 1$,

$$\max_{\text{FPR}\in[0,1]} \left(1 - T(P,Q)(\text{FPR}) - \gamma\text{FPR}\right) = \sup_S \left(Q(S) - \gamma P(S)\right) = E_\gamma(Q\|P). \tag{32.4}$$

To see why, write the gain of a test ϕ as one integral: $1 - \text{FNR} - \gamma\text{FPR} = \mathbb{E}_Q\phi - \gamma\mathbb{E}_P\phi = \int \phi\,(Q - \gamma P)$. The integrand is positive exactly where $Q > \gamma P$, so the gain is largest when the test fires on those outputs and nowhere else, $\phi = \mathbf{1}[Q > \gamma P]$. That test is the event $S = \{Q > \gamma P\}$, and its gain is $\int (Q - \gamma P)_+ = E_\gamma(Q\|P)$. The left side of Equation 32.4 reaches the same number in two stages: at each type I error FPR the largest power is $1 - T(\text{FPR})$ by the definition of T, and maximizing over FPR then picks the best test overall.

At $\gamma = 1$ the gain is $1 - \text{FPR} - \text{FNR}$, the test's advantage, and $E_1(Q\|P)$ is the total variation (TV) distance. So Fact 2 contains Part 1's statement that the best advantage of any test is the TV distance.

32.2.3. Fact 3 — A Gaussian shift in d dimensions is a Gaussian shift in one

When the output is a vector with independent unit-variance Gaussian noise, only the direction of the shift between the two means carries evidence; the noise in every perpendicular direction is the same under both hypotheses. So the d-dimensional problem is a one-dimensional one with shift equal to the length of the mean difference. For $m \in \mathbb{R}^d$,

$$T(\mathcal{N}(0, I_d), \mathcal{N}(m, I_d)) = G_{\|m\|_2}, \qquad G_\mu(\mathrm{FPR}) = \Phi(\Phi^{-1}(1 - \mathrm{FPR}) - \mu). \tag{32.5}$$

Here Φ is the standard normal distribution function, $\Phi(t) = \Pr[Z \le t]$ for $Z \sim \mathcal{N}(0, 1)$, and Φ^{-1} its inverse.

Start with $d = 1$, which is Part 1's Gaussian trade-off curve (Equation 4.10). For $\mathcal{N}(0, 1)$ against $\mathcal{N}(\mu, 1)$ the loss $\frac{\mu^2}{2} - \mu y$ is small when y is large, so the best test fires when $y > \tau$. Its type I error is $\mathrm{FPR} = \Pr[Z > \tau] = 1 - \Phi(\tau)$, so the threshold of the size-FPR test is $\tau = \Phi^{-1}(1 - \mathrm{FPR})$. Its type II error is the chance that a draw from $\mathcal{N}(\mu, 1)$ stays below τ, $\mathrm{FNR} = \Phi(\tau - \mu)$. Substituting τ gives G_μ.

For general d, the likelihood ratio is $\exp\left(\langle m, y\rangle - \frac{1}{2}\|m\|^2\right)$, from the same cancellation of squares as in Fact 1. It depends on y only through the single number $s = \langle m, y\rangle / \|m\|$, the length of the projection of y on the direction of the shift. By Neyman–Pearson, the optimal tests are thresholds on s. Under $\mathcal{N}(0, I)$, $s \sim \mathcal{N}(0, 1)$; under $\mathcal{N}(m, I)$, $s \sim \mathcal{N}(\|m\|, 1)$. Both hold because the inner product of a unit vector with a standard normal vector is a standard normal number (its variance is the squared length of the unit vector, 1), and the mean m contributes $\langle m, m\rangle / \|m\| = \|m\|$. So every optimal test is a threshold test on $\mathcal{N}(0, 1)$ against $\mathcal{N}(\|m\|, 1)$, whose curve is $G_{\|m\|}$.

Figure 32.3 (left) shows the picture: 400 draws from each of $\mathcal{N}(0, I_2)$ and $\mathcal{N}((1, 1), I_2)$. The best boundary is the dashed line perpendicular to the shift. Nothing about the other direction helps.

32.3. f-DP

32.3.1. Context

A definition of privacy should say what an adversary cannot do. In hypothesis-testing terms the strongest such statement is a lower bound on the adversary's type II error at every type I error: however the adversary tunes its test, it must miss at least this often. That bound is a curve, so the definition takes a curve as its parameter.

32.3.2. Statement

Call f a trade-off function if it is the curve of some pair of distributions. Part 1 (Section 4.5) showed this means f is non-increasing, convex, continuous and satisfies $f(\mathrm{FPR}) \le 1 - \mathrm{FPR}$ (a coin flip that fires with probability FPR already achieves $\mathrm{FNR} = 1 - \mathrm{FPR}$). Conversely, every such f is the curve of some pair, its canonical pair (Part 1; Section K.1 in the appendices derives it step by step). A mechanism M is **f-differentially private (f-DP)** if no neighbouring pair is easier to tell apart than f allows,

$$T(M(D), M(D')) \ge f \quad \text{for all neighbours } D \sim D' \tag{32.6}$$

(Dong, Roth & Su 2022, Definition 2.3; cited as Dong et al. from here on).

Two consequences follow. Because the neighbouring relation is symmetric, an f-DP mechanism is also $\max(f, f^{-1})$**-DP**, where $f^{-1}(\text{FPR}) = \inf\{t \in [0,1] : f(t) \le \text{FPR}\}$ is the inverse of f, its graph reflected across the diagonal FPR = FNR (Dong et al., Proposition 2.4). A curve with $f = f^{-1}$ is called **symmetric**. And the old definition is a special case: (ε, δ)-DP is exactly $f_{\varepsilon,\delta}$-DP for the curve made of two straight lines,

$$f_{\varepsilon,\delta}(\text{FPR}) = \max\left(0,\ 1-\delta-e^{\varepsilon}\text{FPR},\ e^{-\varepsilon}(1-\delta-\text{FPR})\right), \tag{32.7}$$

the curve that Part 3 derived in Section 18.5 (Equation 18.18; Wasserman & Zhou 2010; Kairouz, Oh & Viswanath 2015; Dong et al., Proposition 2.5).

32.3.3. Derivation

1. **Swap the roles, then invert.** Since $D' \sim D$ is also a neighbouring pair, f-DP gives $T(M(D'), M(D)) \ge f$ as well. Now relate the curve of (Q, P) to the curve of (P, Q). Take a test ϕ of P against Q with errors (FPR, FNR) and use its opposite, $1-\phi$, as a test of Q against P: it fires when the data was D' exactly when ϕ stays silent, so its type I error is $\mathbb{E}_Q[1-\phi] = \text{FNR}$ and its type II error is $1 - \mathbb{E}_P[1-\phi] = \text{FPR}$. So the achievable error pairs of (Q, P) are those of (P, Q) with the coordinates swapped, and $T(Q, P)$ is the inverse function of $T(P, Q)$, in the generalized sense of f^{-1} above when the curve has flat stretches. Part 1 proves this as Exercise 2 in the exercise book of Hypothesis testing.
2. **Reflecting keeps the order.** A curve lying above f means its region of achievable errors sits inside the region above f. Reflecting both regions across the diagonal keeps that inclusion, so $T(M(D'), M(D)) \ge f$ turns into $T(M(D), M(D')) \ge f^{-1}$. Together with $T(M(D), M(D')) \ge f$ this gives $\ge \max(f, f^{-1})$. The maximum of two convex, non-increasing functions is again convex and non-increasing, so this is a trade-off function.
3. (ε, δ)**-DP is a curve.** This is Part 3's hypothesis-testing reading (Section 18.5), restated in this chapter's letters. (ε, δ)-DP says that for every event S, $Q(S) \le e^{\varepsilon}P(S) + \delta$ and $P(S) \le e^{\varepsilon}Q(S) + \delta$. Read S as the region where a test fires, so $\text{FPR} = P(S)$ and $1 - \text{FNR} = Q(S)$. The first inequality becomes $1 - \text{FNR} \le e^{\varepsilon}\text{FPR} + \delta$, that is $\text{FNR} \ge 1 - \delta - e^{\varepsilon}\text{FPR}$. The second, applied to the complement of S, where $P = 1 - \text{FPR}$ and $Q = \text{FNR}$, becomes $1 - \text{FPR} \le e^{\varepsilon}\text{FNR} + \delta$, that is $\text{FNR} \ge e^{-\varepsilon}(1 - \delta - \text{FPR})$. Together with $\text{FNR} \ge 0$ these are the three pieces of Equation 32.7. A randomized test is a mixture of such region tests, so its errors obey the same linear bounds. Conversely, if every test has $\text{FNR} \ge f_{\varepsilon,\delta}(\text{FPR})$, then reading each event S as a test gives back the two DP inequalities. So $T(P, Q) \ge f_{\varepsilon,\delta}$ for every neighbouring pair exactly when M is (ε, δ)-DP.

32.3.4. Interpretation

f-DP contains (ε, δ)-DP: with $f = f_{\varepsilon,\delta}$ you get back the old definition, and other curves express guarantees that no single (ε, δ) pair can.

The shape of $f_{\varepsilon,\delta}$ shows what the two parameters do. It has two straight pieces, with slopes $-e^{\varepsilon}$ and $-e^{-\varepsilon}$. They meet on the diagonal FPR = FNR: setting $\text{FPR} = 1 - \delta - e^{\varepsilon}\text{FPR}$ gives $\text{FPR} = \frac{1-\delta}{1+e^{\varepsilon}}$. The curve starts at $1 - \delta$ on the FNR-axis, not at 1. That gap is what δ means: a test may catch D' with probability δ at no type I cost.

Post-processing comes for free. Processing the outputs can only make two distributions harder to tell apart, because any test on the processed output is also a test on the raw output, so the trade-off curve can only rise under processing (Part 3, Section 19.1; Dong et al., Lemma 2.9). So f-DP is closed under post-processing.

The curve is also the most informative summary there is. Blackwell's theorem (Dong et al., Theorem 2.10) says that $T(P, Q) \le T(P', Q')$ holds exactly when some randomized map sends P to P' and Q to Q' at the same time. So comparing curves is the same as asking whether one pair can be turned into the other by post-processing. Any quantity that respects post-processing, such as a divergence, can therefore only be a coarsening of the curve.

32.3.5. Example: three mechanisms with "$\varepsilon = 1$"

Binary randomized response with $\varepsilon = 1$ reports the true bit with probability $e/(1 + e) = 0.7311$ and flips it otherwise (randomized response; as a mechanism it protects one person's bit under replace-one neighbours, and here it serves as a pair of distributions). If the bit is 0 under D and 1 under D', the output distributions are $P = (0.7311, 0.2689)$ and $Q = (0.2689, 0.7311)$ over the outputs (0, 1). The only useful test is "fire when the output is 1", with FPR $= 0.2689$ and FNR $= 0.2689$; mixing it with "never fire" and "always fire" fills in the straight lines to $(0, 1)$ and $(1, 0)$. So the curve has a single interior corner at $(0.2689, 0.2689)$. That is exactly $f_{1,0}$, whose corner is at $1/(1 + e) = 0.2689$ by the formula $\frac{1-\delta}{1+e^{\varepsilon}}$ above. The Laplace mechanism with sensitivity 1 and scale $1/\varepsilon$ is also $(1, 0)$-DP, and the Gaussian mechanism with $\sigma = 1$ is shown for comparison.

Table 32.2.: Smallest type II error at three type I errors for three mechanisms. The Laplace curve is Part 1's Equation 4.14 with $\kappa = 1$.

Type I error FPR	$f_{1,0}$ (randomized response)	Laplace, $\varepsilon = 1$	Gaussian, $\sigma = 1$ (G_1)
0.01	0.9728	0.9728	0.9076
0.1	0.7282	0.7282	0.6109
0.25	0.3204	0.3679	0.3724

The $f_{1,0}$ column is the first line $1 - e\,\text{FPR}$: at FPR $= 0.1$, $1 - 0.2718 = 0.7282$. Randomized response sits exactly on $f_{1,0}$: it is the worst $(1, 0)$-DP mechanism. The Laplace mechanism matches it at small FPR, where both have slope $-e$, but is strictly more private in the middle (0.3679 against 0.3204 at FPR $= 0.25$, Table 32.2). The label "$(1, 0)$-DP" cannot tell the two apart; their curves can. Figure 32.1 also shows $f_{1,0.1}$, which starts at FNR $= 0.9$ instead of 1: at FPR $= 0.1$ it allows FNR $= 0.9 - 0.2718 = 0.6282$, exactly $\delta = 0.1$ below $f_{1,0}$.

32.3.6. Check yourself

- Why must $f_{\varepsilon,\delta}$ be symmetric, $f_{\varepsilon,\delta} = f_{\varepsilon,\delta}^{-1}$? *(Its two pieces are reflections of each other across the diagonal: solving* FNR $= 1 - \delta - e^{\varepsilon}$FPR *for* FPR *gives* FPR $= e^{-\varepsilon}(1 - \delta -$ FNR$)$*, which is the second piece with* FPR *and* FNR *swapped. This mirrors the two DP inequalities, one for each order of D, D'.)*

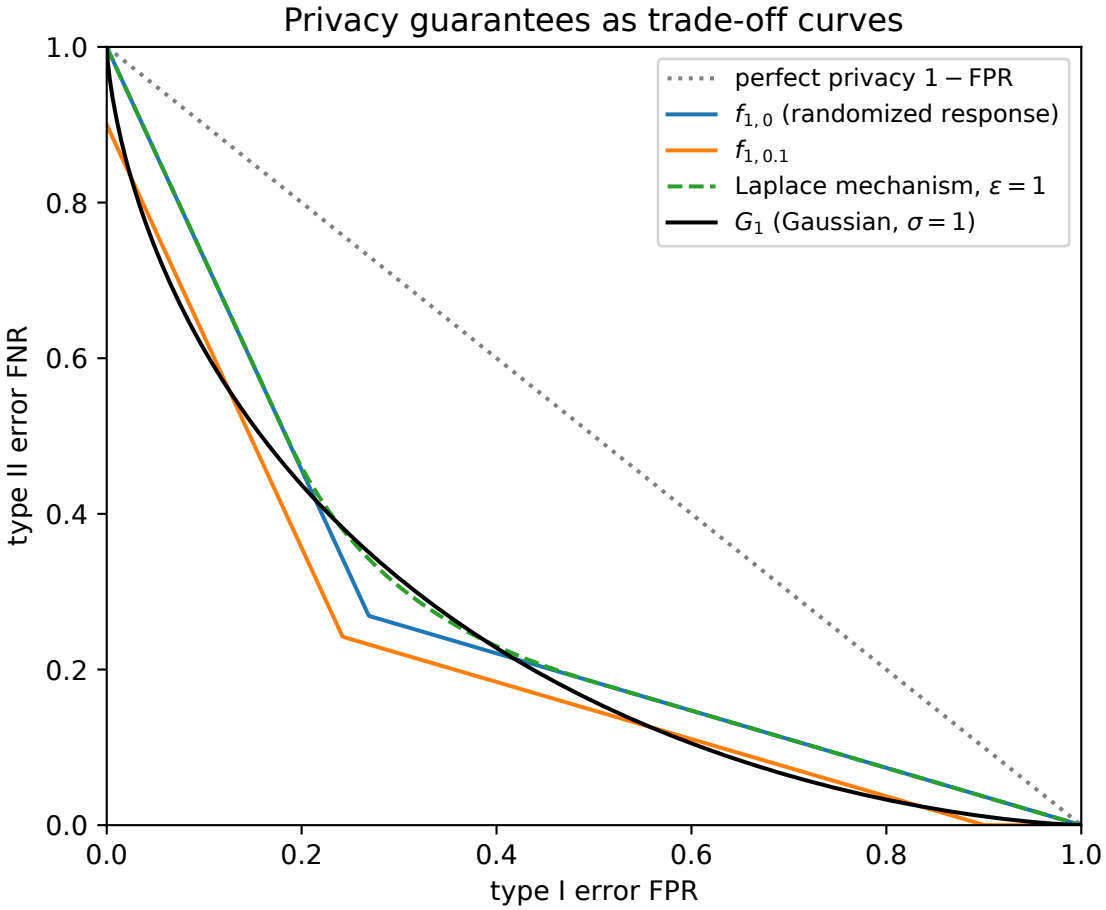

Figure 32.1.: Trade-off curves of $(1, 0)$-DP (randomized response), $(1, 0.1)$-DP, the Laplace mechanism with $\varepsilon = 1$ and the Gaussian mechanism with $\sigma = 1$. A mechanism is f-DP when its curve lies on or above f; the dotted diagonal is perfect privacy.

- The Laplace curve in Table 32.2 coincides with $f_{1,0}$ for small FPR and lies above it in the middle. Is $\varepsilon = 1$ the smallest ε with $\delta = 0$ it satisfies? *(Yes. Near* $\mathrm{FPR} = 0$ *both curves are* $1 - e\,\mathrm{FPR}$*, and any* $f_{\varepsilon,0}$ *with* $\varepsilon < 1$ *is* $1 - e^{\varepsilon}\mathrm{FPR}$ *there, which lies above the Laplace curve.)*

32.4. Gaussian differential privacy

32.4.1. Context

The Gaussian mechanism is the workhorse of private machine learning. By Fact 3, its curve is a Gaussian trade-off curve G_μ, which has one parameter. Using that family as the yardstick gives a one-number definition that is exact for the Gaussian mechanism.

32.4.2. Statement

A mechanism is **μ-GDP** if it is G_μ-DP, with G_μ as in Equation 32.5 (Dong et al., Definition 2.6): no test can separate its neighbouring outputs better than one can separate $\mathcal{N}(0,1)$ from $\mathcal{N}(\mu,1)$. The Gaussian mechanism adds noise to a query g (not f, which in this chapter is a trade-off function), $M(D) = g(D) + \mathcal{N}(0, \sigma^2(\Delta_2 g)^2 I)$, where $\Delta_2 g$ is the ℓ_2 sensitivity of g (the largest Euclidean distance $\|g(D) - g(D')\|_2$ over neighbours) and σ the noise multiplier (the noise standard deviation in units of $\Delta_2 g$). It is

$$\mu\text{-GDP with } \mu = \frac{1}{\sigma}, \tag{32.8}$$

and this is tight: when the sensitivity is attained by some neighbouring pair, that pair has trade-off curve exactly $G_{1/\sigma}$. μ-GDP is closed under post-processing.

32.4.3. Derivation

The plan is to turn the two output distributions, by invertible maps that cannot change any test's errors, into the standard pair of Fact 3, and then read off the shift.

1. **Standardize.** Divide the output by $\sigma\Delta_2 g$. The map is invertible, so any test on the scaled output is a test on the original and vice versa, and no error changes. After it, the noise has identity covariance: $P = \mathcal{N}(g(D)/(\sigma\Delta_2 g), I)$ and $Q = \mathcal{N}(g(D')/(\sigma\Delta_2 g), I)$.
2. **Reduce to one dimension.** Subtract $g(D)/(\sigma\Delta_2 g)$ from both, another invertible map, so that P is centred at 0. Fact 3 then gives $T(P,Q) = G_\nu$ with $\nu = \|g(D) - g(D')\|_2/(\sigma\Delta_2 g)$, the length of the remaining shift.
3. **Bound the shift.** By the definition of sensitivity, $\|g(D) - g(D')\|_2 \le \Delta_2 g$, so $\nu \le 1/\sigma$.
4. **A bigger shift is easier to detect.** $G_\mu(\mathrm{FPR}) = \Phi(\Phi^{-1}(1 - \mathrm{FPR}) - \mu)$ decreases as μ grows, because Φ is increasing. So $G_\nu \ge G_{1/\sigma}$ for every neighbouring pair, which is the statement that the mechanism is $1/\sigma$-GDP. A pair with $\|g(D) - g(D')\|_2 = \Delta_2 g$ has $\nu = 1/\sigma$ and gives equality.
5. **Post-processing.** It is the special case $f = G_\mu$ of the post-processing property of f-DP in Section 32.3.

32.4.4. Interpretation

For the Gaussian mechanism, μ-GDP is not a bound with slack; it is the curve. Every other guarantee for this mechanism, in particular every (ε, δ) pair, follows from μ (Section 32.5).

μ has a direct reading: it is the distance between the two output means in units of the noise standard deviation. Part 1's Table 4.4 gives a feel for it. At a 5% false-alarm rate the threshold is $\Phi^{-1}(0.95) = 1.6449$, so at $\mu = 1$ the best test misses with probability $\Phi(1.6449 - 1) = 0.7405$ and has power $1 - 0.7405 = 0.2595$; at $\mu = 2$ it misses with probability $\Phi(-0.3551) = 0.3612$ and has power 0.6388. Dong et al. suggest that $\mu \leq 0.5$ is a reasonable guarantee and $\mu \geq 6$ promises almost nothing (their discussion of Figure 3, after Definition 2.6).

The guarantee is set by the worst pair. A pair whose outputs differ by half the sensitivity has curve $G_{0.5}$ at $\sigma = 1$, more private than the guarantee G_1, which comes from the pairs that attain the full sensitivity.

32.4.5. Example: one noisy query

A count query g has $\Delta_2 g = 1$, since adding or removing one record changes the count by 1. Released with $\sigma = 1$, it is 1-GDP; with $\sigma = 4$, it is 0.25-GDP. For $\sigma = 1$, Table 32.3 evaluates G_1 at three type I errors, each by setting the threshold $\Phi^{-1}(1-\text{FPR})$ and subtracting the shift 1. For example, at FPR $= 0.01$ the threshold is $\Phi^{-1}(0.99) = 2.3263$ and $G_1(0.01) = \Phi(1.3263) = 0.9076$.

Table 32.3.: The 1-GDP guarantee of the Gaussian mechanism with $\sigma = 1$, read as attack errors.

Type I error FPR	Smallest type II error $G_1(\text{FPR})$	Best power $1 - G_1(\text{FPR})$
0.01	0.9076	0.0924
0.05	0.7405	0.2595
0.1	0.6109	0.3891

A simulation of the threshold test at FPR $= 0.05$ with 1,000,000 draws per hypothesis gives $\widehat{\text{FPR}} = 0.0502$ and $\widehat{\text{FNR}} = 0.7408$, against the exact 0.7405 in Table 32.3. Read as a membership attack, the first row says: whatever the attacker knows about the rest of the data, at a 1% false-positive rate it detects the presence of a record at most 9.24% of the time.

32.4.6. Check yourself

- A query has ℓ_2 sensitivity 3 and you add $\mathcal{N}(0, 6^2 I)$. What is μ? *(The noise multiplier is the noise standard deviation in units of the sensitivity, $\sigma = 6/3 = 2$, so $\mu = 1/\sigma = 0.5$.)*
- Why is it enough to look at the one-dimensional statistic $\langle m, y\rangle / \|m\|$ when the query returns a vector? *(Fact 3: the likelihood ratio depends on y only through it, so by Neyman–Pearson no test can do better than thresholding it.)*

32.5. Duality with (ε, δ)

32.5.1. Context

Regulators, papers and libraries report (ε, δ). So you need to turn a curve into (ε, δ) pairs without losing anything, and you need the (ε, δ) profile of μ-GDP in closed form.

32.5.2. Statement

The idea is geometric. An (ε, δ) guarantee is the line $\mathrm{FNR} = 1 - \delta - e^{\varepsilon}\mathrm{FPR}$ (and its mirror image), and a curve satisfies it when the curve lies above the line. For a given slope $-e^{\varepsilon}$, the smallest δ that works is the one where the line just touches the curve. Doing this for every slope gives the function $\delta(\varepsilon)$, and since a convex curve is the upper envelope of the lines that touch it, these lines together carry all of the curve.

The tool that computes "the line of slope y that just touches f" is the **convex conjugate** $f^*(y) = \sup_{\mathrm{FPR}} (y\,\mathrm{FPR} - f(\mathrm{FPR}))$: for each slope y it gives (minus) the intercept of the touching line. In these terms: for a symmetric trade-off function f, a mechanism is f-DP if and only if it is $(\varepsilon, \delta(\varepsilon))$-DP for every $\varepsilon \geq 0$, with

$$\delta(\varepsilon) = 1 + f^*(-e^{\varepsilon}), \qquad f^*(y) = \sup_{\mathrm{FPR}\in[0,1]} (y\,\mathrm{FPR} - f(\mathrm{FPR})), \tag{32.9}$$

(Dong et al., Proposition 2.12). For $f = G_{\mu}$ the touching point can be found in closed form, and

$$\delta(\varepsilon) = \Phi\Big(-\frac{\varepsilon}{\mu} + \frac{\mu}{2}\Big) - e^{\varepsilon}\,\Phi\Big(-\frac{\varepsilon}{\mu} - \frac{\mu}{2}\Big) \tag{32.10}$$

(Dong et al., Corollary 2.13). This is the exact privacy profile of the Gaussian mechanism, the same formula that Part 3 derived as a hockey-stick divergence (Equation 20.17 in Section 20.4; Balle & Wang 2018, Theorem 8). Here it comes out of the curve by convex duality. Section D.5 in the appendices derives G_{μ} and this profile together from the threshold test, in plain steps.

32.5.3. Derivation of the duality

1. **One (ε, δ) pair is one line.** By Equation 32.7, $f \geq f_{\varepsilon,\delta}$ requires in particular $f(\mathrm{FPR}) \geq 1 - \delta - e^{\varepsilon}\mathrm{FPR}$ for all FPR. Rearranged, $\delta \geq 1 - f(\mathrm{FPR}) - e^{\varepsilon}\mathrm{FPR}$ for every FPR, so the smallest δ that works is $\sup_{\mathrm{FPR}} (1 - f(\mathrm{FPR}) - e^{\varepsilon}\mathrm{FPR})$. With $y = -e^{\varepsilon}$ in the definition of the conjugate, this is $1 + f^*(-e^{\varepsilon})$, the quantity in Equation 32.9. The other piece of $f_{\varepsilon,\delta}$ is the mirror image of this line across the diagonal, and f is its own mirror image (it is symmetric), so the other piece gives the same condition.
2. **So f-DP implies every $(\varepsilon, \delta(\varepsilon))$.** If $T(M(D), M(D')) \geq f$ and, by step 1 with the smallest δ, $f \geq f_{\varepsilon,\delta(\varepsilon)}$, then $T(M(D), M(D')) \geq f_{\varepsilon,\delta(\varepsilon)}$.
3. **Conversely, the lines rebuild the curve.** A convex function is the supremum of the lines that touch it from below. For each $\varepsilon \geq 0$ the line $1 - \delta(\varepsilon) - e^{\varepsilon}\mathrm{FPR}$ touches f where the slope of f is $-e^{\varepsilon}$. As ε runs over $[0, \infty)$ the slopes run over every value from -1 down, which covers the part of the curve left of the diagonal (a symmetric curve has slope -1 where it crosses the diagonal and is steeper to the left). The mirror pieces cover the rest

by symmetry. So $\sup_{\varepsilon\geq 0} f_{\varepsilon,\delta(\varepsilon)} = f$, and a mechanism that is $(\varepsilon, \delta(\varepsilon))$-DP for all ε has $T \geq f_{\varepsilon,\delta(\varepsilon)}$ for every ε, hence $T \geq f$ (Dong et al., Proposition 2.11).

4. **The conjugate is a hockey-stick divergence.** When $f = T(P, Q)$, Fact 2 (Equation 32.4) with $\gamma = e^{\varepsilon}$ says $1 + f^*(-e^{\varepsilon}) = \max_{\text{FPR}}(1 - f(\text{FPR}) - e^{\varepsilon}\text{FPR}) = E_{e^{\varepsilon}}(Q\|P)$. So $\delta(\varepsilon)$ is the familiar privacy profile $\delta(\varepsilon) = E_{e^{\varepsilon}}$ of composition, the smallest δ that goes with each ε. For a symmetric pair the two orders, $E_{e^{\varepsilon}}(Q\|P)$ and $E_{e^{\varepsilon}}(P\|Q)$, agree.

32.5.4. Derivation of the Gaussian profile through the conjugate

To evaluate $1 + G_{\mu}^*(-e^{\varepsilon}) = \max_{\text{FPR}}(1 - G_{\mu}(\text{FPR}) - e^{\varepsilon}\text{FPR})$, find the test where the curve has slope $-e^{\varepsilon}$, then read off its two errors.

1. **Find the touching point.** The expression $1 - G_{\mu}(\text{FPR}) - e^{\varepsilon}\text{FPR}$ is concave in FPR, because G_{μ} is convex, so its maximum is where its derivative vanishes, $G'_{\mu}(\text{FPR}) = -e^{\varepsilon}$. By the slope rule (Fact 1), the slope at the size-FPR threshold $\tau = \Phi^{-1}(1 - \text{FPR})$ is minus the likelihood ratio there. For $\mathcal{N}(0, 1)$ against $\mathcal{N}(\mu, 1)$ that ratio is $Q(\tau)/P(\tau) = e^{\mu\tau - \mu^2/2}$. Setting it equal to e^{ε} gives $\mu\tau - \mu^2/2 = \varepsilon$, so $\tau = \frac{\varepsilon}{\mu} + \frac{\mu}{2}$.
2. **Read off the errors.** The test fires when $y > \tau$. Its type I error is $\text{FPR}^* = 1 - \Phi(\tau) = \Phi(-\frac{\varepsilon}{\mu} - \frac{\mu}{2})$, using $1 - \Phi(\tau) = \Phi(-\tau)$. Its power is the chance a draw from $\mathcal{N}(\mu, 1)$ exceeds τ, $1 - \text{FNR}^* = 1 - \Phi(\tau - \mu) = \Phi(-\frac{\varepsilon}{\mu} + \frac{\mu}{2})$.
3. **Substitute** into $\delta = 1 - \text{FNR}^* - e^{\varepsilon}\text{FPR}^*$ to get Equation 32.10.
4. **Agreement with Part 3.** By Fact 2 this route computes $E_{e^{\varepsilon}}(Q\|P)$. Part 3 instead computed $E_{e^{\varepsilon}}(P\|Q) = \Pr_P[L > \varepsilon] - e^{\varepsilon}\Pr_Q[L > \varepsilon]$ from the Gaussian law of the loss (Fact 1: $L \sim \mathcal{N}(\frac{\mu^2}{2}, \mu^2)$ under P and $\mathcal{N}(-\frac{\mu^2}{2}, \mu^2)$ under Q). The two agree because the Gaussian pair is symmetric: reflecting the line $y \mapsto \mu - y$ swaps $\mathcal{N}(0, 1)$ and $\mathcal{N}(\mu, 1)$, so swapping P and Q changes nothing.

32.5.5. Interpretation

The duality is lossless both ways. Reporting the whole profile $\varepsilon \mapsto \delta(\varepsilon)$ loses nothing, because the lines rebuild the curve. Reporting one point, such as ε at $\delta = 10^{-5}$, keeps one touching line and drops the rest of the curve (Figure 32.2, right).

At $\varepsilon = 0$ the profile is the TV distance. The line of slope -1 touches a symmetric curve on the diagonal, at the test with the best advantage $1 - \text{FPR} - \text{FNR}$. For G_{μ} that test has threshold $\tau = \mu/2$, halfway between the means, and Equation 32.10 at $\varepsilon = 0$ gives $\delta(0) = \Phi(\mu/2) - \Phi(-\mu/2) = 2\Phi(\mu/2) - 1$, Part 1's best advantage.

Small δ costs ε, in proportion to μ. To make δ small, the first term of Equation 32.10, a Gaussian tail $\Phi(-x)$ with $x = \frac{\varepsilon}{\mu} - \frac{\mu}{2}$, must be small. A normal tail falls roughly like $e^{-x^2/2}$, so reaching δ needs x of about $\sqrt{2\ln(1/\delta)}$, and ε grows roughly like $\mu\sqrt{2\ln(1/\delta)}$. Each further factor of ten in δ therefore costs extra ε, a little less with each decade (a square root grows ever more slowly), and about μ times as much as at $\mu = 1$. At $\mu = 1$, going from $\delta = 10^{-4}$ to 10^{-5} to 10^{-6} raises ε from 3.8044 to 4.3772 to 4.8866 (steps of 0.57 and 0.51); at $\mu = 2$, from 8.8769 to 9.9973 to 10.9972 (steps of 1.12 and 1.00, about twice as large). Figure 32.2 (left) and Table 32.4 show the same growth.

32.5.6. Example: reading $\delta(1)$ of 1-GDP off the curve

At $\mu = 1$ and $\varepsilon = 1$ the touching threshold is $\tau = \frac{1}{1} + \frac{1}{2} = 1.5000$. The best test where the slope is $-e$ has type I error $\mathrm{FPR}^* = \Phi(-1.5) = 0.066807$ and power $1 - \mathrm{FNR}^* = \Phi(1 - 1.5) = \Phi(-0.5) = 0.308538$, so $\delta(1) = 0.308538 - e \times 0.066807 = 0.308538 - 0.181601 = 0.126937$. These are the numbers of Part 3's Table 20.4, read in a new way. There, 0.3085 was the probability of the bad event $\{L > 1\}$, where the privacy loss exceeds ε, and 0.1816 its correction. Here they are the power of the best test and the price of its type I error at the exchange rate e. As a check on step 1, maximizing $1 - G_1(\mathrm{FPR}) - e\,\mathrm{FPR}$ over a grid of 20,001 values of FPR gives the same 0.126937, at $\mathrm{FPR} = 0.0668$.

Going the other way, from a target δ to ε, has no closed form, but $\delta(\varepsilon)$ decreases in ε, so the function `gdp_eps` finds the ε where it equals the target by bisection. At $\delta = 10^{-5}$:

Table 32.4.: The ε of μ-GDP at $\delta = 10^{-5}$.

μ	0.5	1	2
ε at $\delta = 10^{-5}$	1.9931	4.3772	9.9973

To check step 3 of the duality, the script rebuilds G_1 from 1001 lines $f_{\varepsilon,\delta(\varepsilon)}$ with $\varepsilon \in [0, 10]$: their supremum is within 4.9×10^{-6} of G_1 on a grid of 999 values of FPR.

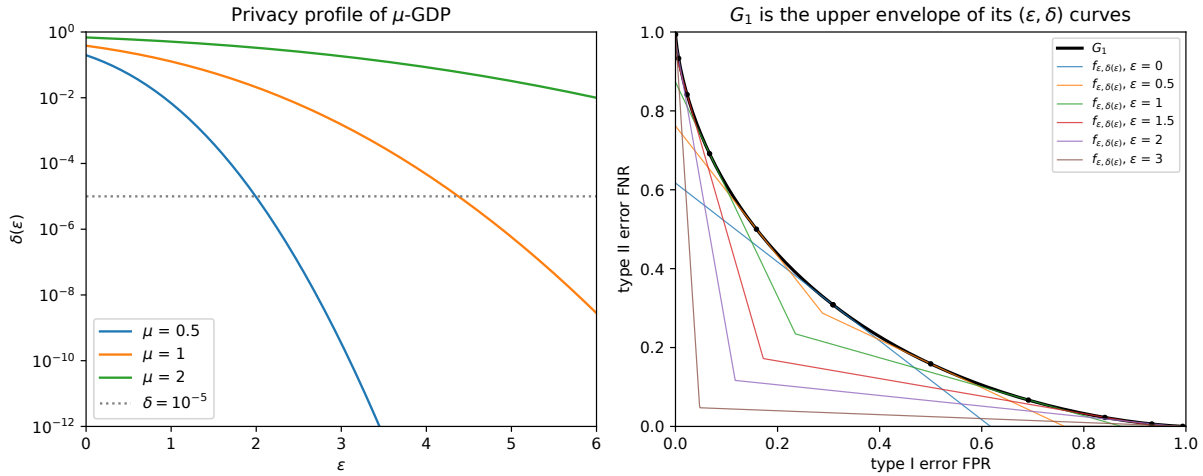

Figure 32.2.: Left: the privacy profile $\delta(\varepsilon)$ of μ-GDP for $\mu = 0.5, 1, 2$, with the level $\delta = 10^{-5}$ dotted. Right: G_1 and six of its $(\varepsilon, \delta(\varepsilon))$ curves. Each touches G_1 at two mirror-image points (dots); their upper envelope is G_1.

32.5.7. Check yourself

- From Figure 32.2 (right), which part of G_1 does the $\varepsilon = 0$ line describe? *(The point where the slope is -1, on the diagonal at $\mathrm{FPR} = \mathrm{FNR} = \Phi(-1/2) = 0.3085$: the best-advantage test. Larger ε describe points closer to the axes.)*

- Is "1-GDP" the same guarantee as "$(4.3772, 10^{-5})$-DP"? *(No. 1-GDP implies it, but the single curve $f_{4.3772,10^{-5}}$ allows far more power: at* FPR $= 0.1$ *its second piece allows* FNR $= e^{-4.3772}(1 - 10^{-5} - 0.1) = 0.0113$*, while* $G_1(0.1) = 0.6109$*.)*

32.6. Composition

32.6.1. Context

Training runs a mechanism thousands of times on the same data. Composing (ε, δ) guarantees directly is lossy (composition). Composing curves is exact, and for Gaussian curves it is a one-line formula.

32.6.2. Statement

When an adversary sees the outputs of two mechanisms run with independent randomness, it faces the pair of joint distributions: $P \times P'$ (both outputs drawn on D) against $Q \times Q'$ (both drawn on D'). The curve of that joint pair defines the composition of curves. The **tensor product** of two trade-off functions $f = T(P, Q)$ and $g = T(P', Q')$ is

$$f \otimes g = T(P \times P', Q \times Q'), \tag{32.11}$$

the curve of the pair of product distributions. It does not depend on which pairs are used to represent f and g (Dong et al., Definition 3.1; Section K.2 in the appendices proves it). If each mechanism M_i is f_i-DP, even when it is chosen adaptively from earlier outputs, then the composition $(M_1, \dots, M_k)$ is $f_1 \otimes \cdots \otimes f_k$-DP, and no better bound holds in general (Dong et al., Theorem 3.2). For Gaussian curves the product is again Gaussian, with the shifts adding like the sides of a right-angled triangle:

$$G_{\mu_1} \otimes G_{\mu_2} \otimes \cdots \otimes G_{\mu_k} = G_\mu, \qquad \mu = \sqrt{\mu_1^2 + \cdots + \mu_k^2} \tag{32.12}$$

(Dong et al., Corollary 3.3).

32.6.3. Derivation

1. **Non-adaptive composition through Blackwell.** Suppose $T(P_i, Q_i) \geq f_i = T(\tilde{P}_i, \tilde{Q}_i)$, where $(\tilde{P}_i, \tilde{Q}_i)$ is some pair whose curve is exactly f_i. By Blackwell's theorem (Dong et al., Theorem 2.10), a curve lies above another exactly when its pair can be produced from the other pair by post-processing, so some randomized map K_i sends $\tilde{P}_i \mapsto P_i$ and $\tilde{Q}_i \mapsto Q_i$. Apply the maps coordinatewise and independently: $(K_1, \dots, K_k)$ sends $\prod \tilde{P}_i \mapsto \prod P_i$ and $\prod \tilde{Q}_i \mapsto \prod Q_i$. Post-processing cannot help a test, so $T(\prod P_i, \prod Q_i) \geq T(\prod \tilde{P}_i, \prod \tilde{Q}_i) = \bigotimes f_i$.
2. **Adaptive composition.** When M_2 depends on the output of M_1, the second coordinate is not independent of the first, and step 1 does not apply. Dong et al. prove the same bound with the Neyman–Pearson lemma alone, conditioning on the first output (their Theorem 3.2 and Appendix C). Section K.2 in the appendices derives it step by step. On each branch of the first output, the attacker's test is swapped for the best test of a fixed pair with curve f_2 at the same type I error, which keeps the type I error and cannot raise the type II error.

3. **Tightness.** If the mechanisms ignore each other's outputs and some neighbouring pair attains each f_i, the composed pair is exactly the product pair, so its curve is exactly $\bigotimes f_i$.
4. **Gaussian curves.** $G_{\mu_i} = T(\mathcal{N}(0,1), \mathcal{N}(\mu_i, 1))$, so $\bigotimes G_{\mu_i}$ is the curve of k independent coordinates, $T(\mathcal{N}(0, I_k), \mathcal{N}(m, I_k))$ with $m = (\mu_1, \dots, \mu_k)$. By Fact 3, this is $G_{\|m\|_2}$, and $\|m\|_2 = \sqrt{\mu_1^2 + \cdots + \mu_k^2}$, which is Equation 32.12.

32.6.4. Interpretation

Under composition, the quantity that adds up is μ^2, just as variances of independent noises add. With k identical steps, μ grows like $\sqrt{k}$. Full-batch noisy gradient descent with clipped gradients and noise multiplier σ for T steps is a composition of T Gaussian mechanisms, each $1/\sigma$-GDP, so it is $\sqrt{T/\sigma^2} = \sqrt{T}/\sigma$-GDP. By step 3 it is in the worst case no better: no accountant can improve on it, and none needs to do more.

Concentrated DP is the same arithmetic. In zero-concentrated DP the Gaussian mechanism has $\rho = \mu^2/2$, and ρ adds under composition (concentrated DP), which is the same as μ^2 adding. The difference is what you can read off at the end: μ-GDP gives the exact curve, ρ only an RDP bound on it (Section 32.9).

For other curves the tensor product is hard. For $f_{\varepsilon,\delta}$ the product is a supremum of many $(\varepsilon_i, \delta_i)$ curves, which is the optimal composition theorem of Kairouz, Oh & Viswanath. Computing it exactly is #P-complete, a class of counting problems believed to have no efficient algorithm, when the $(\varepsilon_i, \delta_i)$ differ from step to step (Murtagh & Vadhan 2016; Part 3, Section 21.4). So numerical accountants compute $\bigotimes f_i$ another way: since the composed privacy loss is the sum of the independent per-step losses, they discretize the PRV and convolve its law with itself. These are the privacy loss distribution (PLD) and PRV accountants of numerical accounting.

32.6.5. Example: two concrete products

Gaussian. By Equation 32.12, two 1-GDP releases compose to $G_{\sqrt{2}} = G_{1.4142}$; three releases with $\mu = (0.5, 0.5, 1)$ to $G_{\sqrt{0.25+0.25+1}} = G_{1.2247}$; four 1-GDP releases to $G_{\sqrt{4}} = G_2$; and 100 releases with $\sigma = 10$ each, so $\mu_i = 0.1$, to $G_{\sqrt{100\times 0.01}} = G_1$. A simulation of the projected test in two dimensions, $\mu = (1, 1)$, at FPR $= 0.05$ with 1,000,000 draws per hypothesis gives $\widehat{\text{FPR}} = 0.0497$ and $\widehat{\text{FNR}} = 0.5913$, against $G_{\sqrt{2}}(0.05) = 0.5912$. The composed release sits strictly between one release, $G_1(0.05) = 0.7405$, and a single release with twice the shift, $G_2(0.05) = 0.3612$ (Figure 32.3).

Randomized response twice. This shows the tensor product for curves that are not Gaussian. Run randomized response with $\varepsilon = 1$ on the same bit twice, independently. Part 3 tabulated the same product at $\varepsilon = \ln 3$ as a sum of privacy losses (Table 21.1); here it is read as a curve. Each run keeps the bit with probability 0.7311. Under P (bit 0) and Q (bit 1) the four output pairs have the probabilities of Table 32.5; for example, 00 has probability $e^2/(1+e)^2 = 0.5344$ under P (both runs keep the bit) and $1/(1+e)^2 = 0.0723$ under Q (both runs flip it).

Table 32.5.: Two independent runs of randomized response with $\varepsilon = 1$.

Outputs	P	Q	Q/P
00	0.5344	0.0723	0.1353
01	0.1966	0.1966	1.0000
10	0.1966	0.1966	1.0000
11	0.0723	0.5344	7.3891

By Neyman–Pearson, the best tests add outcomes to the firing region in decreasing order of the likelihood ratio Q/P (Table 32.5): first 11 ($Q/P = e^2$), then the two mixed pairs ($Q/P = 1$), then 00 (e^{-2}). Each addition raises FPR by the outcome's P and lowers FNR by its Q. Firing on 11 alone gives $(\text{FPR}, \text{FNR}) = (0.0723, 1 - 0.5344) = (0.0723, 0.4656)$; adding one mixed pair gives $(0.2689, 0.2689)$; adding both gives $(0.4656, 0.0723)$. So the curve $f_{1,0} \otimes f_{1,0}$ is the polygon through $(0, 1)$, $(0.0723, 0.4656)$, $(0.2689, 0.2689)$, $(0.4656, 0.0723)$ and $(1, 0)$, with straight segments in between from randomizing at the boundary outcome. Its slopes are minus the likelihood ratios, $-e^2$, -1 and $-e^{-2}$. An $f_{\varepsilon,\delta}$ curve has only two slopes, so this curve is not $f_{\varepsilon,\delta}$ for any pair. It is the supremum of two such curves: $f_{2,0}$, whose first line $1 - e^2\text{FPR}$ is the steep segment, and $f_{0,0.4621}$, whose line $1 - \delta - \text{FPR}$ is the middle segment, with $\delta = 1 - 0.0723 - 0.4656 = 0.4621$, which equals $\tanh(1/2)$ (Exercise 3 in the exercise book). This is the smallest instance of the fact that composed (ε, δ) guarantees are a family of pairs, not one pair.

Composing points loses. Four 1-GDP releases are 2-GDP, so Table 32.4 gives $\varepsilon = 9.9973$ at $\delta = 10^{-5}$. Suppose instead you first turn each release into one (ε, δ) point, giving each a quarter of the δ budget, $(4.6902, 2.5 \times 10^{-6})$, and then compose the points with basic composition, which adds the ε's and the δ's. You get $\varepsilon = 18.7607$ at $\delta = 4 \times 2.5 \times 10^{-6} = 10^{-5}$: almost twice as large. Even optimal composition of the points loses, because each point has already dropped most of its curve; Part 3's Figure 21.4 shows by how much for many steps.

32.6.6. Check yourself

- You may release a vector query g with $\Delta_2 g = 1$ either once with $\sigma = 1$ or twice, independently, with $\sigma = \sqrt{2}$ each. Which is more private? *(Neither: each of the two releases is $1/\sqrt{2}$-GDP, and $\sqrt{(1/\sqrt{2})^2 + (1/\sqrt{2})^2} = 1$, the same G_1.)*
- Why does the product of two $f_{\varepsilon,0}$ curves have a segment of slope -1? *(Outcomes with equal likelihood under P and Q, here the mixed pairs 01 and 10, carry no evidence; adding them to the firing region trades type I for type II error one for one.)*

32.7. The central limit theorem for composition

32.7.1. Context

Most mechanisms are not Gaussian, so Equation 32.12 does not apply directly. But the privacy loss of a composition is the sum of the independent per-step losses, because the densities of independent outputs multiply and logs turn products into sums. Sums of many small independent

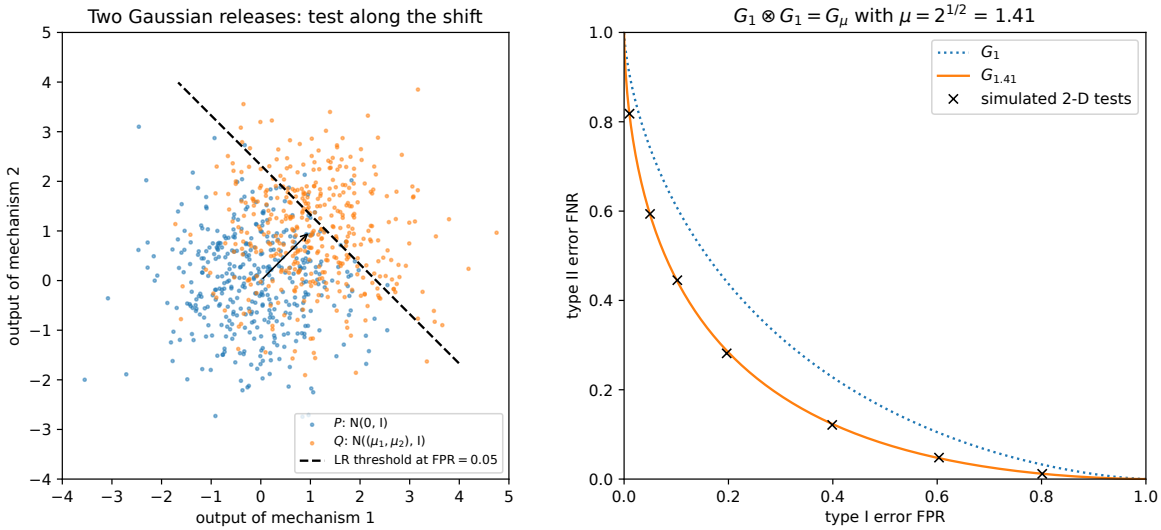

Figure 32.3.: Left: 400 draws each from $\mathcal{N}(0, I_2)$ and $\mathcal{N}((1,1), I_2)$, the outputs of two Gaussian releases on D and D'. The best test thresholds the projection on the shift (arrow); the dashed line is its boundary at FPR $= 0.05$. Right: G_1 for one release, $G_{\sqrt{2}}$ for two, and simulated errors of the projected test (crosses, 20,000 draws per point).

terms are nearly normal, and by Fact 1 a normal privacy loss means a Gaussian curve. The CLT for f-DP turns this into a statement about curves.

32.7.2. Statement

To use the CLT you need the mean, the variance and a third-moment size of the privacy loss. Dong et al. write them as functionals of the curve itself, through its slope: by the slope rule of Fact 1, $-\ln|f'(\mathrm{FPR})|$ is the threshold loss $l(\mathrm{FPR})$, so averaging powers of it over FPR $\in [0,1]$ averages powers of the loss (the derivation makes this precise). For a trade-off function $f = T(P,Q)$ define (Dong et al., §3.2)

$$\mathrm{kl}(f) = -\int_0^1 \ln|f'(\mathrm{FPR})|\,\mathrm{dFPR}, \quad \kappa_2(f) = \int_0^1 \ln^2|f'(\mathrm{FPR})|\,\mathrm{dFPR}, \quad \kappa_3(f) = \int_0^1 \big|\ln|f'(\mathrm{FPR})|\big|^3\,\mathrm{dFPR}, \quad \bar{\kappa}_3 \tag{32.13}$$

In words: kl is the mean of the loss, κ_2 its second moment, κ_3 its third absolute moment and $\bar{\kappa}_3$ its third absolute moment about the mean.

Berry–Esseen form (Dong et al., Theorem 3.4). For k curves, collect each functional into a vector, $\mathrm{kl} = (\mathrm{kl}(f_1), \dots, \mathrm{kl}(f_k))$ and so on, and write $\|\cdot\|_1$ for the sum of the entries and $\|\cdot\|_2^2$ for the sum of their squares. Then $\|\mathrm{kl}\|_1$ is the mean of the summed loss and $\|\kappa_2\|_1 - \|\mathrm{kl}\|_2^2$ its variance. The theorem matches the composition to the Gaussian curve whose loss has the same ratio of mean to standard deviation, and bounds the error by the Berry–Esseen ratio of third moment to variance$^{3/2}$. Let $f_1, \dots, f_k$ be symmetric with $\kappa_3(f_i) < \infty$, and put

$$\mu = \frac{2\|\mathrm{kl}\|_1}{\sqrt{\|\kappa_2\|_1 - \|\mathrm{kl}\|_2^2}}, \qquad \xi = \frac{0.56\,\|\bar{\kappa}_3\|_1}{\left(\|\kappa_2\|_1 - \|\mathrm{kl}\|_2^2\right)^{3/2}}. \tag{32.14}$$

If $\xi < \frac{1}{2}$, then for all FPR $\in [\xi, 1-\xi]$ the composed curve lies in a band around G_μ of width ξ in both directions:

$$G_\mu(\mathrm{FPR}+\xi) - \xi \le f_1 \otimes \cdots \otimes f_k(\mathrm{FPR}) \le G_\mu(\mathrm{FPR}-\xi) + \xi. \tag{32.15}$$

Limit form (Dong et al., Theorem 3.5). As the number of curves grows and each one leaks less, the band shrinks to zero. Precisely, for a triangular array $f_{k1}, \dots, f_{kk}$ of symmetric curves (a fresh list of k curves for each k) with $\sum_i \mathrm{kl}(f_{ki}) \to K \ge 0$, $\max_i \mathrm{kl}(f_{ki}) \to 0$, $\sum_i \kappa_2(f_{ki}) \to s^2 > 0$ and $\sum_i \kappa_3(f_{ki}) \to 0$, the composition converges uniformly to $G_{2K/s}$. For $(\varepsilon_i, 0)$-DP mechanisms with $\sum_i \varepsilon_i^2 \to \mu^2$ and $\max_i \varepsilon_i \to 0$, the limit is G_μ (Dong et al., Theorem 3.6).

32.7.3. Derivation (the idea; the proof is in Dong et al., Appendix D, and in Section K.4)

1. **The functionals are moments of the PRV.** By the slope rule (Fact 1), $-\ln|f'(\mathrm{FPR})| = l(\mathrm{FPR})$, the FPR-quantile of L under P. Now use the quantile transform: if U is uniform on $[0,1]$, then $l(U)$ has the law of L, just as feeding uniform random numbers into the inverse of a distribution function produces samples from that distribution. So $\int_0^1 g(l(\mathrm{FPR}))\,\mathrm{dFPR} = \mathbb{E}[g(l(U))] = \mathbb{E}_P[g(L)]$ for any function g. Taking $g(x) = x$, x^2 and $|x - \mathbb{E}_P L|^3$ gives

$$\mathrm{kl}(f) = \mathbb{E}_P[L] = D_{\mathrm{KL}}(P\|Q), \quad \kappa_2(f) = \mathbb{E}_P[L^2], \quad \bar{\kappa}_3(f) = \mathbb{E}_P\big|L - \mathbb{E}_P L\big|^3. \tag{32.16}$$

   The first is the Kullback–Leibler divergence, the expected log likelihood ratio. And $\kappa_2 - \mathrm{kl}^2$ is the second moment minus the squared mean, the variance of the PRV.
2. **Composition adds independent losses.** For product distributions the densities multiply, so the composed loss is $L_1 + \cdots + L_k$ with independent terms. Means add and, for independent terms, variances add. So under P the composed loss has mean $K = \|\mathrm{kl}\|_1$ and variance $V = \|\kappa_2\|_1 - \|\mathrm{kl}\|_2^2$.
3. **The ordinary CLT.** When no term dominates, the sum is close to $\mathcal{N}(K, V)$. The Berry–Esseen theorem says how close: the distribution function of a sum of independent terms differs from that of the matching normal by at most a constant times the summed third absolute central moments divided by $V^{3/2}$. Here that is $\|\bar{\kappa}_3\|_1 / V^{3/2}$, and with the constant 0.56 it is the ξ of Equation 32.14.
4. **Match a Gaussian pair.** By Fact 1 the pair behind G_μ has PRV $\mathcal{N}(\frac{\mu^2}{2}, \mu^2)$ under P, whose mean-to-standard-deviation ratio is $\frac{\mu^2/2}{\mu} = \mu/2$. Matching that ratio to $K/\sqrt{V}$ gives $\mu = 2K/\sqrt{V}$, Equation 32.14.
5. **Why match the ratio and not the variance alone.** A normal law $\mathcal{N}(m, v)$ is the law of some PRV only if $\mathbb{E}_P[e^{-L}] = 1$ (the change of measure of Fact 1 with $A =$ everything). By the normal moment generating function, $\mathbb{E}[e^{-L}] = e^{-m+v/2}$, so the condition is $m = v/2$, as in the Gaussian pair, where $m = \mu^2/2$ and $v = \mu^2$. Sums of small losses satisfy this only approximately, so at finite k different matches give slightly different μ. The ratio is still not an arbitrary choice. For symmetric curves the loss has mean K under P and $-K$ under Q, with the same variance, so the best tests compare two nearly normal laws that are $2K/\sqrt{V}$ standard deviations apart. That is the Gaussian pair with $\mu = 2K/\sqrt{V}$ (Section K.4 in the appendices, step 4). In the limit the two agree: $K = s^2/2$, and then $2K/s = s$. Dong et al. observe this in all their examples, and for symmetric curves it follows in a few lines. Symmetry means the law of the summed loss under Q is the mirror image of its law under

P, so if $L \to \mathcal{N}(K, s^2)$ under P, then $L \to \mathcal{N}(-K, s^2)$ under Q. For every $c > 0$ the change of measure gives $\mathbb{E}_P[e^{-L}\mathbf{1}[L > -c]] = \Pr_Q[L > -c]$. The integrand on the left is bounded by e^c and jumps only at $-c$, a point of probability 0 under the normal limit, so both sides pass to the limit: $\mathbb{E}[e^{-Z}\mathbf{1}[Z > -c]] = \Pr[Z' > -c]$ with $Z \sim \mathcal{N}(K, s^2)$ and $Z' \sim \mathcal{N}(-K, s^2)$. Letting $c \to \infty$ gives $\mathbb{E}[e^{-Z}] = 1$, that is $e^{-K+s^2/2} = 1$, so $K = s^2/2$.

6. **From the law of the loss to the curve.** By Fact 1 the curve is a functional of the law of the loss under P. Each best test fires when L is below a threshold, so its two errors are values of the distribution functions of L under P and under Q. Berry–Esseen puts each within ξ of a normal value, and eliminating the threshold gives the band of Equation 32.14 (Section K.4 in the appendices, steps 3–6).

32.7.4. Interpretation

This is why GDP is the natural family. The limit of many small compositions is always some G_μ, and the family is closed under composition. The (ε, δ) family is not: two runs of randomized response already leave it (Table 32.5).

For ε-DP pieces, μ is the root sum of squares, $\mu = \sqrt{\sum \varepsilon_i^2}$, in the limit. That is the $\sqrt{k}$ behaviour of advanced composition, with the exact constant.

The CLT is an approximation, not a bound. The Berry–Esseen band ξ is a bound, but it is wide: 0.0562 at $k = 100$ in the example below. The point estimate G_μ can be above or below the true curve, and the error is largest in the tails. That is where small δ lives, because a small δ is decided by rare, large values of the loss, and a CLT controls the bulk of a distribution much better than its tails.

32.7.5. Example: composing randomized response and Laplace

Take k mechanisms, each ε_0-DP with $\varepsilon_0 = 1/\sqrt{k}$, so that $\sum \varepsilon_i^2 = k \cdot \frac{1}{k} = 1$ and the limit is G_1. To judge the CLT you need the true $\delta(1)$ of the composition, and that requires the exact law of the summed loss.

For randomized response this law is simple. Under P each run reports the true bit with probability $e^{\varepsilon_0}/(1 + e^{\varepsilon_0})$, giving loss $+\varepsilon_0$, and flips it otherwise, giving $-\varepsilon_0$. If $B \sim \mathrm{Bin}(k, e^{\varepsilon_0}/(1 + e^{\varepsilon_0}))$ counts the truthful runs, the summed loss is $\varepsilon_0 B - \varepsilon_0(k - B) = \varepsilon_0(2B - k)$. The profile is the hockey-stick divergence $\int (P - e^{\varepsilon} Q)_+$, which after dividing inside by P is $\delta(\varepsilon) = \mathbb{E}_P[(1 - e^{\varepsilon - L})_+]$, an exact finite sum over the $k + 1$ values of B. For the Laplace mechanism the loss has two atoms at $\pm\varepsilon_0$ and a continuous part in between. The script rounds the continuous part down, and then up, to a lattice of spacing $\varepsilon_0/400$, convolves k copies by the fast Fourier transform, and reports both values. Since $\delta(\varepsilon)$ only grows when any loss grows, the two values bracket the exact one.

Table 32.6.: $\delta(1)$ for k-fold randomized response and Laplace with $\varepsilon_0 = 1/\sqrt{k}$, exactly (or bracketed) and from the CLT. The limit G_1 has $\delta(1) = 0.1269$.

k	ε_0	Randomized response, exact $\delta(1)$	Randomized response: μ, ξ of Equation 32.14	Randomized response: GDP $\delta(1)$	Laplace $\delta(1)$	Laplace: μ, ξ	Laplace: GDP $\delta(1)$
1	1.0000	0.0000	1.0422, 0.7663	0.1420	0.0000	0.9075, 0.7348	0.0956
10	0.3162	0.1323	1.0042, 0.1837	0.1284	[0.1112, 0.1114]	0.9569, 0.1889	0.1120
100	0.1000	0.1257	1.0004, 0.0562	0.1271	[0.1211, 0.1214]	0.9844, 0.0569	0.1215
1000	0.0316	0.1269	1.0000, 0.0177	0.1270	[0.1250, 0.1252]	0.9948, 0.0178	0.1251

Three things stand out in Table 32.6. The CLT with the finite-k μ of Equation 32.14 is accurate in the bulk from $k = 100$ on (0.1271 against 0.1257 for randomized response; 0.1215 against the bracket $[0.1211, 0.1214]$ for Laplace). At $k = 10$ the randomized-response value 0.1323 lies *above* the CLT's 0.1284: the CLT under-reports δ there. And Laplace stays on the private side of G_1 at every k shown (its $\delta(1)$ is below 0.1269), while its CLT μ (0.9569, 0.9844, 0.9948) rises toward 1 from below.

The tails are different. At $\delta = 10^{-5}$:

Table 32.7.: ε at $\delta = 10^{-5}$ for k-fold randomized response with $\varepsilon_0 = 1/\sqrt{k}$.

k	Randomized response, exact ε	GDP with the μ of Equation 32.14	GDP with $\mu = 1$	Basic composition $k\varepsilon_0$
10	3.1599	4.3983	4.3772	3.1623
100	4.3068	4.3793	4.3772	10.0000
1000	4.3683	4.3774	4.3772	31.6228

At $k = 10$ the true loss can never exceed $k\varepsilon_0 = 10/\sqrt{10} = 3.1623$, so the exact ε (3.1599) is far below the Gaussian's 4.3983: a Gaussian tail does not know that the loss is bounded. By $k = 1000$ the three values agree to within 0.01 (Table 32.7). In the tail the CLT erred upward at every k. In the bulk (Table 32.6) it erred downward at $k = 10$ and slightly upward from $k = 100$ on. Figure 32.4 shows both effects.

32.7.6. Check yourself

- Why is $\kappa_2(f_{\varepsilon,0}) = \varepsilon^2$ exactly? *(By step 1, κ_2 is the second moment of the loss. The loss of randomized response is $\pm\varepsilon$, so its square is always ε^2.)*

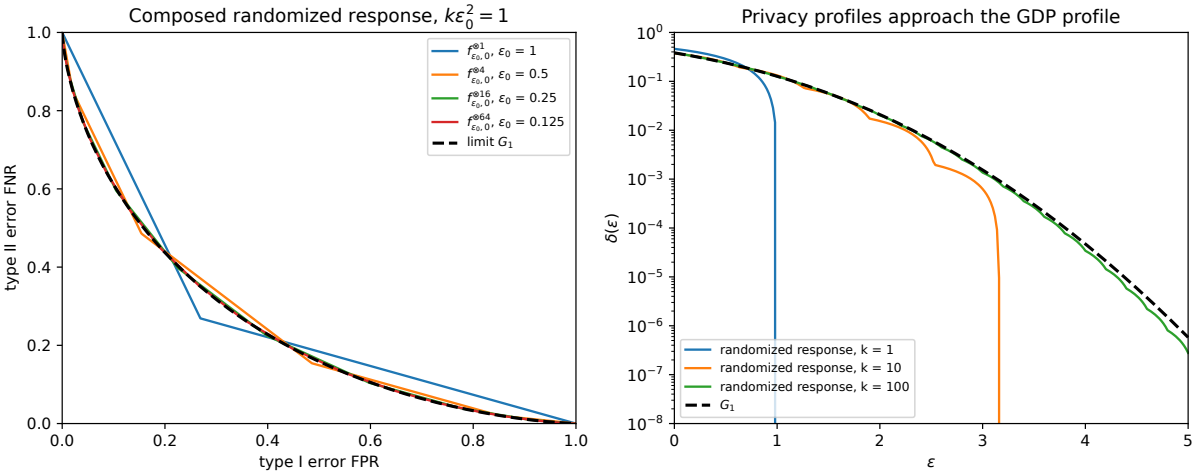

Figure 32.4.: Left: the exact curve $f_{\varepsilon_0,0}^{\otimes k}$ of k-fold randomized response with $\varepsilon_0 = 1/\sqrt{k}$, for $k = 1, 4, 16, 64$, approaching G_1. Right: their privacy profiles $\delta(\varepsilon)$ on a log scale for $k = 1, 10, 100$; each drops to 0 at $\varepsilon = k\varepsilon_0 = \sqrt{k}$ (off the plot for $k = 100$), while the GDP profile has a Gaussian tail.

- In Table 32.6, why is the CLT useless at $k = 1$? *(One term is not a sum: $\xi = 0.7663 > \frac{1}{2}$, so the theorem gives no band, and the true $\delta(1)$ is 0, since one $(1, 0)$-DP run never violates $(1, 0)$.)*

32.8. The subsampled Gaussian and DP-SGD

32.8.1. Context

DP-SGD (subsampling) composes T steps. Each step forms a batch by Poisson subsampling, which includes each record independently with probability q, clips each gradient to norm at most the sensitivity, and adds Gaussian noise with noise multiplier σ to their sum. Each step leaks little when q is small, because the target record is usually not even in the batch, so the CLT applies. Under add/remove neighbours, where D' is D with one record added, one subsampled Gaussian step reduces to the pair of step 1 below: a Gaussian against a two-component mixture (subsampling derives it). The reason is short: the other records contribute the same to both outputs and can be subtracted, and the added record's clipped gradient, at worst a shift of one sensitivity, is present with probability q and absent otherwise. So the derivation here stands on its own. In this section q is the sampling rate; the two output densities of one step are $P(y)$ and $Q(y)$.

32.8.2. Statement

Under add/remove neighbours, if $T \to \infty$ and $q\sqrt{T} \to c$ with σ fixed, T steps of the Poisson-subsampled Gaussian mechanism are asymptotically μ-GDP with

$$\mu = q\sqrt{T(e^{1/\sigma^2} - 1)} \tag{32.17}$$

(Bu, Dong, Long & Su 2020, Section 3, proved as their Theorem 5; Dong et al., Theorem 5.2 and Corollary 5.4, prove the analogous limit for their fixed-size batches under replace-one, with a different constant). This is a limit, used in practice as an approximation at finite T.

32.8.3. Derivation (heuristic, through Equation 32.14)

The plan is to compute the mean and variance of one step's privacy loss for small q, add them over T steps, and plug them into $\mu = 2K/\sqrt{V}$ from the CLT.

1. **One step.** Work in units of the sensitivity, so a present record shifts the mean by 1. The pair is $P = \mathcal{N}(0, \sigma^2)$ (the record is absent) and $Q = (1-q)\mathcal{N}(0, \sigma^2) + q\mathcal{N}(1, \sigma^2)$ (present, so with probability q it is in the batch). The ratio of the $\mathcal{N}(1, \sigma^2)$ density to the $\mathcal{N}(0, \sigma^2)$ density is $e^{(2y-1)/(2\sigma^2)} = e^{(y-1/2)/\sigma^2}$, from the same cancellation of squares as in Fact 1. So the likelihood ratio is

$$\frac{Q(y)}{P(y)} = 1 - q + q\, e^{(y-1/2)/\sigma^2} = 1 + qW(y), \qquad W(y) = e^{(y-1/2)/\sigma^2} - 1. \tag{32.18}$$

   Writing it as $1 + qW$ isolates the small parameter q: W measures how much the output favours "the record was in the batch", and q scales it down.
2. **Moments of W under P.** The mean is 0: $\mathbb{E}_P[W] = \mathbb{E}_P[\mathcal{N}(1, \sigma^2)\text{-density}/P(y)] - 1 = 1 - 1 = 0$, because averaging a density ratio under the denominator integrates the numerator density, which is 1. For the second moment, use the moment generating function of $Y \sim \mathcal{N}(0, \sigma^2)$, $\mathbb{E}[e^{\lambda Y}] = e^{\lambda^2\sigma^2/2}$, with $\lambda = 2/\sigma^2$: $\mathbb{E}_P[e^{2(Y-1/2)/\sigma^2}] = e^{2/\sigma^2} e^{-1/\sigma^2} = e^{1/\sigma^2}$. Expanding the square, $\mathbb{E}_P[W^2] = \mathbb{E}_P[(W+1)^2] - 2\,\mathbb{E}_P[W+1] + 1 = e^{1/\sigma^2} - 2 + 1 = e^{1/\sigma^2} - 1$. This is the χ^2 divergence between the two Gaussians, the mean squared deviation of their density ratio from 1.
3. **Expand the loss.** The loss is $L = \ln \frac{P(y)}{Q(y)} = -\ln(1 + qW)$. For small q, the Taylor series $\ln(1+x) = x - \frac{x^2}{2} + O(x^3)$ gives $L = -qW + \frac{q^2W^2}{2} + O(q^3W^3)$. Taking moments under P with step 2: the first term has mean 0, so $\mathbb{E}_P[L] \approx \frac{q^2}{2}\mathbb{E}_P[W^2] = \frac{q^2}{2}(e^{1/\sigma^2} - 1)$, and to leading order the variance is that of $-qW$, $\mathrm{Var}_P(L) \approx q^2(e^{1/\sigma^2} - 1)$.
4. **Sum over T steps.** Means and variances of independent losses add, so $K \approx \frac{Tq^2}{2}(e^{1/\sigma^2} - 1)$ and $V \approx Tq^2(e^{1/\sigma^2} - 1)$. Then $\mu = 2K/\sqrt{V} = Tq^2(e^{1/\sigma^2} - 1)/(q\sqrt{T(e^{1/\sigma^2} - 1)}) = q\sqrt{T(e^{1/\sigma^2} - 1)}$, Equation 32.17.
5. **The regime.** With $q\sqrt{T} \to c$, each step's moments are $O(q^2) = O(1/T)$, so K and V converge to finite limits, $\max_i \mathrm{kl} \to 0$, and $\sum \kappa_3 = O(Tq^3) \to 0$. These match the conditions of the limit form of the CLT. That theorem assumes symmetric curves, though, and the subsampled pair is not symmetric, so it does not apply as stated. Section K.5 in the appendices treats the laws under P and Q separately, bounds the remainders by $O(q^3)$, and proves the limit (Bu et al., Theorem 5). The other order of P and Q gives the same leading terms.

32.8.4. Interpretation

Subsampling buys a factor of about q. Full-batch training ($q = 1$) for T steps is $\sqrt{T}/\sigma$-GDP. Dividing Equation 32.17 by $\sqrt{T}/\sigma$, subsampling multiplies this by about $q\sqrt{e^{1/\sigma^2} - 1} \cdot \sigma$, which for $\sigma = 1$ is $q \times 1.3108$.

It is an approximation, not a bound. Two approximations stack: the CLT itself, and the expansion in step 3 (the exact per-step moments are smaller than the leading terms). Neither is controlled in the tail, which is where $\delta = 10^{-5}$ lives. Gopi, Lee & Wutschitz (2021) showed that the CLT value can lie below the true ε of DP-SGD. The example below confirms it for the running example; numerical accounting computes certified values and choosing an accountant compares all the accountants on this example.

Watch the neighbouring relation. Corollary 5.4 of Dong et al. analyses fixed-size batches under replace-one neighbours, where D' swaps one record of D for another, and gets a different constant ($\mu = 1.7101$ at $T = 10{,}000$ in the running example). Do not mix the two (subsampling explains why).

32.8.5. Example: the running DP-SGD example

The running example has sampling rate $q = 0.01$, noise multiplier $\sigma = 1$ and target $\delta = 10^{-5}$. Then $e^{1/\sigma^2} - 1 = 1.7183$ and $\sqrt{1.7183} = 1.3108$, so Equation 32.17 gives $\mu = 0.01 \times 1.3108\sqrt{T}$; at $T = 100$, for example, $\mu = 0.01 \times 1.3108 \times 10 = 0.1311$. Table 32.8 turns each μ into ε with Equation 32.10 and compares it with a numerical accountant.

Table 32.8.: The running DP-SGD example: the CLT's μ and ε, and a numerical bracket for the true ε.

Steps T	$q\sqrt{T}$	CLT μ	CLT ε at 10^{-5}	Numerical accountant ε	Full batch, $\mu = \sqrt{T}$
100	0.10	0.1311	0.4575	[0.7175, 0.7185]	10.0
1,000	0.32	0.4145	1.6177	[1.8232, 1.8332]	31.6
10,000	1.00	1.3108	6.0071	[6.1377, 6.2377]	100.0

The bracket in Table 32.8 comes from the same lattice-and-convolve method as the Laplace example, applied to the per-step loss on a lattice of spacing $h = 10^{-5}$, taking the worse of the two orders of neighbours. Rounding each step's loss down or up by at most h moves the composed loss by at most Th, so the bracket's width is Th by construction (0.0010, 0.0100 and 0.1000), and the informative number is its lower end. That lower end is exact up to the quadrature error in the per-step weights. In all three rows the CLT value lies below the lower end of the bracket. The ratio of the CLT value to that lower end is 0.638 at $T = 100$, 0.887 at $T = 1{,}000$ and 0.979 at $T = 10{,}000$, where $q\sqrt{T}$ is largest and the CLT regime fits best.

Computing the exact per-step moments by quadrature shows the second approximation at work. In the order of the derivation ($P = \mathcal{N}(0, 1)$, the record absent), the mean of the loss is 8.1890×10^{-5} against the leading term $q^2(e-1)/2 = 8.5914 \times 10^{-5}$, and the variance 1.6009×10^{-4} against $q^2(e-1) = 1.7183 \times 10^{-4}$. Plugging the exact moments into Equation 32.14 gives $\mu = 1.2944$ at $T = 10{,}000$ and $\varepsilon = 5.9184$. The other order (the record present in D) gives $\mu = 1.2795$ and $\varepsilon = 5.8379$. Both are below the CLT's 6.0071, and further below the lower end 6.1377. So a smaller "more exact" μ is not more conservative; only a certified accountant is.

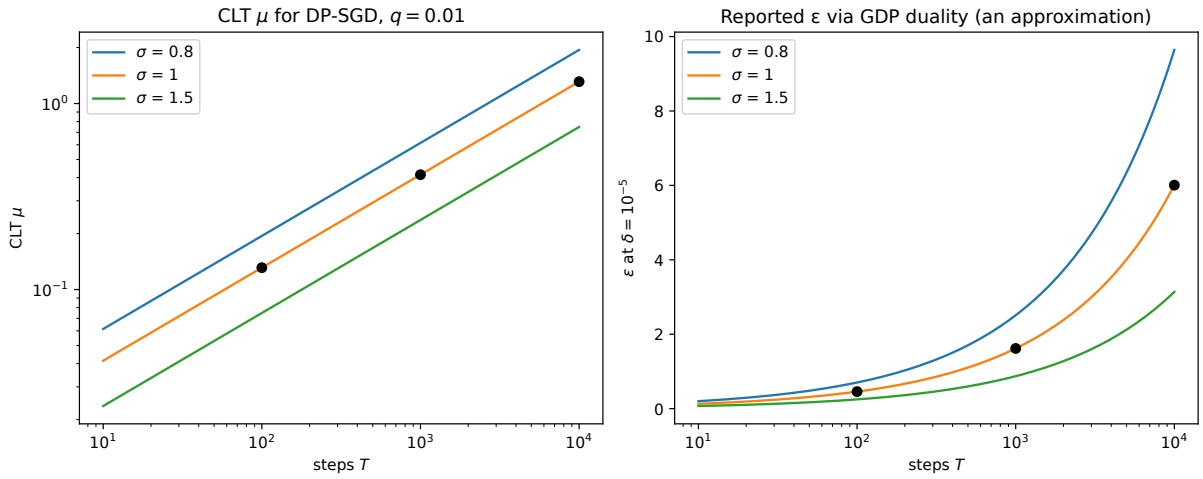

Figure 32.5.: CLT approximation for DP-SGD with $q = 0.01$. Left: $\mu = q\sqrt{T(e^{1/\sigma^2} - 1)}$ against the number of steps for three noise multipliers. Right: the ε at $\delta = 10^{-5}$ it implies through Equation 32.10. Dots mark the running example at $T = 100$, 1,000 and 10,000.

Figure 32.5 shows how quickly ε grows with T once μ passes 1, and how strongly it depends on σ: $e^{1/\sigma^2} - 1$ is 3.7707 at $\sigma = 0.8$, 1.7183 at $\sigma = 1$ and 0.5596 at $\sigma = 1.5$.

32.8.6. Check yourself

- At fixed q and σ, how does the CLT μ scale with the number of epochs $E = Tq$? *(As $\sqrt{T}$, so as $\sqrt{E/q}$: ten times more epochs multiplies μ by $\sqrt{10}$.)*
- Why can you not report "$\varepsilon = 6.0071$" for the running example at $T = 10{,}000$ as a DP guarantee? *(It is an asymptotic approximation with no error bound, and a numerical accountant shows the true ε is at least 6.1377, up to quadrature error.)*

32.9. RDP as a lossy summary of the curve

32.9.1. Context

Rényi DP tracks $\varepsilon(\alpha) = D_\alpha(P\|Q)$ over orders $\alpha > 1$, where the Rényi divergence $D_\alpha(P\|Q) = \frac{1}{\alpha-1} \ln \mathbb{E}_P[(P/Q)^{\alpha-1}]$ is a log-moment of the likelihood ratio. Conversions (Section 30.5) turned an RDP curve into the region of test errors it allows, with lower boundary f_{RDP}, and showed that each point of that boundary is attained by a two-outcome pair. This section reads that construction in the language of f-DP. What kind of guarantee is f_{RDP}, and where does it sit between the true curve and a single (ε, δ) pair?

32.9.2. Statement

The construction rests on one observation: a test turns any pair into a pair of coins. Its output is "fire" with probability FPR under P and $1-\mathrm{FNR}$ under Q, so it maps P to $\mathrm{Bern}(\mathrm{FPR})$ and Q to $\mathrm{Bern}(1-\mathrm{FNR})$, and processing cannot increase a Rényi divergence. So the test's errors must keep these two coins within the RDP budget at every order. The lowest type II error that passes this check at each FPR is f_{RDP}.

Let $\varepsilon(\alpha)$ be an RDP curve, known at the orders of the part's grid (the fixed list of orders that the accountants of this part evaluate) and in both orders of neighbours, and let

$$f_{\mathrm{RDP}}(\mathrm{FPR}) = \min\left\{\mathrm{FNR} : D_\alpha(\mathrm{Bern}(\mathrm{FPR}) \,\|\, \mathrm{Bern}(1-\mathrm{FNR})) \le \varepsilon(\alpha) \text{ and } D_\alpha(\mathrm{Bern}(1-\mathrm{FNR}) \,\|\, \mathrm{Bern}(\mathrm{FPR})) \le \varepsilon \right. \tag{32.19}$$

be the lowest type II error it allows (Equation 30.11). Then:

1. The trade-off curve of a pair determines its RDP curve.
2. f_{RDP} is a symmetric trade-off function, and a mechanism with this RDP curve is f_{RDP}-DP. At each FPR, no higher value follows from the RDP values alone.
3. The best $\delta(\varepsilon)$ that the RDP values certify is the privacy profile of f_{RDP}: $\delta_{\mathrm{RDP}}(\varepsilon) = 1 + f^*_{\mathrm{RDP}}(-e^\varepsilon)$, which is the optimal conversion Equation 30.12 of Conversions.

For the Gaussian pair, $\varepsilon(\alpha) = \alpha\mu^2/2$ (Part 1). At $\mu = 1$, f_{RDP} lies on or below G_1 everywhere (step 6), and strictly below at every FPR the script computed.

32.9.3. Derivation

1. **The curve determines the Rényi divergence.** By Fact 1 the curve fixes the law of L under P. Since $P/Q = e^L$, the Rényi divergence is $D_\alpha(P\|Q) = \frac{1}{\alpha-1}\ln \mathbb{E}_P[e^{(\alpha-1)L}]$, a functional of that law (Divergences).
2. **RDP implies f_{RDP}-DP.** A test with errors $(\mathrm{FPR}, \mathrm{FNR})$ maps P to $\mathrm{Bern}(\mathrm{FPR})$ and Q to $\mathrm{Bern}(1-\mathrm{FNR})$. By data processing for Rényi divergence (post-processing cannot increase it), the two Bernoullis satisfy the constraints whenever P and Q do. So every point of the true curve is feasible, and $T(P,Q) \ge f_{\mathrm{RDP}}$.
3. **f_{RDP} is a trade-off function.** Each constraint is convex in $(\mathrm{FPR}, \mathrm{FNR})$, because each term of the Bernoulli divergence has the form $x^\alpha y^{1-\alpha}$, which is jointly convex for $\alpha > 1$ ("Computing it" in Conversions; Section F.5 proves it). So the feasible set is convex and its lower boundary f_{RDP} is convex. The point $(\mathrm{FPR}, 1-\mathrm{FPR})$ is feasible, because two equal Bernoullis have divergence 0, so $f_{\mathrm{RDP}}(\mathrm{FPR}) \le 1-\mathrm{FPR}$ and $f_{\mathrm{RDP}}(1) = 0$. A convex function on $[0,1]$ whose minimum is at $\mathrm{FPR} = 1$ is non-increasing: for $\mathrm{FPR} < \mathrm{FPR}' < 1$, write $\mathrm{FPR}' = t\mathrm{FPR} + (1-t)\cdot 1$ with $t \in (0,1)$, and then $f(\mathrm{FPR}') \le tf(\mathrm{FPR}) + (1-t)f(1) \le f(\mathrm{FPR})$. Swapping FPR and FNR swaps the two constraints (the coins $\mathrm{Bern}(\mathrm{FPR})$ and $\mathrm{Bern}(1-\mathrm{FNR})$ trade places after relabelling their outcomes), so the feasible set is symmetric about the diagonal and $f_{\mathrm{RDP}} = f^{-1}_{\mathrm{RDP}}$.
4. **No higher value at any** FPR**.** For each feasible $(\mathrm{FPR}, \mathrm{FNR})$ the pair $(\mathrm{Bern}(\mathrm{FPR}), \mathrm{Bern}(1-\mathrm{FNR}))$ is itself a mechanism that satisfies the constraints at every order of the grid, and its test "fire on outcome 1" has errors $(\mathrm{FPR}, \mathrm{FNR})$, so its curve passes through $(\mathrm{FPR}, \mathrm{FNR})$ (step 5 of the derivation in Conversions). So at each FPR some pair consistent with the RDP values reaches $f_{\mathrm{RDP}}(\mathrm{FPR})$. Different values of FPR need different pairs.

5. **The optimal conversion is the conjugate.** Equation 30.12 writes the best certified δ as $\max_{\mathrm{FPR}} [1 - \mathrm{FPR} - e^{\varepsilon} f_{\mathrm{RDP}}(\mathrm{FPR})]$, with the roles of FPR and FNR the other way round from the duality of Section 32.5. Because f_{RDP} is symmetric, its graph contains $(\mathrm{FNR}, \mathrm{FPR})$ whenever it contains $(\mathrm{FPR}, \mathrm{FNR})$, so swapping the roles changes nothing: the maximum equals $\max_{\mathrm{FPR}} [1 - f_{\mathrm{RDP}}(\mathrm{FPR}) - e^{\varepsilon}\mathrm{FPR}] = 1 + f^{*}_{\mathrm{RDP}}(-e^{\varepsilon})$, the duality of Equation 32.9 applied to f_{RDP}.
6. **Below G_1.** Step 2 applies to any pair with these RDP values, and the Gaussian pair with $\mu = 1$ is one, so its curve is never below f_{RDP}: $G_1 \geq f_{\mathrm{RDP}}$ at every FPR. That the gap is strict, and how wide it is, the script finds numerically: it computes f_{RDP} for $\mu = 1$ by bisection on FNR over the grid of orders, and finds it strictly below G_1 everywhere it looked. More orders impose more constraints and can only raise f_{RDP}, but not by much: at $\mathrm{FPR} = \Phi(-1/2) = 0.3085$, a dense set of orders in $[1.01, 3000]$ raises it from 0.2201 to 0.2219, still far below $G_1(0.3085) = 0.3085$.

32.9.4. Interpretation

The results form a ladder of summaries. For the Gaussian mechanism, G_{μ} is the exact curve, f_{RDP} is what its RDP curve keeps, and an (ε, δ) pair is one touching line of f_{RDP}. So the slack of an RDP conversion has two parts: the gap between the line and f_{RDP}, which the optimal conversion removes, and the gap between f_{RDP} and the true curve, which no conversion removes (Section 30.7).

RDP loses because it keeps only the exponential moments $\mathbb{E}_P[e^{(\alpha-1)L}]$ at a few orders. Different laws of the loss share them, and f_{RDP} has to allow the worst of those laws. The absolute gap in FNR is largest in the bulk. Relative to the attacker's power $1 - \mathrm{FNR}$, though, the RDP curve allows roughly the same factor more power than the Gaussian has from the bulk down to $\mathrm{FPR} = 10^{-6}$ (Table 30.5), so the loss is not confined to the bulk.

32.9.5. Example: what 1-GDP's RDP curve forgets

Table 32.9 compares G_1 with f_{RDP} computed from $\varepsilon(\alpha) = \alpha/2$. The third row is the best advantage, which for a symmetric curve sits at the diagonal point $\mathrm{FPR} = \mathrm{FNR}$, where it equals $1 - \mathrm{FPR} - \mathrm{FNR} = 1 - 2\mathrm{FPR}$; for G_1 that is $1 - 2 \times 0.3085 = 0.3829$. The last row is the duality of Section 32.5 applied to each curve.

Table 32.9.: The trade-off curve of 1-GDP against the best curve its RDP curve implies over the part's grid of orders, read at the diagonal and through the duality.

Quantity	Exact curve G_1	f_{RDP} from $\varepsilon(\alpha) = \alpha/2$
FNR at $\mathrm{FPR} = \Phi(-1/2) = 0.3085$	0.3085	0.2201
Diagonal point, $\mathrm{FPR} = \mathrm{FNR}$	0.3085	0.2585
Best advantage	0.3829	0.4830
$\delta(0) = 1 - 2\mathrm{FPR}$ at the diagonal point		
$\delta(1)$	0.1269	0.2149

In the bulk the RDP summary gives a lot away (Table 32.9). It allows an attacker an advantage of 0.4830 where the best possible is 0.3829, and the best $\delta(1)$ it can certify is 0.2149, 1.69 times the exact 0.1269. Figure 32.6 draws both curves with their touching lines at $\varepsilon = 1$.

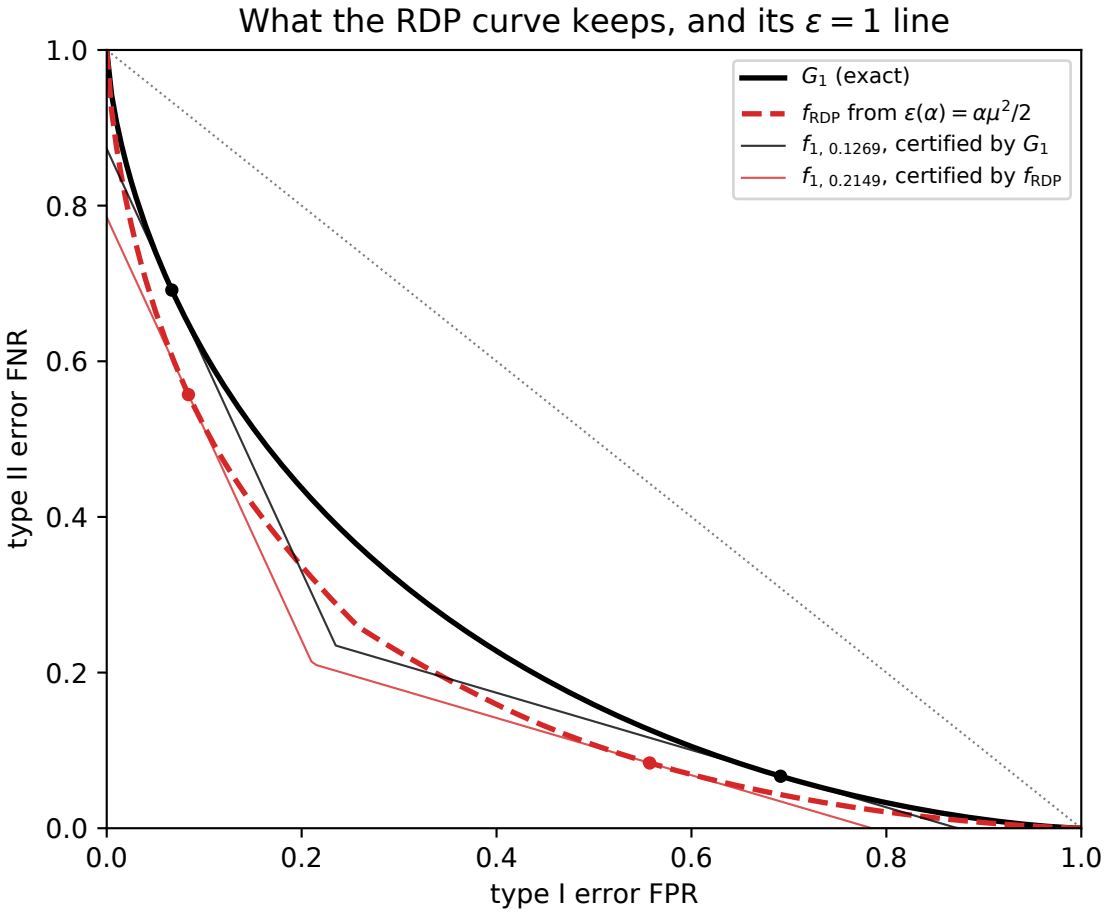

Figure 32.6.: G_1 (black) and the lowest curve f_{RDP} compatible with its RDP curve $\varepsilon(\alpha) = \alpha/2$ over the part's grid of orders (red, dashed). The thin lines are the (ε, δ) curves at $\varepsilon = 1$ that each one certifies, $f_{1,0.1269}$ for G_1 and $f_{1,0.2149}$ for f_{RDP}; each touches its own curve at two mirror-image points (dots). An RDP conversion can only report lines under f_{RDP}.

32.9.6. Check yourself

- If a mechanism's RDP curve is no larger than the Gaussian's at every order of the grid, must its trade-off curve lie on or above G_μ? *(No. By step 4, for each* FPR *the two-outcome pair through* $(\text{FPR}, f_{\text{RDP}}(\text{FPR}))$ *satisfies the Gaussian's RDP curve at every order of the grid, yet its curve passes below* G_μ *at* FPR.*)*
- Why is GDP accounting for full-batch noisy gradient descent strictly better than RDP accounting for it? *(Both compose exactly, but GDP keeps the whole curve* $G_{\sqrt{T}/\sigma}$*, while RDP keeps only* $\varepsilon(\alpha) = \alpha T/(2\sigma^2)$*, from which only* f_{RDP}*, which lies below* $G_{\sqrt{T}/\sigma}$*, can be*

recovered.)

32.10. Code: check every result by computation and simulation

The script code/gaussian_dp.py computes every number quoted in this chapter and draws every figure. The public functions `gdp_delta`, `gdp_eps`, `gaussian_tradeoff`, `eps_delta_tradeoff`, `compose_gdp` and `clt_mu_subsampled_gaussian` are the ones later chapters import. It uses the standard library and NumPy only: Φ comes from `math.erfc` and Φ^{-1} from bisection. From the repository root:

```
uv run python code/part04-privacy-accounting/gaussian_dp.py
```

Output (seed 0):

Table 32.10.: Results printed by the script with seed 0.

Experiment	Result
$f_{1,0}$, Laplace and G_1 at FPR $= 0.25$	0.3204, 0.3679, 0.3724
Simulated threshold test on G_1 at FPR $= 0.05$	$\widehat{\text{FPR}} = 0.0502$, $\widehat{\text{FNR}} = 0.7408$; exact 0.7405
$\delta(1)$ of 1-GDP: formula, hockey-stick integral, conjugate on a grid	0.126937 each
ε at $\delta = 10^{-5}$ for $\mu = 0.5, 1, 2$	1.9931, 4.3772, 9.9973
Envelope of 1001 (ε, δ) lines against G_1	max gap 4.9×10^{-6}
Simulated 2-D test, $\mu = (1, 1)$, FPR $= 0.05$	$\widehat{\text{FNR}} = 0.5913$; $G_{\sqrt{2}}(0.05) = 0.5912$
Four 1-GDP releases at $\delta = 10^{-5}$	exact 9.9973; composing points 18.7607
Randomized response, $k = 100$, $\varepsilon_0 = 0.1$: $\delta(1)$	exact 0.1257; CLT 0.1271
DP-SGD, $T = 10{,}000$	CLT $\mu = 1.3108$, $\varepsilon = 6.0071$; numerical $[6.1377, 6.2377]$
1-GDP vs its RDP curve: best advantage; $\delta(1)$	0.3829 vs 0.4830; 0.1269 vs 0.2149

tests/test_gaussian_dp.py checks that the output still matches Table 32.10 and every other number in the text.

What to take from it. The GDP profile is exact: the closed form, the hockey-stick integral of the PRV and the conjugate of the curve agree to six digits, three routes to one number. Composing curves rather than points matters: turning each step into one (ε, δ) point before composing nearly doubled ε. The CLT is good in the bulk and unreliable in the tail: it erred in both directions on randomized response and under-reported ε for the running DP-SGD example at every T. And RDP forgets part of the curve, even for the Gaussian mechanism, where it is as good as it gets.

32.12. Cheat sheet

Table 32.11 collects every result in the chapter. Type I error is FPR, type II error FNR; α is a Rényi order.

Table 32.11.: Every result in this chapter.

Result	Statement	Where it comes from
f-DP	$T(M(D), M(D')) \geq f$ for all neighbours; then also $\max(f, f^{-1})$-DP	Neyman–Pearson; swap D, D'
(ε, δ)-DP as a curve	$f_{\varepsilon,\delta}(\mathrm{FPR}) = \max(0, 1-\delta-e^{\varepsilon}\mathrm{FPR}, e^{-\varepsilon}(1-\delta-\mathrm{FPR}))$	The two DP inequalities on a rejection region
μ-GDP	$G_{\mu}(\mathrm{FPR}) = \Phi(\Phi^{-1}(1-\mathrm{FPR})-\mu)$; Gaussian mechanism: $\mu = 1/\sigma$	Projection on the shift (Fact 3)

Result	Statement	Where it comes from
Duality	f-DP $\iff$ $(\varepsilon, 1 + f^*(-e^\varepsilon))$-DP for all $\varepsilon \geq 0$	Supporting lines of a convex curve
GDP profile	$\delta(\varepsilon) = \Phi(-\frac{\varepsilon}{\mu} + \frac{\mu}{2}) - e^\varepsilon \Phi(-\frac{\varepsilon}{\mu} - \frac{\mu}{2})$	Conjugate, or hockey stick of $L \sim \mathcal{N}(\frac{\mu^2}{2}, \mu^2)$
Composition	$\bigotimes f_i$, tight; $\bigotimes G_{\mu_i} = G_{\sqrt{\sum \mu_i^2}}$	Blackwell / Neyman–Pearson; rotation invariance
CLT	$\bigotimes f_i \approx G_\mu$, $\mu = 2\|\mathrm{kl}\|_1 / \sqrt{\|\kappa_2\|_1 - \|\mathrm{kl}\|_2^2}$, error band ξ	Berry–Esseen for the summed PRV
Subsampled Gaussian	$\mu \approx q\sqrt{T(e^{1/\sigma^2} - 1)}$ as $q\sqrt{T} \to c$	Second-order expansion of $\ln(1 + qW)$
RDP from the curve	$\varepsilon(\alpha)$ is a functional of T; RDP implies f_{RDP}-DP, a symmetric trade-off function below T; the optimal conversion is its conjugate	Data processing on $(\mathrm{Bern}(\mathrm{FPR}), \mathrm{Bern}(1 - \mathrm{FNR}))$; duality

Rules of thumb

- The trade-off curve is the guarantee; (ε, δ), RDP and ρ are summaries of it. Summarize as late as possible.
- For Gaussian noise without subsampling, account in GDP: μ^2 adds, and the (ε, δ) profile at the end is exact.
- $\mu = 1$ means $\varepsilon \approx 4.4$ at $\delta = 10^{-5}$; $\mu = 0.5$ means about 2.
- Use the CLT for intuition and quick estimates, never as the reported guarantee: it under-reported ε for the running DP-SGD example at every T. Report a certified numerical accountant instead.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

33. Amplification by subsampling

33.1. Why this matters

Differential privacy (DP) for deep learning would be useless without one trick. Stochastic gradient descent (SGD) with per-example clipping and Gaussian noise, DP-SGD, runs ten thousand steps or more. Each step is a Gaussian mechanism: it clips every example's gradient, sums them and adds Gaussian noise whose standard deviation is the **noise multiplier** σ times the clipping norm. Composing ten thousand such steps with $\sigma = 1$, and paying for every record at every step, gives $\varepsilon = 5425.5$ at $\delta = 10^{-5}$, as Rényi DP computes: a privacy loss nobody would report.

The trick is that each step only looks at a small random batch. If a record is in the batch only with probability q, an adversary who sees the step's output must first guess whether the record was used at all. That uncertainty is worth a lot. With $q = 0.01$, it turns a step that costs $\varepsilon = 1$ into one that costs about 0.017. In the language of Rényi differential privacy (RDP), which describes a mechanism by a curve $\varepsilon(\alpha)$ giving its privacy cost at each order $\alpha > 1$, it turns the curve of a Gaussian step from $\alpha/2$ into something of order $10^{-4}\alpha$ for small orders.

This chapter answers three questions. How much privacy does random sampling buy, exactly? Which sampling scheme does the answer hold for? And how do you compute it for the Gaussian steps of DP-SGD?

Notation. In this chapter q is always the **sampling rate**, never a density. Output distributions are capital letters, as in the rest of this part, and the same letter names a distribution and its density. P_0 is a step's output without the record and P_1 its output with it. For the subsampled Gaussian, $P_0 = \mathcal{N}(0, \sigma^2)$, $P_1 = \mathcal{N}(1, \sigma^2)$, and the output with the record sampled at rate q is the mixture $P_q = (1-q)P_0 + qP_1$: with probability $1-q$ the record is left out and the output is drawn from P_0, with probability q it is used and the output is drawn from P_1. The mixture lemma of the toolkit mixes three generic distributions R, P, P'. Its weight is q, the probability that the record is used. An output is y.

33.1.1. The one idea: the output is a mixture, and mixtures are closer

Fix a dataset D and add one record x to get $D' = D \cup \{x\}$. Under **Poisson sampling**, each record enters the batch independently with probability q, by its own coin flip. Condition on which records of D were drawn. On D, the mechanism then outputs some distribution P_0. On D', it outputs P_1 if x was drawn and P_0 otherwise. Since x is drawn with probability q, the output on D' is the **mixture**, compared with the output on D:

$$(1-q)P_0 + qP_1 \quad \text{against} \quad P_0. \tag{33.1}$$

With probability $1-q$ the two runs are identical. The difference between the runs is diluted by a factor q, and every likelihood ratio, the ratio of the two densities at an output y that measures

how much more likely y is in one run than in the other, is pulled toward 1. Divide the mixture by P_0 to see it: the ratio P_1/P_0 becomes $(1-q)+q\,P_1/P_0$, a weighted average of 1 and the old ratio. All of DP-SGD's privacy rests on this dilution, and the dilution depends on how the batch was drawn. A different sampling scheme gives a different mixture, and an accountant that assumes one scheme while the training code runs another reports a number that does not apply.

Table 33.1 lists the results of the chapter and where each is used.

Table 33.1.: The results of this chapter and where each is used.

Result	Where it is used
The mixture lemma	Every amplification statement in this chapter
(ε, δ) amplification, Poisson sampling, add/remove	One-step guarantees; the naive DP-SGD accountant
The same for a fixed-size batch, replace-one	Accounting for fixed-size batches; why the scheme must match the neighbouring relation
RDP of the Poisson-subsampled Gaussian	The RDP accountant for DP-SGD, and the input of numerical accounting
Small-q asymptotics, the moments accountant	Quick estimates; reading Abadi et al. (2016)
The RDP accountant for DP-SGD, against per-step composition	The running example; Choosing an accountant
No tight generic RDP amplification	Why accountants special-case the Gaussian

How to read this chapter. Read the toolkit and Section 33.3, then Section 33.4 on sampling schemes. It holds the warning that matters most in practice. Section 33.5 is the computation every DP-SGD accountant performs; do its $\alpha = 2$ walk-through by hand. Section 33.6 and Section 33.8 can wait for a second reading.

The chapter uses the Rényi divergence D_α and the hockey-stick divergence E_γ from Divergences, RDP and its composition from Rényi DP, and the conversions to (ε, δ) from From RDP to (ε, δ). Each is restated where it is used.

33.2. Toolkit: three facts every derivation uses

33.2.1. Fact 1 — (ε, δ) is a statement about events, and averaging preserves it

A mechanism is (ε, δ)-DP when, for every pair of neighbouring datasets taken in both orders, the output distributions P and Q satisfy $P(A) \le e^\varepsilon Q(A) + \delta$ for every event A (Definition): no set of outputs becomes more than e^ε times more likely, except for a slack δ. The **hockey-stick divergence** packs this into one number. It is the largest amount by which P exceeds γ times Q on any event, $E_\gamma(P\|Q) = \max_A[P(A) - \gamma Q(A)]$, so the DP condition for the pair is exactly $E_{e^\varepsilon}(P\|Q) \le \delta$.

Because the condition is a bound on each event separately, it survives averaging. Suppose $P = \sum_t w_t P_t$ and $Q = \sum_t w_t Q_t$ are averages with the same weights w_t, for instance over some random choice t that both runs share. For every event the excess is the average of the excesses, $P(A) - \gamma Q(A) = \sum_t w_t [P_t(A) - \gamma Q_t(A)]$. If each bracket is at most δ, so is their weighted average. So $E_\gamma(P\|Q) \le \max_t E_\gamma(P_t\|Q_t)$. This is **joint convexity** of E_γ, restricted to a shared mixing variable.

The subsampled mechanism is exactly such an average, over which other records were drawn. Fact 1 lets you fix those records and prove the bound for one draw.

33.2.2. Fact 2 — The mixture lemma

This is the fact that does the amplifying. Picture two runs whose outputs are mixtures with the same weight q: with probability $1-q$ both draw from a common distribution R, where the runs agree, and with probability q the first draws from P and the second from P', where they may differ. Where they agree the likelihood ratio is 1; where they differ it is at most about e^ε. The mixture's ratio should then be at most the weighted average $(1-q)\cdot 1 + qe^\varepsilon = 1 + q(e^\varepsilon - 1)$, and the slack δ, which only enters through the differing part, should shrink to $q\delta$. The lemma makes this precise, with one subtlety: P must be close not only to P' but also to R, because a high-probability event of P could otherwise be one that R never produces.

Let R, P, P' be three distributions, $\varepsilon \ge 0$, $\delta \in [0,1]$ and $q \in [0,1]$. Suppose that for every event A,

$$P(A) \le e^\varepsilon P'(A) + \delta \qquad \text{and} \qquad P(A) \le e^\varepsilon R(A) + \delta. \tag{33.2}$$

Then for every event A,

$$(1-q)R(A) + qP(A) \le e^{\varepsilon'}\left[(1-q)R(A) + qP'(A)\right] + q\delta, \qquad e^{\varepsilon'} = 1 + q(e^\varepsilon - 1). \tag{33.3}$$

So the ε shrinks to ε' and the δ to $q\delta$. This is an (ε,δ) form of what Balle, Barthe & Gaboardi (2018, Theorem 2) call **advanced joint convexity**.

Proof. The plan is to treat the three probabilities of A as unknowns, see that the gap between the two sides gets larger only when $P'(A)$ and $R(A)$ get smaller, and push them down to the smallest values the assumptions allow. Fix A and write $a = P(A)$, $b = P'(A)$, $c = R(A)$, and F for the left side minus the right side without the $q\delta$. The claim is $F \le q\delta$.

1. *Expand.* The $(1-q)c$ on the left and the $e^{\varepsilon'}(1-q)c$ on the right combine to $(1-q)c(1-e^{\varepsilon'})$, and $1 - e^{\varepsilon'} = -q(e^\varepsilon - 1)$. So

$$F = qa - q(1-q)(e^\varepsilon - 1)\,c - q\big(1 + q(e^\varepsilon - 1)\big)\,b. \tag{33.4}$$

2. *Signs.* The coefficients of b and c are negative, so F is largest when b and c are as small as the assumptions allow. Solving each assumption for the smaller side gives $b \ge e^{-\varepsilon}(a-\delta)$ and $c \ge e^{-\varepsilon}(a-\delta)$, and both are also ≥ 0, being probabilities. Which of the two lower bounds binds depends on whether a exceeds δ.
3. *Case $a \le \delta$.* Drop the negative terms: $F \le qa \le q\delta$.
4. *Case $a > \delta$.* Put $b = c = e^{-\varepsilon}(a-\delta)$ into step 1. The two coefficients add up to $(1-q)(e^\varepsilon - 1) + 1 + q(e^\varepsilon - 1) = e^\varepsilon$, so $F \le qa - qe^{-\varepsilon}(a-\delta)e^\varepsilon = q\delta$.

The script checks the lemma on random examples. It draws 20,000 random triples (R, P, P') on four outcomes, computes the smallest δ for which the two assumptions hold in both directions at $\varepsilon = 1$, and checks Equation 33.3 with $q = 0.1$. For each triple it divides the left side's excess over $e^{\varepsilon'}$ times the bracket by $q\delta$. The largest value of this ratio is 1.0000: the lemma holds, and some triples meet it with equality to four digits, so it cannot be improved.

33.2.3. Fact 3 — Group privacy

A guarantee for datasets one record apart also covers datasets two records apart, at a price. If a mechanism is (ε, δ)-DP for datasets one step apart, apply the definition twice along the chain D_0, D_1, D_2: $P_0(A) \le e^{\varepsilon} P_1(A) + \delta \le e^{\varepsilon}(e^{\varepsilon} P_2(A) + \delta) + \delta = e^{2\varepsilon} P_2(A) + (1 + e^{\varepsilon})\delta$. So it is $(2\varepsilon, (1 + e^{\varepsilon})\delta)$-DP for datasets two steps apart (Properties). Replacing a record is a removal followed by an addition, so a guarantee for add/remove neighbours gives one for replace-one neighbours at this price.

33.3. Amplification for (ε, δ)-DP under Poisson sampling

33.3.1. Context

You have a mechanism M that is (ε, δ)-DP for add/remove neighbours, datasets that differ by one record being present in one and absent from the other. You run it on a Poisson sample of the data, each record kept with probability q. What are the privacy parameters of the combined mechanism? This is the oldest amplification result. Kasiviswanathan et al. (2008) used it to learn privately from a sample, and the tight form below is due to Li, Qardaji & Su (2012) and Balle, Barthe & Gaboardi (2018).

33.3.2. Statement

The answer is the mixture lemma with the sampling rate as the weight: the likelihood ratio becomes a weighted average of 1 and e^{ε}, and δ is paid only when the record is drawn. Let M be (ε, δ)-DP for add/remove neighbours and let $M \circ S_q$ run M on a Poisson sample with rate q. Then $M \circ S_q$ is (ε', δ')-DP for add/remove neighbours with

$$\varepsilon' = \ln\left(1 + q(e^{\varepsilon} - 1)\right), \qquad \delta' = q\delta. \tag{33.5}$$

The bound is tight: for every ε and q some mechanism attains it (Balle, Barthe & Gaboardi 2018, Theorems 8 and 13).

33.3.3. Derivation

The idea is to fix every random choice except whether x is drawn, apply the mixture lemma once for each order of the pair, and then average the fixed choices back in with Fact 1. Let $D' = D \cup \{x\}$.

1. **Condition on the rest of the sample.** Let $\tilde{D}$ be the Poisson sample of D. Because each record has its own coin, the sample of D' is $\tilde{D}$ or $\tilde{D} \cup \{x\}$, the second with probability q, independently of $\tilde{D}$. Given $\tilde{D}$, write $P_0 = M(\tilde{D})$ and $P_1 = M(\tilde{D} \cup \{x\})$. Then $M \circ S_q(D)$ given $\tilde{D}$ is P_0, and $M \circ S_q(D')$ given $\tilde{D}$ is $(1-q)P_0 + qP_1$.
2. **Direction "D' against D".** Here the mixture is on the left. Apply the mixture lemma (Fact 2) with $R = P_0$, $P = P_1$, $P' = P_0$ and weight q. Both of its assumptions then read $P_1(A) \le e^{\varepsilon} P_0(A) + \delta$, which holds because $\tilde{D}$ and $\tilde{D} \cup \{x\}$ are neighbours and M is DP. The right side of Equation 33.3 becomes $e^{\varepsilon'}[(1-q)P_0(A) + qP_0(A)] + q\delta = e^{\varepsilon'} P_0(A) + q\delta$. This is the **remove** direction in the naming of Numerical accounting: the dataset with the record comes first, and its neighbour is obtained by removing x.
3. **Direction "D against D'".** Now the mixture is on the right. Apply the lemma with $R = P_0$, $P = P_0$, $P' = P_1$. The assumptions are $P_0(A) \le e^{\varepsilon} P_1(A) + \delta$, which is DP of M again, and $P_0(A) \le e^{\varepsilon} P_0(A) + \delta$, which is always true. The left side is $(1-q)P_0(A) + qP_0(A) = P_0(A)$ and the right side $e^{\varepsilon'}[(1-q)P_0(A) + qP_1(A)] + q\delta$. This is the **add** direction.
4. **Average over $\tilde{D}$.** Both bounds hold for every $\tilde{D}$ with the same $(\varepsilon', q\delta)$, and both runs average over $\tilde{D}$ with the same weights, so they hold for the averages over $\tilde{D}$ (Fact 1).

Tightness. To show ε' cannot be smaller, you need a mechanism whose likelihood ratio actually reaches $1 + q(e^{\varepsilon} - 1)$. Randomized response does it. It reports a bit truthfully with probability $e^{\varepsilon}/(1+e^{\varepsilon})$ and flipped otherwise (Randomized response), so the probability of any report changes by a factor of exactly e^{ε} when the true bit changes. Let M apply it to the bit "the sample contains a flagged record". Take D with no flagged record and x flagged. Then the bit is 0 whenever x is not drawn and 1 whenever it is, so P_0 and P_1 are the same for every $\tilde{D}$, and $P_1(1)/P_0(1) = e^{\varepsilon}$. The likelihood ratio of the mixture to P_0 at the output "1" is

$$\frac{(1-q)P_0(1) + qP_1(1)}{P_0(1)} = (1-q) + q\frac{P_1(1)}{P_0(1)} = 1 + q(e^{\varepsilon} - 1). \tag{33.6}$$

With $\delta = 0$ the event $\{1\}$ forces $e^{\varepsilon'} \ge 1 + q(e^{\varepsilon} - 1)$, so ε' in Equation 33.5 cannot be improved.

33.3.4. Interpretation

The formula behaves differently for small and large ε. For small ε, amplification is linear in q. When $\varepsilon \ll 1$, $e^{\varepsilon} - 1 \approx \varepsilon$ and $\ln(1+y) \approx y$ for small y, so $\varepsilon' \approx q\varepsilon$. A 1% sample makes each step a hundred times cheaper.

For large ε, amplification only subtracts. When $qe^{\varepsilon} \gg 1$, the 1 inside the logarithm is negligible and $1 + q(e^{\varepsilon} - 1) \approx qe^{\varepsilon}$, so $\varepsilon' \approx \ln(qe^{\varepsilon}) = \varepsilon - \ln(1/q)$. Sampling can never remove more than $\ln(1/q)$ nats, because in the worst case the record was drawn, and that happens with probability q. At $q = 0.01$ and $\varepsilon = 10$, Table 33.3 gives 5.3993, close to $10 - \ln 100 = 5.395$. Figure 33.1 shows the switch between the two regimes around $\varepsilon \approx \ln(1/q)$, where qe^{ε} reaches 1.

The δ always shrinks by q, because the failure event of M only matters when the record was drawn. Finally, Equation 33.5 is a statement about one step, and it is tight for one step. Composing per-step (ε', δ') pairs is not tight, and the running example shows by how much (Section 33.7).

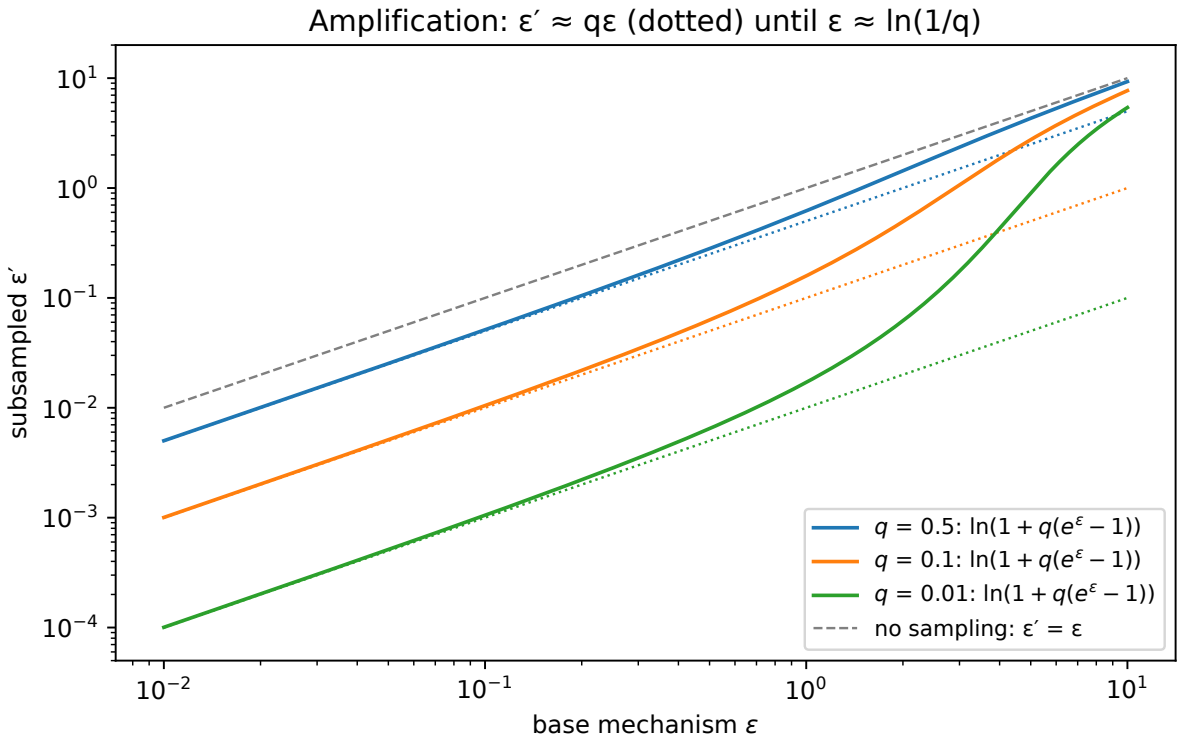

Figure 33.1.: The subsampled ε' against the base ε for three sampling rates, with the small-ε approximation $q\varepsilon$ dotted and no sampling dashed. Amplification is a factor q for small ε and only a shift by $\ln(1/q)$ for large ε.

33.3.5. Example: randomized response, sampled at 10%

Take $\varepsilon = 1$ and $q = 0.1$, and the randomized-response mechanism of the tightness argument. When the record is not drawn the true bit is 0, which is reported as 0 with probability $e/(1+e) = 0.7311$ and as 1 with probability $1/(1+e) = 0.2689$; when it is drawn the two probabilities swap. The mixture weights these by 0.9 and 0.1: for the output 1, $0.9 \times 0.2689 + 0.1 \times 0.7311 = 0.3152$. Table 33.2 shows both outputs and the likelihood ratios in both directions.

Table 33.2.: Randomized response with $\varepsilon = 1$ on a 10% Poisson sample. The likelihood ratios of the unsampled mechanism are $e^{\pm 1}$; sampling pulls them to at most 1.1718.

Output y	$P_0(y)$, record not drawn	$P_1(y)$, record drawn	Mixture $0.9P_0 + 0.1P_1$	Mixture / P_0	P_0 / mixture
0	0.7311	0.2689	0.6848	0.9368	1.0675
1	0.2689	0.7311	0.3152	1.1718	0.8534

Without sampling the ratios are $e = 2.718$ and $1/e$. With sampling the largest is $1.1718 = 1 + 0.1(e-1)$, so $\varepsilon' = \ln 1.1718 = 0.1586$, as Equation 33.5 says, against $q\varepsilon = 0.1$. The other direction's largest ratio, 1.0675, is smaller: removing the record from a mixture changes less than adding it, because the mixture never puts less than 0.9 times P_0's probability on any output. Table 33.3 gives ε' for more cases.

Table 33.3.: The amplified $\varepsilon' = \ln(1 + q(e^{\varepsilon} - 1))$ for three sampling rates.

q	$\varepsilon = 0.1$	$\varepsilon = 1$	$\varepsilon = 5$	$\varepsilon = 10$
0.01	0.0011	0.0170	0.9059	5.3993
0.1	0.0105	0.1586	2.7563	7.6978
0.5	0.0512	0.6201	4.3136	9.3069

33.3.6. Check yourself

- At $q = 0.01$, roughly how large must ε be before amplification stops being a factor of 100? *(Around $\ln(1/q) = 4.6$, where $q(e^{\varepsilon} - 1)$ reaches 1. At $\varepsilon = 5$, Table 33.3 gives $\varepsilon' = 0.9059$, not 0.05.)*
- Why does the derivation need $\tilde{D}$ and x to be drawn independently? *(So that, given T, the record is included with probability exactly q. The mixture weights must not depend on the rest of the sample.)*

33.4. The sampling scheme must match the neighbouring relation

33.4.1. Context

Poisson sampling gives batches of random size. Most training code draws fixed-size batches: either a random batch of m out of n records at each step, or a random permutation of the data

cut into n/m consecutive batches per epoch (**shuffle and partition**). Does the amplification of Equation 33.5 still apply? Only if you change what you compare. A fixed batch size pairs naturally with **replace-one** neighbours, datasets of the same size that differ in one record's value, because with a fixed batch size adding a record would change the size. Accounting for one scheme while running another is a bug that can multiply ε several times over.

33.4.2. Statement

Fixed-size batches, replace-one. A uniformly random batch of m out of n contains a given record with probability m/n, so m/n plays the role of q, and the same formula holds, as long as the base guarantee is for replace-one neighbours. Draw a uniformly random batch of m records from n, and let M be (ε, δ)-DP for replace-one neighbours on datasets of size m. Then the subsampled mechanism is (ε', δ')-DP for replace-one neighbours on datasets of size n, with

$$\varepsilon' = \ln\Big(1 + \frac{m}{n}(e^{\varepsilon} - 1)\Big), \qquad \delta' = \frac{m}{n}\delta \tag{33.7}$$

(Balle, Barthe & Gaboardi 2018, Theorem 9). The formula is that of Equation 33.5 with $q = m/n$, but the base guarantee is a different one.

The matching rule. Each combination of sampling scheme and neighbouring relation produces its own pair of output distributions, and needs its own base guarantee. Table 33.4 lists them. Its last column applies them to DP-SGD's noisy gradient sum, where every gradient is clipped to norm C and the noise has standard deviation σC; what matters is how far one record can move the sum, measured in units of the noise. The zero-out relation in the last row compares a dataset with the same dataset in which the target's gradient is set to 0.

Table 33.4.: What to account for under each combination of sampling scheme and neighbouring relation.

Sampling	Neighbours	Pair to account for	Base guarantee needed	Gaussian sum, clipping norm C
Poisson, rate q	add/remove	$(1-q)P_0 + qP_1$ against P_0	add/remove	means differ by C: noise multiplier σ
Fixed size m of n	replace-one	$(1-q)R + qP$ against $(1-q)R + qP'$, $q = m/n$	replace-one	means differ by $2C$: noise multiplier $\sigma/2$
Fixed size m of n	add/remove	dominated by the Poisson pair with noise multiplier $\sigma/2$ (Lebeda et al. 2024, Proposition 9)	replace-one	$\sigma/2$

Sampling	Neighbours	Pair to account for	Base guarantee needed	Gaussian sum, clipping norm C
Poisson, rate q	replace-one	both sides are mixtures, base pair two steps apart	$(2\varepsilon, (1+e^{\varepsilon})\delta)$ by group privacy	means differ by up to $2C$
Shuffle and partition	zero-out (the target's gradient set to 0)	the record is in exactly one batch per epoch	no simple formula; see below	measured, not derived

33.4.3. Derivation

Equation 33.7 by a coupling. A fixed-size batch is not drawn record by record, so there is no independent coin for the differing record. The trick, called a **coupling**, is to build the batch in a way that has such a coin, and then to use the same coin and the same other records for both datasets. Let D and D' differ in record i: x in D, x' in D'.

1. **Build a batch that avoids i in two stages.** Draw B, a uniform $(m-1)$-subset of the other $n-1$ records, then z, a uniform record from the $(n-1)-(m-1)=n-m$ others not in B. The batch $B\cup\{z\}$ is a uniform m-subset that avoids i: each such subset arises from m choices of which element is z, equally often.
2. **Write both outputs as mixtures over (B, z).** A uniform m-subset of n contains i with probability $q=m/n$. Given that it does, the rest of it is a uniform $(m-1)$-subset of the others, which is B; given that it does not, it is a uniform m-subset avoiding i, which is $B\cup\{z\}$. So flip an independent coin with probability q: on heads the batch is $B\cup\{x\}$ in D and $B\cup\{x'\}$ in D', on tails it is $B\cup\{z\}$ in both. Given (B, z), the outputs are $(1-q)R+qP$ and $(1-q)R+qP'$ with $R=M(B\cup\{z\})$, $P=M(B\cup\{x\})$, $P'=M(B\cup\{x'\})$.
3. **Check the lemma's assumptions.** The three batches $B\cup\{x\}$, $B\cup\{x'\}$, $B\cup\{z\}$ have size m and differ pairwise in one element, so they are pairwise replace-one neighbours. Hence $P\le e^{\varepsilon}P'+\delta$ and $P\le e^{\varepsilon}R+\delta$ on every event, and the same with P and P' swapped.
4. **Apply the mixture lemma and average.** Fact 2 with weight q gives the bound in one direction, and again with P and P' swapped in the other. Both runs average over (B, z) with the same weights, so Fact 1 carries the bound to the full mechanism.

The Gaussian column. For a sum of gradients clipped to norm C, adding or removing a record moves the sum by at most C, and replacing one moves it by up to $2C$: the old gradient leaves and a new one, possibly pointing the opposite way, comes in. A Gaussian mechanism's privacy depends only on the shift divided by the noise's standard deviation, and $2C/(\sigma C)=C/((\sigma/2)C)$, so noise σC with shift $2C$ is the same as shift C with noise multiplier $\sigma/2$. Lebeda, Regehr, Kamath & Steinke (2024, Proposition 9) show, using Zhu, Dong & Wang (2022, Theorem 11), that for fixed-size batches this shift of $2C$ is the worst case under the add relation and under the remove relation, each taken separately, because a record entering the batch pushes another one out.

Poisson with replace-one. Given the rest of the sample $\tilde{D}$, the target is drawn with probability q in both runs, so the outputs are $(1-q)R+qP$ and $(1-q)R+qP'$ with $R=M(\tilde{D})$, $P=M(\tilde{D}\cup\{x\})$, $P'=M(\tilde{D}\cup\{x'\})$. The pair (P, R) is one add/remove step apart, but (P, P') is two: remove x,

then add x'. The mixture lemma needs one guarantee for both pairs, so use the weaker one. Fact 3 gives the base guarantee $(2\varepsilon, (1+e^{\varepsilon})\delta)$ for both, and Fact 2 then gives $\varepsilon' = \ln(1+q(e^{2\varepsilon}-1))$ and $\delta' = q(1+e^{\varepsilon})\delta$. For small q both logarithms are close to their arguments' excess over 1, and since $e^{2\varepsilon}-1 = (e^{\varepsilon}-1)(e^{\varepsilon}+1)$, this bound is about $e^{\varepsilon}+1$ times the add/remove value.

The bound is not tight: the pair (P, R) is only one step apart, but the lemma charges it the two-step guarantee. For pure DP ($\delta = 0$) the exact value follows from likelihood ratios. Pure DP of M says that every likelihood ratio between neighbours lies in $[e^{-\varepsilon}, e^{\varepsilon}]$, so both P/R and P'/R do. Divide the two mixtures by R: their ratio is $\frac{(1-q)+qP/R}{(1-q)+qP'/R}$. It is largest when the numerator is largest and the denominator smallest, that is with $P/R = e^{\varepsilon}$ and $P'/R = e^{-\varepsilon}$, which gives at most $\frac{1-q+qe^{\varepsilon}}{1-q+qe^{-\varepsilon}}$. Taking the logarithm, and writing $1-q+qe^{-\varepsilon} = 1-q(1-e^{-\varepsilon})$,

$$\varepsilon' = \ln\left(1+q(e^{\varepsilon}-1)\right) - \ln\left(1-q(1-e^{-\varepsilon})\right). \tag{33.8}$$

The Laplace mechanism on a sum attains it (Exercise 3 in the exercise book). For small ε each of the two logarithms is about $q\varepsilon$, so the value is about twice the add/remove value. At $\varepsilon = 1$ and $q = 0.01$ it is 0.02338, against 0.06193 for the group-privacy bound and 0.01704 for add/remove: a ratio of 1.37, not 3.64.

33.4.4. Interpretation

Why mixing them is a bug. Each row of Table 33.4 is correct on its own. The bug is to train with one row and report the number from another. Two cases are common.

The first is fixed-size sampled batches with a Poisson accountant. The accountant assumes a shift of C; the training run has a shift of $2C$. You are reporting the privacy of twice as much noise as you added. Lebeda et al. (2024, Table 1) give an example with $q = 0.001$, $\sigma = 0.8$ and 10,000 steps: at $\delta = 10^{-5}$ they report $\varepsilon = 0.80$ for Poisson sampling and $\varepsilon = 12.98$ for fixed-size batches, from a numerical accountant. (The tight privacy-loss-distribution accountants of the `dp_accounting` and `prv_accountant` libraries give 0.78 for Poisson sampling; that value comes from those libraries, not from this chapter's script.) The RDP accountant of this chapter reproduces the gap: 1.38 against 15.30.

The second is shuffle and partition with a Poisson accountant, and it is worse, because the mechanism of amplification is missing altogether. In one epoch the record is in exactly one batch, never absent, so no step's output is a mixture with "not used". The only uncertainty is *which* batch held the record, and the other records can give that away.

Chua et al. (2024) build a bad case. Every other record has gradient -1, the target has $+1$, and the neighbouring dataset zeroes the target out. Recentre each batch sum by adding the batch size, which removes the -1 contributions of a full batch of other records. Batches without the target then output $\mathcal{N}(0, \sigma^2)$. The target's batch has one -1 fewer and a $+1$ instead, so it outputs $\mathcal{N}(2, \sigma^2)$, or $\mathcal{N}(1, \sigma^2)$ when the target is zeroed. You don't know which batch holds it, so with b batches the epoch's output is a mixture, over the batch index t, of $\mathcal{N}(2e_t, \sigma^2 I)$ against the same mixture of $\mathcal{N}(e_t, \sigma^2 I)$, where e_t is the vector with 1 in position t and 0 elsewhere.

A natural test looks at the largest of the b batch outputs and says "target present" when it exceeds a threshold τ. The largest output stays below τ only if every batch output does, and the batches are independent. The target's batch stays below τ with probability $\Phi(\frac{\tau-2}{\sigma})$, where Φ is the standard normal distribution function, and each of the $b-1$ others with probability $\Phi(\frac{\tau}{\sigma})$.

This does not depend on which batch holds the target, so mixing over t changes nothing, and the test fires with probability $1 - \Phi(\frac{\tau-2}{\sigma})\Phi(\frac{\tau}{\sigma})^{b-1}$ under the first distribution and $1 - \Phi(\frac{\tau-1}{\sigma})\Phi(\frac{\tau}{\sigma})^{b-1}$ under the second. Recall that $\delta(\varepsilon)$, the smallest δ that works with a given ε, is the largest value of $P(A) - e^{\varepsilon}Q(A)$ over events A (Fact 1). Any one event, such as "the largest output exceeds τ", gives a value no larger, so it gives a lower bound on $\delta(\varepsilon)$. Maximizing over τ gives the best such lower bound, and the smallest ε it does not rule out at a given δ is a lower bound on the true ε.

This is the zero-out relation, not add/remove. Under zero-out, a Poisson step's clipped sum also moves by at most C, as under add/remove, so the Poisson accountant's number applies to the same relation, and the comparison below is like with like.

The script reproduces Chua et al.'s headline check: with $\sigma = 0.4$ and $b = 10{,}000$ batches, the test gives $\delta(4) \geq 0.226$ for shuffling, against $\delta(4) = 0.244$ for a fixed, non-random batch order. They report that a Poisson accountant gives $\delta(4) \leq 1.18 \times 10^{-5}$ for the same parameters.

33.4.5. Example: one epoch of the running example

Take $q = 0.01$, so one epoch is $b = 100$ batches, and $\delta = 10^{-5}$. Table 33.5 compares three batch samplers for one epoch. With deterministic batches the record is used once, in a known batch, so the epoch is a plain Gaussian mechanism and its ε is exact. For shuffle and partition the table gives the lower bound from the test above, and for Poisson sampling the upper bound from the RDP accountant of Section 33.7.

Table 33.5.: The ε at $\delta = 10^{-5}$ of one epoch of 100 batches under three batch samplers. Shuffling is a lower bound and Poisson an upper bound, so wherever the shuffled column exceeds the Poisson column, the Poisson number is provably wrong for shuffled training.

σ	Deterministic batches (exact)	Shuffled batches (lower bound)	Poisson sampling (upper bound)
0.5	10.00	10.00	8.03
1	4.38	4.06	1.21
1.5	2.75	1.46	0.47
2	1.99	0.48	0.26
2.5	1.55	0.20	0.17
3	1.27	0.10	0.14

At the running example's $\sigma = 1$, shuffled training has $\varepsilon \geq 4.06$ after one epoch, while the Poisson accountant reports at most 1.21. Shuffling buys almost nothing over a fixed order (4.38). The gap closes as σ grows (Figure 33.2). At $\sigma = 3$ the shuffled lower bound falls below the Poisson upper bound, which says only that this particular test is too weak there to show a gap. For fixed-size sampled batches over many epochs, the running example gives $\varepsilon = 47.42$ after 10,000 steps against 6.71 for Poisson (both by RDP; the first uses noise multiplier $\sigma/2 = 0.5$).

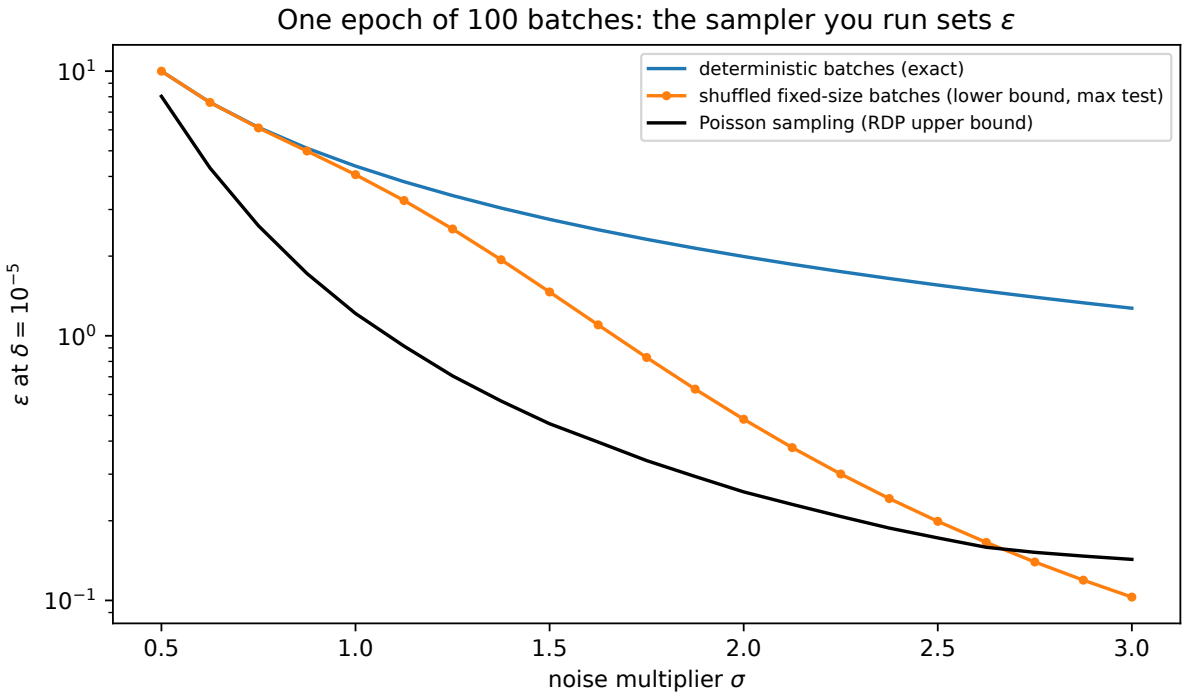

Figure 33.2.: The ε at $\delta = 10^{-5}$ of one epoch of 100 batches as a function of the noise multiplier: deterministic batches (exact), shuffled fixed-size batches (a lower bound from the largest-batch-output test of Chua et al. 2024), and Poisson sampling with $q = 0.01$ (an RDP upper bound). For σ up to about 2.5, shuffled training is provably less private than the Poisson accountant claims.

33.4.6. Check yourself

- Your code draws a fresh random batch of exactly 256 out of 25,600 records at each step. Which noise multiplier should you give a Poisson-sampling RDP accountant with $q = 0.01$? *(Half of the one you use, $\sigma/2$: the base mechanism's shift is $2C$.)*
- Why can't the mixture lemma be applied to one step of shuffled training? *(Given the other records' positions, the record's batch is fixed, so the step's output on D' is not a mixture of "used" and "not used". The randomness is only in which step uses it.)*

33.5. RDP of the Poisson-subsampled Gaussian

33.5.1. Context

Per-step (ε, δ) amplification composes badly (Section 33.7). RDP composes better. A mechanism is $(\alpha, \varepsilon(\alpha))$-RDP when the Rényi divergence of order α between its outputs on any two neighbouring datasets is at most $\varepsilon(\alpha)$. The Rényi divergence $D_\alpha(P\|Q) = \frac{1}{\alpha-1} \ln \mathbb{E}_{y\sim Q}\left[(P(y)/Q(y))^\alpha\right]$ is a log-average of a power of the likelihood ratio; a larger order α weights large ratios more heavily. Under composition the RDP curves of the steps simply add (Rényi DP), so you want the RDP curve of one subsampled Gaussian step. That is a Rényi divergence between a Gaussian mixture and a Gaussian. It has no closed form, but it has an exact series for integer orders and a stable numerical integral for the rest. Figure 33.3 shows the pair and its privacy loss, the logarithm of the likelihood ratio at each output.

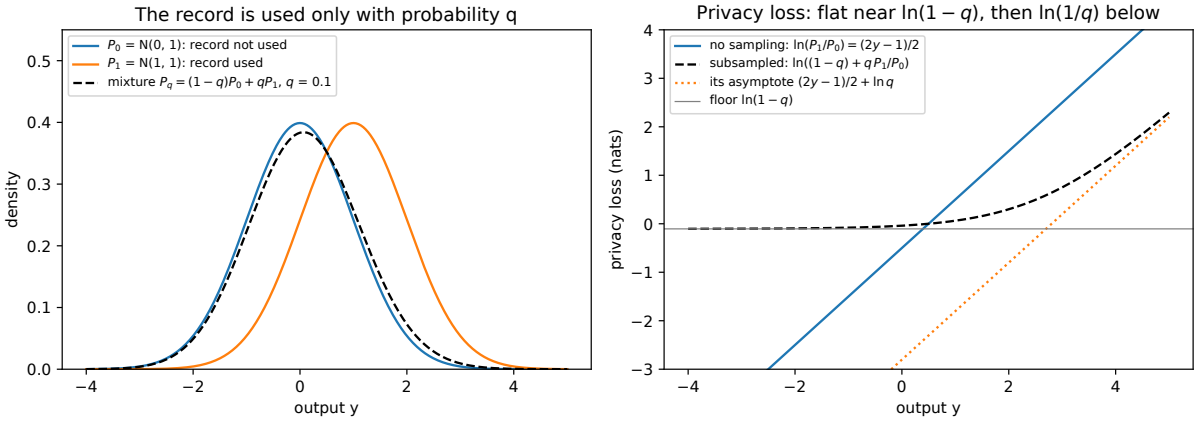

Figure 33.3.: Left: one subsampled Gaussian step with $q = 0.1$. The output with the record is the mixture (dashed), barely distinguishable from P_0. Right: the privacy loss $\ln\left((1-q) + q\,P_1/P_0\right)$. Where the record is unlikely to have been used it is flat near $\ln(1-q)$; in the far right tail it runs parallel to the unsubsampled loss, $\ln(1/q)$ lower.

33.5.2. Statement

The statement reduces the whole problem to one dimension and one direction. Whatever the data, the worst case is a single coordinate in which the record moves the sum by the full sensitivity, and

of the two orders of the pair the one with the mixture first is always the larger. That divergence is the average under P_0 of the mixture's likelihood ratio raised to the power α, and for integer α the binomial theorem expands it into a finite sum.

Let $P_0 = \mathcal{N}(0, \sigma^2)$, $P_1 = \mathcal{N}(1, \sigma^2)$ and $P_q = (1-q)P_0 + qP_1$. The Poisson-subsampled Gaussian mechanism with ℓ_2 sensitivity 1 (one record moves the sum by Euclidean length at most 1) and noise multiplier σ is $(\alpha, \varepsilon(\alpha))$-RDP for add/remove neighbours with

$$\varepsilon(\alpha) = \max\{D_\alpha(P_q \| P_0),\ D_\alpha(P_0 \| P_q)\} = D_\alpha(P_q \| P_0) = \frac{\ln A_\alpha}{\alpha - 1}, \tag{33.9}$$

$$A_\alpha = \mathbb{E}_{y \sim P_0}\Big[\Big((1-q) + q\frac{P_1(y)}{P_0(y)}\Big)^\alpha\Big], \qquad \frac{P_1(y)}{P_0(y)} = e^{(2y-1)/(2\sigma^2)}. \tag{33.10}$$

For integer α,

$$A_\alpha = \sum_{j=0}^{\alpha} \binom{\alpha}{j} (1-q)^{\alpha-j} q^j \exp\Big(\frac{j^2 - j}{2\sigma^2}\Big). \tag{33.11}$$

The first direction, $D_\alpha(P_q \| P_0)$, puts the dataset with the record first: it is the remove direction of Section 33.3 and of Numerical accounting. The reduction to one dimension is Mironov, Talwar & Zhang (2019, Theorem 4), the dominance of the first direction their Theorem 5 and Corollary 7, and Equation 33.11 their Section 3.3. Section L.1 in the appendices derives the dominance.

33.5.3. Derivation

The derivation first removes everything except the one coordinate along which the record moves the output, then evaluates the divergence of the remaining one-dimensional pair.

1. **Condition on the rest of the sample** (Mironov, Talwar & Zhang 2019, Theorem 4). Let f be the clipped gradient sum, divided by C so that the sensitivity is 1. Condition on the rest of the sample $\tilde{D}$. The outputs are $\mathcal{N}(f(\tilde{D}), \sigma^2 I)$ and the mixture $(1-q)\mathcal{N}(f(\tilde{D}), \sigma^2 I) + q\mathcal{N}(f(\tilde{D} \cup \{x\}), \sigma^2 I)$, and both runs average these over $\tilde{D}$ with the same weights.
2. **Averaging cannot increase the divergence.** This is the RDP counterpart of Fact 1. For $\alpha > 1$, $e^{(\alpha-1)D_\alpha(P\|Q)} = \int P(y)^\alpha Q(y)^{1-\alpha}\,\mathrm{d}y$. Write the integrand as $Q\,(P/Q)^\alpha$. The function t^α is convex, and a function of the form $Q\,g(P/Q)$ with g convex, called the **perspective** of g, is jointly convex in the pair (P, Q): the value at an average of pairs is at most the average of the values. So for averages with shared weights w_t, $\int (\sum_t w_t P_t)^\alpha (\sum_t w_t Q_t)^{1-\alpha} \le \sum_t w_t \int P_t^\alpha Q_t^{1-\alpha} \le \max_t \int P_t^\alpha Q_t^{1-\alpha}$, in either order of the pair. The divergence of the averages over $\tilde{D}$ is at most the largest divergence for one $\tilde{D}$. This is the **quasi-convexity** of the Rényi divergence (van Erven & Harremoës 2014, Theorem 13; Section F.5 in the appendices derives it).
3. **Shift, rotate and rescale.** Moving both distributions by the same amount or rotating both does not change any likelihood ratio, so it does not change the divergence. Shift by $f(\tilde{D})$ and rotate so the difference $f(\tilde{D} \cup \{x\}) - f(\tilde{D})$ lies along the first axis. The other coordinates have the same distribution in both runs and are independent of the first, and the Rényi divergence of independent coordinates is the sum of theirs (additivity, Divergences), so the identical ones contribute 0 and drop out. A difference of length $c < 1$ is, after rescaling by $1/c$, the same as length 1 with noise $\sigma/c > \sigma$. That pair is the length-1 pair with extra independent noise added, and no processing of the outputs can increase a divergence (data processing), so it cannot be worse. What is left is the pair (P_q, P_0) in both orders.

4. **Write the first direction as an expectation under P_0.** By the definition of D_α given in the context, $D_\alpha(P_q\|P_0) = \frac{1}{\alpha-1}\ln \mathbb{E}_{P_0}[(P_q/P_0)^\alpha]$, and dividing the mixture by P_0 gives $P_q/P_0 = (1-q)+q\,P_1/P_0$. This is Equation 33.10. The ratio P_1/P_0 is the Gaussian likelihood ratio: the normalizing constants cancel and $\exp\left(\frac{-(y-1)^2+y^2}{2\sigma^2}\right) = e^{(2y-1)/(2\sigma^2)}$.
5. **Expand for integer α.** Write $r = P_1/P_0$. The binomial theorem gives $(1-q+qr)^\alpha = \sum_j \binom{\alpha}{j}(1-q)^{\alpha-j}q^j r^j$, and the expectation of a sum is the sum of the expectations, so A_α is this sum with each r^j replaced by $\mathbb{E}_{P_0}[r^j]$.
6. **Compute each moment.** $\mathbb{E}_{P_0}[r^j] = \mathbb{E}[e^{j(2y-1)/(2\sigma^2)}]$ for $y \sim \mathcal{N}(0,\sigma^2)$. The moment generating function of this normal is $\mathbb{E}[e^{\lambda y}] = e^{\lambda^2\sigma^2/2}$, and with $\lambda = j/\sigma^2$ it gives $e^{j^2/(2\sigma^2)}$. Multiplying by the constant factor $e^{-j/(2\sigma^2)}$, the j-th moment is $e^{(j^2-j)/(2\sigma^2)}$, which gives Equation 33.11. Equivalently, $\mathbb{E}_{P_0}[(P_1/P_0)^j] = e^{(j-1)D_j(P_1\|P_0)}$ by the definition of D_j, and $D_j(P_1\|P_0) = j/(2\sigma^2)$ for two Gaussians with unit shift (Divergences, Equation 3.15).
7. **Fractional α: integrate numerically.** For non-integer α the binomial sum does not terminate, so compute Equation 33.10 as an integral. Its integrand is $P_0(y)$ times a power of the mixture ratio. Huge and tiny factors would overflow, so work with its logarithm, $\ln P_0(y)+\alpha\,\mathrm{logaddexp}(\ln(1-q), \ln q+\frac{2y-1}{2\sigma^2})$, where $\mathrm{logaddexp}(u,v) = \ln(e^u+e^v)$ is computed without forming e^u or e^v. Sum on a grid of step $\sigma/100$ with log-sum-exp, the same trick for a sum of many exponentials. The integrand has a bump near $y=0$ and, for large α, a second one near $y=\alpha$. The second comes from the part $q^\alpha e^{\alpha(2y-1)/(2\sigma^2)}$: multiplied by $P_0(y) \propto e^{-y^2/(2\sigma^2)}$, it gives an exponent $(-y^2+2\alpha y)/(2\sigma^2)$, a Gaussian centred at $y=\alpha$ (the tilted distributions of Divergences). So the grid runs from -12σ to $\alpha+12\sigma$.
8. **The other direction.** By the definition, $D_\alpha(P_0\|P_q) = \frac{1}{\alpha-1}\ln \mathbb{E}_{P_q}[(P_0/P_q)^\alpha]$. Changing the expectation from P_q to P_0 multiplies the integrand by P_q/P_0, which turns $(P_0/P_q)^\alpha$ into $(P_0/P_q)^{\alpha-1}$, so $D_\alpha(P_0\|P_q) = \frac{1}{\alpha-1}\ln \mathbb{E}_{P_0}[(P_q/P_0)^{-(\alpha-1)}]$. The power is negative, so there is no finite binomial sum; integrate it numerically. Mironov, Talwar & Zhang (2019, Theorem 5) prove $D_\alpha(P_q\|P_0) \geq D_\alpha(P_0\|P_q)$ for every $\alpha \geq 1$. Their argument uses the reflection $y \mapsto 1-y$, which swaps P_0 and P_1. The reflection cuts the pair into randomized-response pairs, and Section L.1 in the appendices derives the inequality that way, step by step. The script computes both and takes the larger, which is always the first. This dominance is for Rényi divergences. For $\delta(\varepsilon)$, Section 34.7 computes both directions, because neither dominates in general.

Walk-through at $\alpha = 2$. With $q = 0.01$ and $\sigma = 1$, Equation 33.11 has three terms, one for each possible number j of factors r (Table 33.6).

Table 33.6.: The binomial sum for A_2 with $q = 0.01$, $\sigma = 1$. Without the exponential factors the terms would sum to exactly 1.

j	$\binom{2}{j}(1-q)^{2-j}q^j$	$e^{(j^2-j)/2}$	Term
0	$(0.99)^2 = 0.9801$	1	0.980100
1	$2 \times 0.99 \times 0.01 = 0.0198$	1	0.019800
2	$(0.01)^2 = 0.0001$	$e = 2.718$	0.000272

Without the exponential factors the three coefficients add up to $(1-q+q)^2 = 1$. The exponential factor only changes the last term, from q^2 to $q^2 e^{1/\sigma^2}$, so the terms sum to $A_2 = 1+q^2(e^{1/\sigma^2}-1) = 1+0.0001\times 1.71828 = 1.00017183$, and $\varepsilon(2) = \ln A_2/(2-1) = 1.7181\times 10^{-4}$. Without sampling,

$\varepsilon(2) = 2/(2\sigma^2) = 1$. Only the $j = 2$ term carries any privacy cost, because the terms $j = 0$ and 1 have the same factor 1 that a mixture of identical distributions would have.

33.5.4. Interpretation

Two regimes. Figure 33.4 shows the curve for $q = 0.01$, $\sigma = 1$. Up to about $\alpha = 8$ the curve stays within 30% of the small-q line, the $j = 2$ term alone, worked out in Section 33.6 (1.30 times it at $\alpha = 8$, Table 33.8): $\varepsilon(8) = 8.9364 \times 10^{-4}$, against 4 without sampling. Between $\alpha = 8$ and 16 it climbs steeply: $\varepsilon(16) = 3.0879$ and $\varepsilon(32) = 11.246$, against 8 and 16 without sampling. The reason is in the right panel of Figure 33.3. Low orders average the privacy loss over the bulk, where sampling flattens it. High orders look at the far tail, where the loss is the unsubsampled one minus $\ln(1/q)$. In the tail, sampling saves only $\ln(1/q)$, as for (ε, δ) at large ε. The one-term lower bound Equation 31.21 of Concentrated DP makes this precise. Every term of Equation 33.11 is positive, so A_α is at least its last term, $q^\alpha e^{\alpha(\alpha-1)/(2\sigma^2)}$, and dividing its logarithm by $\alpha - 1$ gives $\varepsilon(\alpha) \geq \frac{\alpha \ln q}{\alpha-1} + \frac{\alpha}{2\sigma^2}$: the unsubsampled curve minus about $\ln(1/q)$.

Which orders matter. An accountant turns the RDP curve into an (ε, δ) guarantee by a conversion that holds at every order, such as $\varepsilon = T\,\varepsilon(\alpha) + \ln(1/\delta)/(\alpha - 1)$ for T steps, and it only uses the order that makes this smallest. For long DP-SGD runs that order sits in the quadratic regime. For a few steps it sits at the foot of the steep rise, where $T\,\varepsilon(\alpha)$ is still small next to the conversion term (Section 33.7).

33.5.5. Example: checking the computation

The binomial sum is exact but only exists at integer orders; the numerical integral covers every order but could be wrong if the grid were too coarse or too short. Comparing them where both exist tests the integral. Table 33.7 does this at integer orders, and also compares the two directions at several orders, for $q = 0.01$ and $\sigma = 1$.

Table 33.7.: The two ways of computing $D_\alpha(P_q \| P_0)$ agree to seven digits, and the reverse direction is always smaller. $q = 0.01$, $\sigma = 1$.

α	Binomial sum	Integral	$D_\alpha(P_q \| P_0)$	$D_\alpha(P_0 \| P_q)$
1.5	—	—	1.2725×10^{-4}	1.2148×10^{-4}
2	1.718134×10^{-4}	1.718134×10^{-4}	1.7181×10^{-4}	1.6022×10^{-4}
3	2.646376×10^{-4}	2.646376×10^{-4}	—	—
8	—	—	8.9364×10^{-4}	5.7239×10^{-4}
10	3.827042×10^{-2}	3.827042×10^{-2}	—	—
32	1.124628×10^{1}	1.124628×10^{1}	1.1246×10^{1}	1.6923×10^{-3}

The integral agrees with the exact sum to all printed digits, from 10^{-4} to 10^1, so the grid is fine enough. The reverse direction is smaller at every order. At $\alpha = 32$ it is nearly four orders of magnitude smaller (1.6923×10^{-3} against 11.246), because it raises the mixture ratio to a negative power and so looks at the left tail, where the ratio P_0/P_q is bounded by $1/(1 - q)$: the mixture always keeps at least $1 - q$ of P_0. The script also checks every order of the grid for $\sigma = 0.5$ and

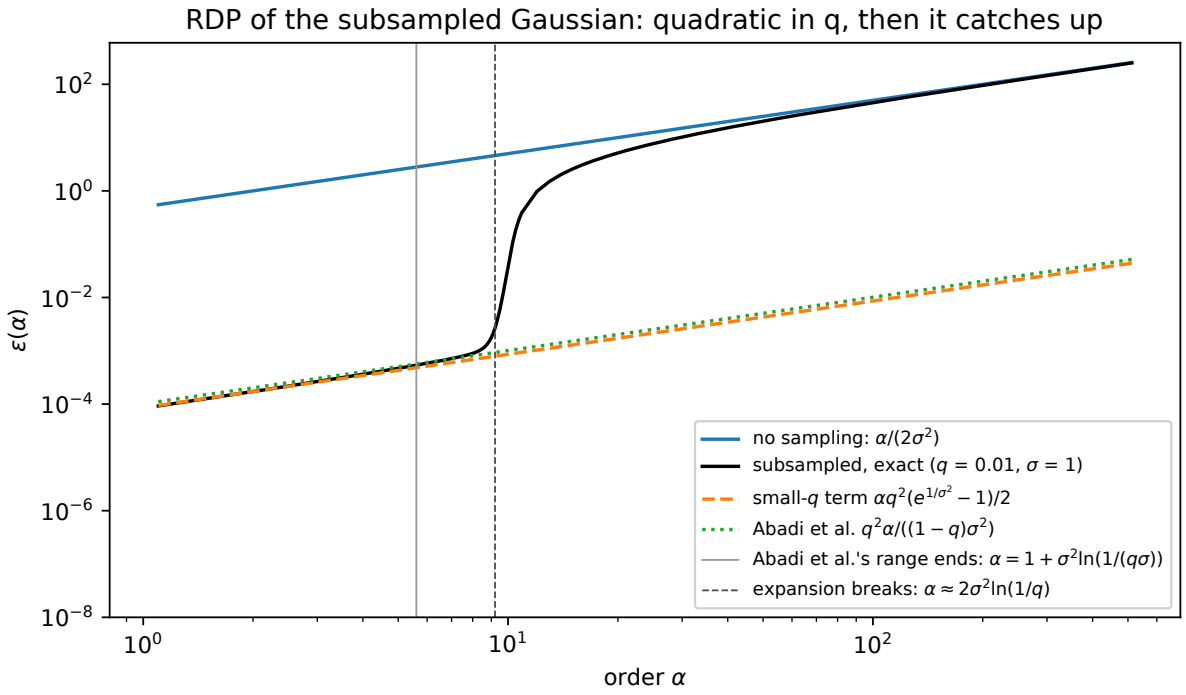

Figure 33.4.: The RDP curve of the Poisson-subsampled Gaussian with $q = 0.01$, $\sigma = 1$ (black), against the unsubsampled Gaussian $\alpha/(2\sigma^2)$, the small-q term $\alpha q^2(e^{1/\sigma^2}-1)/2$ and the leading term of Abadi et al.'s bound. The vertical line marks where Abadi et al.'s bound stops applying. The dashed vertical line marks $\alpha = 2\sigma^2\ln(1/q)$, where the quadratic expansion breaks. The exact curve stays near the quadratic term up to about $\alpha = 8$, then rises toward the unsubsampled line.

$\sigma = 2$: the largest excess of the reverse direction is negative in both cases (-5.09×10^{-4} and -5.67×10^{-8}).

33.5.6. Check yourself

- In Equation 33.11, why do the terms $j = 0$ and $j = 1$ never cost privacy? *(Their exponential factor is $e^0 = 1$. They are the terms in which the record's influence enters at most linearly, and a linear term averages to the same value under both distributions, since $\mathbb{E}_{P_0}[P_1/P_0] = 1$.)*
- Why does the numerical grid for $D_\alpha(P_q \| P_0)$ extend to $y = \alpha + 12\sigma$, far beyond where P_0 has any mass? *(For large α the integrand is dominated by $q^\alpha P_0(y) e^{\alpha(2y-1)/(2\sigma^2)}$, which is a Gaussian bump centred at $y = \alpha$. Cutting the grid at 12σ would miss it.)*

33.6. Small q and the moments accountant

33.6.1. Context

Abadi et al. (2016) introduced DP-SGD together with the **moments accountant**. Its central quantity is built from the **privacy loss**, $L = \ln\big(P(y)/Q(y)\big)$ for an output y drawn from P: the log-likelihood ratio of the output, which is large when the output gives the record away. The accountant tracks the logarithm of the moment generating function of L, which Abadi et al. call $\alpha_M(\lambda)$ and Rényi DP renames $K_M(\lambda) = \ln \mathbb{E}[e^{\lambda L}]$, because α is our order. It adds K_M over steps and converts the total to (ε, δ) with a tail bound.

This is RDP in disguise, as Rényi DP shows. Since $e^{\lambda L} = (P/Q)^\lambda$, the expectation under P is $\mathbb{E}_P[(P/Q)^\lambda] = \mathbb{E}_Q[(P/Q)^{\lambda+1}] = e^{\lambda D_\alpha(P\|Q)}$ with $\alpha = \lambda + 1$, so $K_M(\lambda) = \lambda\, \varepsilon(\lambda+1)$. The tail bound is Markov's inequality applied to $e^{\lambda L}$: $\Pr[L > \varepsilon] \le \mathbb{E}[e^{\lambda L}] e^{-\lambda\varepsilon}$, which gives $\delta = \min_\lambda e^{K_M(\lambda) - \lambda\varepsilon}$, Mironov's conversion. Abadi et al. did not have Equation 33.11 in general. They proved an asymptotic bound for small q. How good is it, and where does it stop holding?

33.6.2. Statement

When q is small, the walk-through at $\alpha = 2$ generalizes: the terms $j = 0$ and 1 of Equation 33.11 cost nothing, every term from $j = 3$ on carries q^3 or a higher power, and the $j = 2$ term dominates. For $q \to 0$ at fixed α and σ, the leading term of the subsampled Gaussian's RDP curve is

$$\varepsilon(\alpha) \approx \frac{\alpha q^2 (e^{1/\sigma^2} - 1)}{2} \approx \frac{\alpha q^2}{2\sigma^2} \quad \text{for large } \sigma. \tag{33.12}$$

Abadi et al. (2016, Lemma 3) prove a bound of the same shape, under conditions that limit the order. For $\sigma \ge 1$, $q < 1/(16\sigma)$ and integer $\lambda \le \sigma^2 \ln \frac{1}{q\sigma}$,

$$K_M(\lambda) \le \frac{q^2 \lambda(\lambda+1)}{(1-q)\sigma^2} + O\Big(\frac{q^3\lambda^3}{\sigma^3}\Big), \quad \text{that is} \quad \varepsilon(\alpha) \lesssim \frac{q^2\alpha}{(1-q)\sigma^2} \ \text{ for } \ \alpha \le 1 + \sigma^2 \ln \frac{1}{q\sigma}. \tag{33.13}$$

The second form divides by λ and substitutes $\alpha = \lambda + 1$.

33.6.3. Derivation

1. **Subtract what costs nothing.** Without the exponential factors, Equation 33.11 is $\sum_j \binom{\alpha}{j}(1-q)^{\alpha-j}q^j = (1-q+q)^\alpha = 1$ by the binomial theorem. Subtracting this 1 from A_α leaves each term multiplied by its exponential factor minus 1:

$$A_\alpha = 1 + \sum_{j=2}^{\alpha} \binom{\alpha}{j}(1-q)^{\alpha-j}q^j\left(e^{(j^2-j)/(2\sigma^2)} - 1\right). \tag{33.14}$$

   The $j = 0$ and $j = 1$ terms are gone, because their factor is $e^0 - 1 = 0$.
2. **Keep the lowest power of q.** The $j = 2$ term is $\binom{\alpha}{2}q^2(1-q)^{\alpha-2}(e^{1/\sigma^2} - 1)$. Every other term carries q^3 or more, so for small q it is negligible next to this one.
3. **Take the logarithm.** For small y, $\ln(1+y) = y + O(y^2)$, and $(1-q)^{\alpha-2} = 1 + O(q)$. So $(\alpha-1)\varepsilon(\alpha) = \ln A_\alpha = \frac{\alpha(\alpha-1)}{2}q^2(e^{1/\sigma^2} - 1) + O(q^3)$.
4. **Divide by** $\alpha - 1$ to get Equation 33.12. For large σ, $e^{1/\sigma^2} - 1 \approx 1/\sigma^2$, since $e^u \approx 1 + u$ for small u.
5. **Where does the expansion break?** The expansion assumes the $j = 2$ term dominates, so look at how the terms change with j. Going from j to $j+1$, the binomial coefficient is multiplied by $\frac{\alpha-j}{j+1}$, the power of q by q, and the exponential by $e^{((j+1)^2-(j+1)-j^2+j)/(2\sigma^2)} = e^{j/\sigma^2}$. So the terms first fall, and grow once $q\,e^{j/\sigma^2}$ passes 1, near $j \approx \sigma^2\ln(1/q)$. The expansion fails only later, when the last term, $q^\alpha e^{\alpha(\alpha-1)/(2\sigma^2)}$, overtakes the $j = 2$ term, about q^2e^{1/σ^2}. Ignoring the binomial coefficient and comparing logarithms, that happens when $\alpha\ln q + \frac{\alpha(\alpha-1)}{2\sigma^2} > 2\ln q + \frac{1}{\sigma^2}$. Move everything to one side: the terms in $\ln q$ give $-(\alpha-2)\ln\frac{1}{q}$, and the others give $\frac{\alpha^2-\alpha-2}{2\sigma^2}$. Since $\alpha^2 - \alpha - 2 = (\alpha-2)(\alpha+1)$, the condition is $(\alpha-2)(\frac{\alpha+1}{2\sigma^2} - \ln\frac{1}{q}) > 0$, that is $\alpha > 2\sigma^2\ln(1/q) - 1$. So the expansion holds up to about

$$\alpha \approx 2\sigma^2\ln(1/q), \tag{33.15}$$

   and the curve leaves the quadratic regime abruptly there. At $q = 0.01$, $\ln(1/q) = 4.605$, so this is 9.2 for $\sigma = 1$ and 147.4 for $\sigma = 4$. The exact curve first exceeds twice the leading term at 8.9 and 147.4 (Table 33.8). Abadi et al.'s condition $\lambda \le \sigma^2\ln\frac{1}{q\sigma}$ has the same form with about half the constant, so it is conservative.

33.6.4. Interpretation

The first thing to notice is that the cost is quadratic, not linear, in q. The (ε, δ) amplification of Section 33.3 gives a per-step ε' linear in q. In RDP the cost per step is quadratic in q, about $\alpha q^2/(2\sigma^2)$. Since $T = E/q$ steps make E epochs, the total RDP after E epochs is about $(E/q) \times \alpha q^2/(2\sigma^2) = E\,q\,\alpha/(2\sigma^2)$. It shrinks as batches get smaller at a fixed number of epochs.

Abadi et al.'s bound is about twice the leading term for large σ: $q^2\alpha/\sigma^2$ against $q^2\alpha/(2\sigma^2)$. It is a valid but loose upper bound, and it is the source of the "$\varepsilon(\alpha) \approx q^2\alpha/\sigma^2$" you will see quoted.

The real limit of the expansion is not its constant but its order range. Up to $\alpha = \sigma^2\ln(1/q)$ the leading term is within 8% (1.08 at $\alpha = 4.6$ for $\sigma = 1$, 1.05 at $\alpha = 73.7$ for $\sigma = 4$). Beyond $\alpha \approx 2\sigma^2\ln(1/q)$ (Equation 33.15) it is wrong by orders of magnitude, 2246 times too small at $\alpha = 16$ for $\sigma = 1$, and an accountant that uses it there under-reports ε.

33.6.5. Example: where the expansion breaks

Table 33.8 compares the exact curve with Equation 33.12 and Equation 33.13 at $q = 0.01$. For instance, at $\alpha = 2$ and $\sigma = 1$ the Abadi column is $q^2\alpha/((1-q)\sigma^2) = 0.0002/0.99 = 2.0202\times10^{-4}$.

Table 33.8.: The exact RDP of the subsampled Gaussian against its small-q expansion and Abadi et al.'s leading term, $q = 0.01$.

α	Exact, $\sigma = 1$	Leading term, $\sigma = 1$	Abadi, $\sigma = 1$	Exact / leading, $\sigma = 1$	Exact / leading, $\sigma = 4$
2	1.7181×10^{-4}	1.7183×10^{-4}	2.0202×10^{-4}	1.00	1.00
4	3.6315×10^{-4}	3.4366×10^{-4}	4.0404×10^{-4}	1.06	1.00
6	5.8350×10^{-4}	5.1548×10^{-4}	6.0606×10^{-4}	1.13	1.00
8	8.9364×10^{-4}	6.8731×10^{-4}	8.0808×10^{-4}	1.30	1.00
10	3.8270×10^{-2}	8.5914×10^{-4}	1.0101×10^{-3}	44.54	1.01
32	1.1246×10^{1}	2.7493×10^{-3}	3.2323×10^{-3}	4090.67	1.02

At $\sigma = 1$, Abadi et al.'s range ends at $\alpha = 1 + \sigma^2 \ln \frac{1}{q\sigma} = 1 + \ln 100 = 5.6$, and the exact curve first exceeds twice the leading term at the grid order $\alpha = 8.9$ (8.9 also by bisection over fractional orders), just below $2\sigma^2 \ln(1/q) = 9.2$. Inside its range Abadi et al.'s value is above the exact one, as an upper bound should be. At $\alpha = 8$, outside it, the leading term of their bound (8.0808×10^{-4}) is already below the exact 8.9364×10^{-4}.

Step 5 of the derivation predicted terms that first fall and then grow; at $\alpha = 10$ you can see it. The binomial terms for $j = 2, \dots, 10$ are 1.1×10^{-2}, 2.2×10^{-3}, 8.0×10^{-4}, 5.3×10^{-4}, 6.6×10^{-4}, 1.5×10^{-3}, 6.4×10^{-3}, 4.3×10^{-2} and 3.5×10^{-1}: they first fall and then grow, and the last one dominates. At $\sigma = 4$ the range ends at $\alpha = 52.5$ and the leading term is within 2% of the exact value up to $\alpha = 32$; the exact curve first exceeds twice the leading term between the grid orders 128 and 256, at $\alpha = 147.4$ by bisection, where Equation 33.15 puts it.

Abadi et al.'s headline number. With $q = 0.01$, $\sigma = 4$, $\delta = 10^{-5}$ and 10,000 steps they report $\varepsilon \approx 1.26$ from the moments accountant. The exact RDP curve, composed over the 10,000 steps and converted with Mironov's conversion, gives 1.2586, at $\alpha = 20$, which matches their number to the digits they report. The improved conversion of From RDP to (ε, δ) gives 1.0355, at $\alpha = 17$.

33.6.6. Check yourself

- At a fixed number of epochs, does halving the batch size (and so q) raise or lower the RDP accountant's total, to first order? *(Lower it. There are twice as many steps, each costing a quarter as much, so the total halves, as long as the orders used stay in the quadratic regime.)*
- Why does a small σ shrink the range where Equation 33.12 holds? *(The higher terms grow like $q^j e^{j^2/(2\sigma^2)}$. A small σ makes the exponential overtake the power of q at a smaller j, and so at a smaller α.)*

33.7. The running example: DP-SGD

33.7.1. Context

Everything is now in place to account for the running example: DP-SGD with Poisson rate $q = 0.01$, noise multiplier $\sigma = 1$, $\delta = 10^{-5}$, and T up to 10,000 steps. How large is ε, and how much does the accounting route matter?

33.7.2. Statement

The RDP accountant adds the per-step curve of Equation 33.9 over the T steps and converts the total to (ε, δ) once. A conversion takes an RDP guarantee at one order α and returns an ε for the target δ. It holds at every order, so the accountant takes the order that gives the smallest ε. Mironov's conversion adds $\ln(1/\delta)/(\alpha - 1)$ to the RDP value; the improved conversion subtracts two small corrections from that amount. DP-SGD is (ε, δ)-DP for add/remove neighbours with

$$\varepsilon = \min_{\alpha} \left[T\,\varepsilon(\alpha) + \frac{\ln(1/\delta)}{\alpha - 1} \right] \quad \text{(Mironov)}, \qquad \varepsilon = \min_{\alpha} \left[T\,\varepsilon(\alpha) + \ln \frac{\alpha - 1}{\alpha} - \frac{\ln \delta + \ln \alpha}{\alpha - 1} \right] \quad \text{(improved)}, \tag{33.16}$$

with $\varepsilon(\alpha)$ from Equation 33.9 and the minimum over the grid of orders shared by this part (Section C.4 and Section C.5 in the appendices derive both from scratch, with worked numbers).

33.7.3. Derivation

1. **One step is a subsampled Gaussian.** Clipping each per-example gradient to norm C and adding $\mathcal{N}(0, \sigma^2 C^2 I)$ to the sum makes one step the mechanism of Section 33.5, after dividing by C. Its RDP curve is $\varepsilon(\alpha)$.
2. **Compose.** Each step may depend on the previous outputs, through the model it starts from. RDP curves add under such adaptive composition (Rényi DP), so T steps have curve $T\,\varepsilon(\alpha)$.
3. **Convert.** Mironov's conversion is from Rényi DP: it is the Markov bound on the privacy loss recalled in Section 33.6, solved for ε. The improved one (Balle et al. 2020, Theorem 21) is from From RDP to (ε, δ). Each holds at every order, so take the smallest.

The naive routes, for comparison, amplify each step in (ε, δ) form with Equation 33.5 and then compose the per-step pairs.

1. **Per step.** Give each step a share δ_0 of δ before amplification. The plain Gaussian mechanism with sensitivity 1 and noise σ is $(\varepsilon_0, \delta_0)$-DP exactly when $\delta_0 = \Phi(\frac{1}{2\sigma} - \varepsilon_0 \sigma) - e^{\varepsilon_0}\Phi(-\frac{1}{2\sigma} - \varepsilon_0\sigma)$, the hockey-stick divergence of the two Gaussians, with Φ the standard normal distribution function (The Laplace and Gaussian mechanisms). Solve this for ε_0, then amplify with Equation 33.5 to $(\varepsilon_1, q\delta_0)$.
2. **Basic composition.** The εs and δs of the steps add, so T steps are $(T\varepsilon_1, Tq\delta_0)$-DP (Composition). Setting $Tq\delta_0 = \delta$ fixes $\delta_0 = \delta/(Tq)$.
3. **Advanced composition.** Advanced composition trades a little extra δ' for an ε that grows like $\sqrt{T}$ instead of T: T steps are $(\varepsilon_1\sqrt{2T\ln(1/\delta')} + T\varepsilon_1(e^{\varepsilon_1} - 1),\ Tq\delta_0 + \delta')$-DP (Composition). The script splits δ between $Tq\delta_0$ and δ', trying shares of δ' from 0.01 to 0.99, and keeps the best.

33.7.4. Interpretation

RDP is the only usable route for long runs. After 10,000 steps it gives $\varepsilon = 6.71$; the per-step routes give numbers in the thousands (Table 33.9). The example below shows where the per-step routes lose.

For one step, though, RDP loses. At $T = 1$ the per-step route gives 0.20 and RDP 0.96. The reason is the conversion: it costs $\ln(1/\delta)/(\alpha - 1)$ no matter how small the curve is. RDP pays this once, so it wins once there are a handful of steps to compose: from $T = 4$ here (Figure 33.5).

The improved conversion saves from 27.5% at $T = 1$ to 9.6% at $T = 10{,}000$: 0.96 against 1.32, and 6.71 against 7.43.

The best order falls as T grows, from 9.9 to 4.1, because the curve term $T\,\varepsilon(\alpha)$ grows with T and pulls the minimum toward smaller orders, where the curve is lower. For a few steps the best order sits at the foot of the steep rise in Figure 33.4: at the best orders for $T = 1$, 10 and 100, the exact curve is 30.61, 5.44 and 1.82 times the quadratic term. It is chosen there because $T\,\varepsilon(\alpha)$ is still small next to the conversion term (0.026, 0.044 and 0.138), so a larger order, which shrinks the conversion term, is worth it. Only for long runs does the best order move into the quadratic regime: the ratio is 1.26 at $T = 1000$ and 1.06 at $T = 10{,}000$.

How tight is 6.71? It is an upper bound with two sources of slack: the conversion from RDP, and the RDP curve itself, which keeps only one summary of the privacy loss distribution. Numerical accounting computes the tight value for the same run, and Choosing an accountant compares all the accountants of this part on it.

33.7.5. Example: the running example at T = 10,000

Table 33.9 and Figure 33.5 give ε for the running example under the four routes.

Table 33.9.: The ε at $\delta = 10^{-5}$ of DP-SGD with $q = 0.01$, $\sigma = 1$ under four accounting routes.

Steps T	RDP, Mironov	RDP, improved	Best order (improved)	Per step, basic	Per step, advanced
1	1.32	0.96	9.9	0.20	1.13
10	1.41	1.04	9.4	3.64	7.88
100	1.61	1.21	8.8	58.01	78.10
1,000	2.54	2.10	7.8	839.39	1258.64
10,000	7.43	6.71	4.1	11296.93	24379.55

Follow the per-step route at $T = 10{,}000$ to see where it loses. The first loss is weak amplification. With basic composition the route must spend $\delta_0 = \delta/(Tq) = 10^{-5}/100 = 10^{-7}$ per step. That forces $\varepsilon_0 = 5.35$, in the regime where amplification only subtracts (Figure 33.1): $\ln\left(1+0.01(e^{5.35}-1)\right)$ gives the amplified $\varepsilon_1 = 1.130$, only about five times smaller, and basic composition then multiplies it by 10,000.

Advanced composition does not rescue it; it is worse than basic at every T here. Its first term, $\varepsilon_1\sqrt{2T\ln(1/\delta')}$, beats $T\varepsilon_1$ only when $T \gg 2\ln(1/\delta')$. Its second term, $T\varepsilon_1(e^{\varepsilon_1}-1)$, alone exceeds

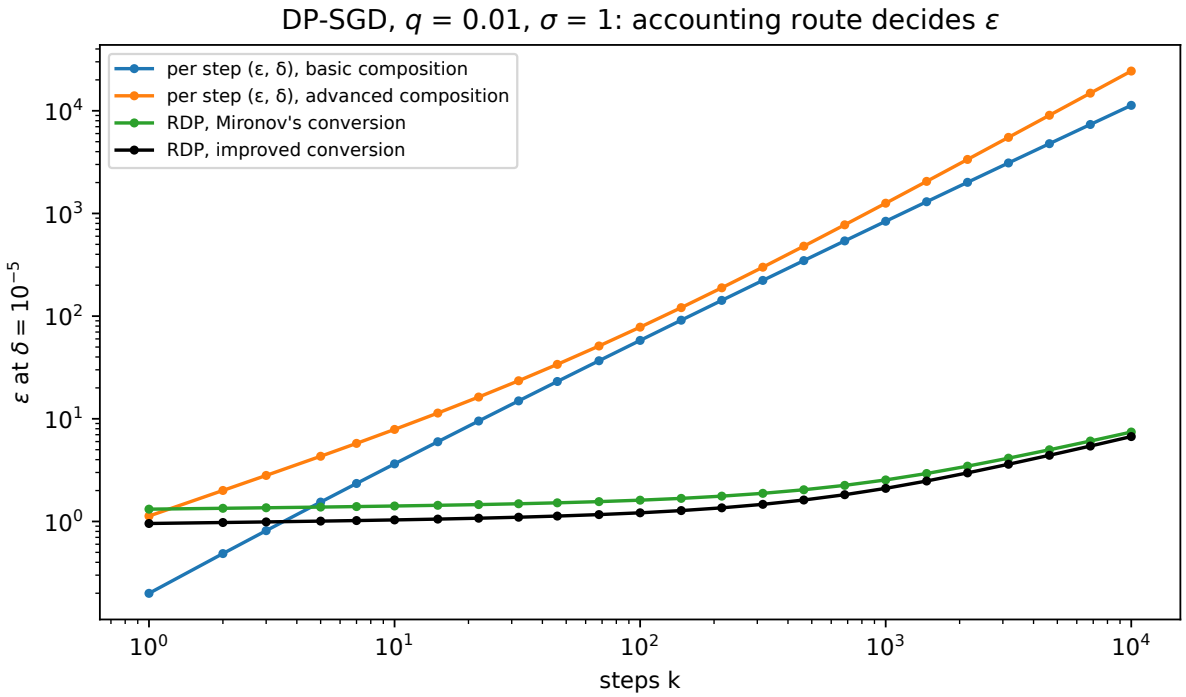

Figure 33.5.: The ε at $\delta = 10^{-5}$ of DP-SGD with $q = 0.01$, $\sigma = 1$ against the number of steps, under four accounting routes. The RDP accountant grows slowly; per-step amplification followed by basic or advanced composition grows almost linearly and is useless beyond a few steps.

$T\varepsilon_1$ once $e^{\varepsilon_1}-1>1$, that is $\varepsilon_1>\ln 2$, as here. The sharper form of Composition, with $\tanh(\varepsilon_1/2)$ in place of $e^{\varepsilon_1}-1$, gives 6433: better than basic composition, and still useless.

The RDP accountant, by contrast, composes the whole curve, where each step costs almost nothing at moderate orders, and converts once, at the order 4.1.

33.7.6. Check yourself

- At $T=10{,}000$ the best order is about 4. If you only had orders $\alpha\geq 8$ available, would the reported ε go up or down? *(Up. The conversion is a minimum over orders, and removing orders can only raise it.)*
- Why does the RDP column barely move between $T=1$ and $T=100$? *(For small T the conversion term $\ln(1/\delta)/(\alpha-1)$ dominates and $T\varepsilon(\alpha)$ is negligible at the chosen order.)*

33.8. No tight amplification theorem for every mechanism

33.8.1. Context

For (ε,δ), Equation 33.5 is one formula, and it is tight over the class of (ε,δ)-DP mechanisms: for every ε and q, randomized response attains it. Is there an RDP analogue: a function that takes any mechanism's RDP curve and q and returns the subsampled curve, tightly? No. The best general results are tight only up to small constant factors, and accountants special-case the Gaussian because it is the case where the exact answer is known.

33.8.2. Statement

The general bound starts from the same binomial expansion as the Gaussian case, with each moment of the likelihood ratio bounded by the mechanism's own RDP curve at that order, and pays a factor 3 on the higher terms to cover the direction the expansion does not reach. Let M be any mechanism with RDP curve $\varepsilon(\alpha)$ for add/remove neighbours, and let q be the Poisson rate. For integer $\alpha\geq 2$, Zhu & Wang (2019, Theorem 5) show that the subsampled mechanism has RDP at most

$$\frac{1}{\alpha-1}\ln\Big[(1-q)^{\alpha-1}(\alpha q-q+1)+\binom{\alpha}{2}q^2(1-q)^{\alpha-2}e^{\varepsilon(2)}+3\sum_{j=3}^{\alpha}\binom{\alpha}{j}(1-q)^{\alpha-j}q^j e^{(j-1)\varepsilon(j)}\Big]. \tag{33.17}$$

The first term collects $j=0$ and $j=1$: $(1-q)^\alpha+\alpha q(1-q)^{\alpha-1}=(1-q)^{\alpha-1}(\alpha q-q+1)$. Without the factor 3 the same expression is a lower bound for some mechanisms (their Theorem 6). It is exact under a condition on the privacy loss that the Gaussian and Laplace mechanisms satisfy (their Theorem 8 and Proposition 10). For sampling a fixed batch without replacement under replace-one neighbours, Wang, Balle & Kasiviswanathan (2019, Theorem 9) give a bound of the form $\frac{1}{\alpha-1}\ln\left(1+\sum_{j\geq 2}\binom{\alpha}{j}q^j c_j\right)$ with $q=m/n$, where $c_2\leq 4(e^{\varepsilon(2)}-1)$ and $c_j\leq 2e^{(j-1)\varepsilon(j)}$ for $j\geq 3$, and a lower bound (Proposition 11) that matches it up to constant factors.

33.8.3. Derivation (why the Gaussian is special)

1. **The first direction expands for any mechanism.** The binomial expansion (step 5 of the derivation in Section 33.5) never used the Gaussian: for integer α, $D_\alpha((1-q)P_0 + qP_1 \| P_0)$ expands into moments $\mathbb{E}_{P_0}[(P_1/P_0)^j]$. By the definition of the Rényi divergence each moment equals $e^{(j-1)D_j(P_1\|P_0)}$, and RDP of M bounds it by $e^{(j-1)\varepsilon(j)}$. Bounding each term this way gives Equation 33.17 without the factor 3.
2. **But each term may come from a different pair.** $\varepsilon(j)$ is a maximum over neighbouring pairs, taken separately for each j. The bound in step 1 is attained only if one pair attains $\varepsilon(j)$ for every j at once. For the Gaussian it does: the pair whose sums differ by the full sensitivity is the worst for every order.
3. **The second direction does not expand.** $D_\alpha(P_0 \| (1-q)P_0 + qP_1)$ has the mixture in the denominator, raised to a negative power, as in step 8 of the derivation in Section 33.5, so there is no finite binomial sum. For a general mechanism this direction can exceed the first. A general bound must cover it too, and Zhu & Wang's bound carries a factor 3 that the first-direction expansion of step 1 does not need. For the Gaussian, the reflection argument of Mironov, Talwar & Zhang (2019, Theorem 5) shows that the first direction always dominates in Rényi divergence.

33.8.4. Interpretation

For the Gaussian, the general bound Equation 33.17 is close but not exact, and the factor 3 costs most at the orders in between (see the example). That is why accountants use Equation 33.11 for the Gaussian and keep the general bounds for other mechanisms.

Lebeda et al. (2024) add two further warnings. For add/remove neighbours, the worst pair of datasets for one step need not be the worst for the composition of many steps; they give a counterexample with the subsampled Laplace mechanism, so a numerical accountant must check its worst-case pair, not assume it. And under replace-one neighbours there may be several candidate worst-case pairs, all of which an accountant must consider.

33.8.5. Example: the general bound on the Gaussian

Table 33.10 evaluates Equation 33.17 with the Gaussian's curve $\varepsilon(j) = j/(2\sigma^2)$ against the exact curve.

Table 33.10.: Zhu & Wang's general bound applied to the Gaussian against the exact RDP, $q = 0.01$, $\sigma = 1$.

α	2	4	8	16	32
General bound Equation 33.17	1.7181×10^{-4}	4.1880×10^{-4}	1.4036×10^{-3}	3.1611	11.282
Exact Equation 33.9	1.7181×10^{-4}	3.6315×10^{-4}	8.9364×10^{-4}	3.0879	11.246

Ratio	1.00	1.15	1.57	1.02	1.00

The factor 3 costs nothing at $\alpha = 2$, where there are no $j \geq 3$ terms. It costs little at high orders, where the last term dominates the sum inside the logarithm, so multiplying it by 3 adds only about $\ln 3$ to the logarithm and $\ln 3/(\alpha - 1)$ to the RDP value. It costs most in between, a factor 1.57 at $\alpha = 8$, near where DP-SGD's best orders lie for $T \approx 100$ to 1000 (8.8 and 7.8 in Table 33.9).

33.8.6. Check yourself

- Why is the (ε, δ) amplification of Equation 33.5 tight in the worst case, when no RDP formula is? *(An (ε, δ) guarantee is one number per event, and randomized response attains the worst case of the mixture lemma for every ε. An RDP curve constrains infinitely many orders at once, and different mechanisms with the same curve can subsample differently.)*
- In Table 33.10, why is the ratio 1.00 at $\alpha = 2$? *(For $\alpha = 2$ the sum over $j \geq 3$ is empty, so the factor 3 never enters, and the remaining terms are exact for the Gaussian.)*

33.9. Code: check every number by computation

The script code/subsampling.py computes every number in this chapter and draws every figure. The amplification formulas are small functions. The RDP of the subsampled Gaussian is computed by the binomial sum for integer orders and by integration on a grid for the rest, and the two are compared. The comparison of batch samplers reproduces checks from Chua et al. (2024) and Lebeda et al. (2024). From the repository root:

```
uv run python code/part04-privacy-accounting/subsampling.py
```

Its public functions are used by later chapters: `amplify_eps_delta(eps, delta, q)`, `subsampled_gaussian_rdp(alpha, q, sigma)`, `subsampled_gaussian_rdp_curve(q, sigma, orders)` (cached per (q, σ)) and `dpsgd_eps_rdp(q, sigma, steps, delta, conversion)`.

Output (seed 0), summarized in Table 33.11:

Table 33.11.: The script's output with the default seed.

Experiment	Result
Mixture lemma, 20,000 random triples	Largest ratio of the left side's excess to $q\delta$: 1.0000
Randomized response, $\varepsilon = 1$, $q = 0.1$	Exact $\varepsilon' = 0.1586$; formula 0.1586
Replace-one under Poisson, $\varepsilon = 1$, $q = 0.01$	Group-privacy bound 0.06193 (ratio 3.64 to add/remove's 0.01704); exact pure-DP value 0.02338 (ratio 1.37)

Experiment	Result
One epoch, 100 batches, $\sigma = 1$	Poisson ≤ 1.21; shuffled ≥ 4.06; deterministic 4.38
Chua et al. check, $\sigma = 0.4$, 10,000 batches	Shuffled $\delta(4) \geq 0.226$; deterministic 0.244
Lebeda et al. check, $q = 0.001$, $\sigma = 0.8$, 10,000 steps	RDP: Poisson 1.38, fixed-size 15.30
Subsampled Gaussian RDP, $q = 0.01$, $\sigma = 1$	Binomial and integral agree to seven digits; reverse direction always smaller (Table 33.7)
Small-q breakdown, $q = 0.01$	Exact first exceeds twice the leading term at $\alpha = 8.9$ ($\sigma = 1$) and 147.4 ($\sigma = 4$); $2\sigma^2 \ln(1/q) = 9.2$ and 147.4
Abadi et al. example, $\sigma = 4$	Mironov 1.2586 at $\alpha = 20$; improved 1.0355 at $\alpha = 17$
Running example, $T = 10{,}000$	RDP improved 6.71 at $\alpha = 4.1$; Mironov 7.43; fixed-size batches 47.42; RDP beats per-step basic composition from $T = 4$

tests/test_subsampling.py checks that the output still matches.

What to take from it. Three things. First, the numerical integral is trustworthy: it matches the exact binomial sum at every integer order checked, from 10^{-4} to 10^{1}, so the fractional orders of the grid can use it. Second, published numbers reproduce: Abadi et al.'s 1.26, Chua et al.'s 0.226 and the direction of Lebeda et al.'s gap all come out of a few dozen lines. Third, the sampling scheme moves ε more than the accountant does. Switching from Mironov's to the improved conversion saves about a tenth at 10,000 steps (7.43 to 6.71), while accounting for the batch sampler you actually run can multiply ε by seven ($47.42/6.71 \approx 7.1$).

33.11. Cheat sheet

q is the sampling rate; $P_0 = \mathcal{N}(0, \sigma^2)$ and $P_1 = \mathcal{N}(1, \sigma^2)$ are a step's output without and with the record, and q is also the mixing weight of the mixture lemma. Table 33.12 collects the results.

Table 33.12.: Every result of the chapter.

Result	Formula	Conditions	Tight?
Mixture lemma	$(1-q)R + qP \le e^{\varepsilon'}[(1-q)R + qP'] + q\delta$, $e^{\varepsilon'} = 1 + q(e^\varepsilon - 1)$	$P \le e^\varepsilon P' + \delta$ and $P \le e^\varepsilon R + \delta$ on every event	Yes

Result	Formula	Conditions	Tight?
Poisson, add/remove	$\varepsilon' = \ln(1 + q(e^{\varepsilon} - 1))$, $\delta' = q\delta$	Base (ε, δ) for add/remove	Yes, per step
Fixed size m of n, replace-one	Same with $q = m/n$	Base (ε, δ) for replace-one	Yes, per step
Poisson, replace-one	$\varepsilon' = \ln(1 + q(e^{2\varepsilon} - 1))$, $\delta' = q(1 + e^{\varepsilon})\delta$	Group privacy on the base	No: an upper bound. For pure DP the exact value is Equation 33.8, about twice the add/remove cost for small ε
Fixed size, add/remove	Account the Poisson pair with noise multiplier $\sigma/2$	Clipped Gaussian sums (Lebeda et al. 2024)	Dominating pair, each relation separately
Shuffle and partition	Max test: $1 - \Phi(\frac{\tau-2}{\sigma})\Phi(\frac{\tau}{\sigma})^{b-1}$ against $1 - \Phi(\frac{\tau-1}{\sigma})\Phi(\frac{\tau}{\sigma})^{b-1}$	b batches, zero-out	A lower bound on $\delta(\varepsilon)$
Subsampled Gaussian RDP	$\varepsilon(\alpha) = \frac{1}{\alpha-1} \ln \mathbb{E}_{P_0}[(1 - q + qP_1/P_0)^{\alpha}]$	Poisson, add/remove, sensitivity 1	Exact
Integer orders	$A_\alpha = \sum_j \binom{\alpha}{j}(1-q)^{\alpha-j} q^j e^{(j^2-j)/(2\sigma^2)}$	Integer α	Exact
Small q	$\varepsilon(\alpha) \approx \alpha q^2 (e^{1/\sigma^2} - 1)/2$	$\alpha \lesssim 2\sigma^2 \ln(1/q)$ (Equation 33.15)	Leading term; within 8% up to $\sigma^2 \ln(1/q)$ here
Abadi et al.	$\varepsilon(\alpha) \lesssim q^2\alpha/((1-q)\sigma^2)$	$\alpha \le 1 + \sigma^2 \ln \frac{1}{q\sigma}$, $q < \frac{1}{16\sigma}$, $\sigma \ge 1$	About twice the exact value for large σ ($2.0202/1.7181 = 1.18$ times at $\sigma = 1$, $\alpha = 2$); below it outside its order range
High orders	$\varepsilon(\alpha) \ge \frac{\alpha \ln q}{\alpha-1} + \frac{\alpha}{2\sigma^2}$ (Equation 31.21)	Any α	Nearly exact once $\alpha \gtrsim 2\sigma^2 \ln(1/q)$; negative, so useless, well below it
DP-SGD, RDP accountant	Equation 33.16: $T\,\varepsilon(\alpha)$, converted at the best order	Poisson, add/remove, adaptive steps	Upper bound; 6.71 for the running example
Any mechanism, Poisson	Equation 33.17	Integer α	Within a factor 3 inside the logarithm

Rules of thumb

- Sampling at rate q multiplies a small ε by q, but takes at most $\ln(1/q)$ off a large one.

- In RDP the per-step cost is quadratic in q: about $\alpha q^2/(2\sigma^2)$ for large σ, valid up to $\alpha \approx 2\sigma^2 \ln(1/q)$, and it breaks abruptly there.
- Never compose per-step (ε, δ) for DP-SGD. Compose RDP curves, or privacy loss distributions, and convert once.
- Account for the sampler you run. Poisson pairs with add/remove. Fixed-size batches need the base mechanism's replace-one guarantee, which for clipped Gaussian sums means half the noise multiplier. Shuffle and partition has no simple amplification theorem, and the Poisson number can be far too small for it.
- For the Gaussian, use the exact binomial sum and the numerical integral; keep the general bounds for other mechanisms.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

34. Numerical accounting with privacy loss distributions

34.1. Why this matters

You trained a model with differential privacy (DP): 10,000 steps of stochastic gradient descent (SGD), each on a Poisson sample of the data with rate $q = 0.01$, each with clipped gradients and Gaussian noise of multiplier $\sigma = 1$. This is DP-SGD. You need one number: the smallest ε such that the whole run is $(\varepsilon, 10^{-5})$-DP, which means that for any two datasets that differ in one person's record, the probability of any set of outcomes of the run changes by at most a factor e^{ε}, plus a slack of 10^{-5}. Rényi differential privacy (RDP), from Rényi DP, gives an upper bound: it tracks one Rényi divergence per order and adds them up over the steps, but converting that Rényi curve to (ε, δ) loses something you cannot see. The Gaussian central limit theorem (CLT) of f-DP and Gaussian DP says that many composed steps look like one Gaussian mechanism, which gives an approximation, but not a bound. Neither tells you how far it is from the truth. This chapter computes the truth itself, to any precision you are willing to pay for, together with a lower and an upper bound that bracket it.

34.1.1. The one idea: δ is an average over the privacy loss, and composition adds losses

Let P be the distribution of the output when the run uses your dataset D, and Q the distribution when it uses the neighbour D'. Composition measured how much one output y gives the two datasets away by the log of the ratio of its two probabilities, the **privacy loss** $L(y) = \ln \frac{P(y)}{Q(y)}$. It is positive when y is more likely under D, negative when it is more likely under D', and zero when y says nothing. With the output drawn as $Y \sim P$, the loss $L(Y)$ is a random variable, the privacy loss random variable (PRV). Two facts make it the right object to track.

The first is that the guarantee $\delta(\varepsilon)$, the smallest δ that works for a given ε, depends on the pair (P, Q) only through the distribution of $L(Y)$. Each output contributes to $\delta(\varepsilon)$ an amount that depends only on its own loss: nothing if its loss is at most ε, a fraction $(1 - e^{\varepsilon - \ell})_+$ of its probability if its loss ℓ is larger. So $\delta(\varepsilon)$ is the average of that fixed function of the loss. We call the distribution of $L(Y)$ the **privacy loss distribution (PLD)**.

The second is that the privacy loss of a composition is the sum of the per-step losses, because the probability of a sequence of independent outputs is a product and the logarithm turns the product into a sum. For independently run steps the terms are independent, and the distribution of a sum of independent variables is the convolution of their distributions. So the PLD of k steps is the k-fold convolution of the per-step PLDs (Section 34.4 handles steps chosen adaptively).

Everything in this chapter follows from these two facts. Discretize the per-step loss on a grid of width h, convolve with a fast Fourier transform (FFT), and read $\delta(\varepsilon)$ off the result. Since a

larger loss never contributes less to δ, rounding moves δ in a known direction. If you **round each loss up** to the grid, the δ you compute is an upper bound on the true δ for every composition. If you **round down**, it is a lower bound. The true value is sandwiched, and the width of the sandwich is known in advance: each step's two roundings are at most h apart, so after k steps the two totals are at most kh apart, which makes the sandwich at most kh wide in ε, and exactly kh for a continuous PLD without truncation.

Table 34.1 lists the results and where each is used.

Table 34.1.: The results of this chapter and where each is used.

Result	Where it is used
$\delta(\varepsilon) = \mathbb{E}_{Y\sim P}[(1 - e^{\varepsilon - L(Y)})_+]$ (Equation 34.3)	Every accountant in this chapter; reading (ε, δ) off any PLD
The Gaussian PLD $\mathcal{N}(\mu^2/2, \mu^2)$	Checking the code; the Gaussian mechanism; Gaussian DP
Composition is convolution (Equation 34.5), dominating pairs	Accounting for k steps, adaptive or not
Pessimistic and optimistic rounding (Equation 34.6)	Turning a numerical answer into a certified upper bound and a lower bound
FFT convolution, padding, repeated squaring	Fast accountants: the PLD accountant, the PRV accountant
PLD of the Poisson-subsampled Gaussian, two directions	DP-SGD accounting
The running example	Comparing PLD against RDP and the CLT in Choosing an accountant

Conventions. In this chapter q is the sampling rate. Since the lowercase letter is taken, the densities of the two output distributions are written with the same letter as the distribution, $P(y)$ and $Q(y)$. σ is the noise multiplier and the sensitivity is 1: one record moves the quantity being noised by at most 1. A **PLD** ω is the law of $L(Y)$ under $Y \sim P$. It may have an atom at $+\infty$, which is the P-mass of the outputs where $Q(y) = 0$: those outputs are impossible under D', so seeing one proves the dataset was D. Φ is the standard normal distribution function, $\Phi(x) = \Pr[Z \le x]$ for $Z \sim \mathcal{N}(0, 1)$. Logs are natural. The running example is DP-SGD with $q = 0.01$, $\sigma = 1$, $\delta = 10^{-5}$ and up to $T = 10{,}000$ steps. The RDP accountant of Amplification by subsampling and the CLT approximation of Gaussian differential privacy (GDP) serve as comparisons.

34.2. Toolkit: three facts the derivations reuse

34.2.1. Fact 1 — Change of measure: $Q(y) = e^{-L(y)}P(y)$

You often need a probability under Q but only know the distribution of the loss under P. The way across is to reweight: an output's Q-probability is its P-probability times the ratio $Q(y)/P(y)$, and that ratio is $e^{-L(y)}$ by the definition of the loss. Wherever $P(y) > 0$ and $Q(y) > 0$, $Q(y) = P(y)\,\frac{Q(y)}{P(y)} = e^{-L(y)}P(y)$. Summing any function f of the loss against both sides gives, for any f,

$$\mathbb{E}_Q[f(L)\,\mathbf{1}[P > 0]] = \mathbb{E}_P\big[f(L)\,e^{-L}\big]. \tag{34.1}$$

The indicator $\mathbf{1}[P > 0]$ is there because the reweighting only reaches outputs that P can produce; the outputs with $P(y) = 0$ are invisible from the P side. With $f = 1$ the left side is the total Q-mass on outputs that P can produce: $\mathbb{E}_P[e^{-L}] = Q(P > 0) \le 1$, with equality when Q puts no mass where P puts none. This is Fact 1 of Divergences, read with the likelihood ratio $r = e^L$.

Two things follow that the chapter uses. The law of L under Q is determined by the PLD, because every Q-probability of a loss event is a reweighted P-probability. And a distribution ω can only be a PLD if $\mathbb{E}_\omega[e^{-L}] \le 1$.

34.2.2. Fact 2 — Monotone coupling

If you move every value of a random variable up, any non-decreasing function of it can only go up too, and so can its average. Formally, let g be non-decreasing. If two random variables, built on the same random draw, satisfy $X \le X'$ for every outcome, then $\mathbb{E}[g(X)] \le \mathbb{E}[g(X')]$. This is just $g(X) \le g(X')$ outcome by outcome, averaged. Building two variables from one draw like this, so that they can be compared outcome by outcome, is called a **coupling**. The chapter uses it to show that moving privacy loss upward can only increase δ (Section 34.5).

34.2.3. Fact 3 — The discrete convolution theorem

Convolving two sequences directly means summing $a_i b_j$ over every pair (i, j) with the same $i + j$, which costs a number of operations proportional to the product of their lengths. The Fourier transform turns this into a pointwise product. The reason is that the transform attaches to index i the power ζ^i of a fixed complex number, and powers multiply by adding exponents, $\zeta^i\zeta^j = \zeta^{i+j}$: indices add exactly the way losses add. For sequences $a_0, \dots, a_{N-1}$, the discrete Fourier transform of length N is $\hat{a}_m = \sum_{i=0}^{N-1} a_i\,\zeta^{im}$ with $\zeta = e^{-2\pi\mathrm{i}/N}$, an N-th root of unity. Multiplying two transforms and grouping the terms by $i + j$ gives, since $\zeta^N = 1$ means exponents only matter modulo N,

$$\hat{a}_m\,\hat{b}_m = \sum_{i,j} a_i b_j\,\zeta^{(i+j)m} = \sum_{n=0}^{N-1} \Big(\sum_{i+j \equiv n \bmod N} a_i b_j \Big) \zeta^{nm}. \tag{34.2}$$

The bracket is the coefficient at index n, so the inverse transform of $\hat{a}\hat{b}$ is the **circular** convolution: index sums are taken modulo N, and a sum that reaches N or more folds back to the start. To get the ordinary convolution you make the window long enough that nothing folds back. If a has n_a nonzero entries at the start, b has n_b, and $N \ge n_a + n_b - 1$, then $i + j \le n_a + n_b - 2 < N$ always, no index wraps around, and the circular convolution equals the ordinary one. The FFT

computes such a transform in $O(N \log N)$ operations instead of $O(N^2)$. The chapter uses it to convolve PLDs (Section 34.6).

34.3. The privacy loss distribution

34.3.1. Context

The guarantee you report is $\delta(\varepsilon) = E_{e^\varepsilon}(P\|Q)$, the **hockey-stick divergence** between the output distributions on two neighbouring datasets (see Divergences and Definition). It is the smallest δ for which $P(S) \le e^\varepsilon Q(S) + \delta$ holds for every set S of outputs. The largest gap $P(S) - e^\varepsilon Q(S)$ comes from the set that holds exactly the outputs with $P(y) > e^\varepsilon Q(y)$, since each of them adds a positive amount and any other output would subtract, so the divergence is the sum $\sum_y \big(P(y) - e^\varepsilon Q(y)\big)_+$, where $(x)_+ = \max\{x, 0\}$. That is a sum over outputs, and the output space of a training run is enormous. This section shows that you never need the output space: the one-dimensional distribution of the privacy loss carries all of $\delta(\varepsilon)$.

34.3.2. Statement

Each output adds to δ only if its loss exceeds ε, and then it adds the fraction $1 - e^{\varepsilon-\ell}$ of its probability, which grows from 0 at $\ell = \varepsilon$ towards 1 for a very large loss. So δ is an average of that weight over the PLD. Equivalently, it is the chance under P that the loss exceeds ε, minus e^ε times the same chance under Q: the second form is the hockey-stick gap of the best set $S = \{L > \varepsilon\}$. Let ω be the PLD of (P, Q), the law of $L(Y)$ with $Y \sim P$, including its atom $\omega(\{+\infty\})$. Then for every ε,

$$\delta(\varepsilon) = \mathbb{E}_{L\sim\omega}\big[(1 - e^{\varepsilon - L})_+\big] = \Pr_P[L > \varepsilon] - e^\varepsilon \Pr_Q[L > \varepsilon], \tag{34.3}$$

with the convention $(1 - e^{\varepsilon-\infty})_+ = 1$: an output impossible under D' counts fully. The right side also needs the law of L under Q, but that is no extra information. By Fact 1 it is the PLD reweighted by $e^{-\ell}$, namely $e^{-\ell}\,\omega(\mathrm{d}\ell)$ on finite ℓ, plus an atom at $-\infty$ of size $1 - \mathbb{E}_\omega[e^{-L}]$ for the Q-mass that sits where P is zero. So ω alone determines both sides.

For the **Gaussian pair** $P = \mathcal{N}(0, \sigma^2)$, $Q = \mathcal{N}(s, \sigma^2)$, the two outputs of a Gaussian mechanism whose query moves by s, write $\mu = s/\sigma$ for the shift measured in noise standard deviations. The privacy loss turns out to be a linear function of the output, so it is itself Gaussian, with mean $\mu^2/2$ and variance μ^2. Plugging its two tails into Equation 34.3 gives δ in closed form:

$$L \sim \mathcal{N}(\tfrac{\mu^2}{2}, \mu^2) \text{ under } P, \qquad \delta(\varepsilon) = \Phi\Big(\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) - e^\varepsilon\, \Phi\Big(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big). \tag{34.4}$$

34.3.3. Derivation

δ as an average over the PLD. The plan is to start from the hockey-stick sum, factor each output's probability out of its term so that what remains depends only on its loss, and then recognize an average.

1. **Write the hockey-stick divergence as a sum over outputs.** As the Context explains (Fact 3 of Divergences), the best set of outputs is the one where $P > e^{\varepsilon}Q$, so $\delta(\varepsilon) = \sum_y \big(P(y) - e^{\varepsilon}Q(y)\big)_+$.
2. **Sort the outputs into three kinds, because the loss behaves differently on each.** Where $P(y) = 0$ the term is $(-e^{\varepsilon}Q(y))_+ = 0$, so these outputs drop out. Where $Q(y) = 0 < P(y)$ the term is $P(y)$, and $L(y) = +\infty$. Elsewhere both are positive and the loss is finite.
3. **Factor out $P(y)$ on the third kind,** using $Q(y)/P(y) = e^{-L(y)}$: $P(y)(1 - e^{\varepsilon}\frac{Q(y)}{P(y)})_+ = P(y)(1 - e^{\varepsilon - L(y)})_+$.
4. **Recognize an expectation under P.** A sum of $P(y)$ times something is the average of that something with $Y \sim P$. Adding up the second and third kinds gives $\mathbb{E}_P[(1 - e^{\varepsilon - L(Y)})_+]$, where an infinite loss gets the value 1, as step 2 requires. The thing being averaged depends on y only through $L(y)$, so the expectation is an average over ω. This is the first form of Equation 34.3.
5. **Split the positive part into two terms.** When $L > \varepsilon$ the bracket $1 - e^{\varepsilon - L}$ is positive and the positive part keeps it; when $L \le \varepsilon$ it is zero. So $(1 - e^{\varepsilon - L})_+ = \mathbf{1}[L > \varepsilon] - e^{\varepsilon}e^{-L}\mathbf{1}[L > \varepsilon]$. The first term averages to $\Pr_P[L > \varepsilon]$.
6. **Change measure in the second term.** Fact 1 with $f = \mathbf{1}[\cdot > \varepsilon]$ turns the P-average reweighted by e^{-L} into a Q-probability: $\mathbb{E}_P[e^{-L}\mathbf{1}[L > \varepsilon]] = \Pr_Q[L > \varepsilon]$. The outputs where $P = 0$, which Fact 1 cannot reach, have $L = -\infty$ and are not in the event anyway. This gives the second form of Equation 34.3.
7. **Find the law of L under Q the same way.** Fact 1 with $f = \mathbf{1}[L \in A]$ gives $\Pr_Q[L \in A] = \int_A e^{-\ell}\omega(\mathrm{d}\ell)$ for sets A of finite losses. The remaining Q-mass sits where $P = 0$, at $L = -\infty$.

The Gaussian PLD. The point is that for two Gaussians with the same variance the log-ratio of the densities is linear in the output, because the quadratic terms cancel.

1. **The loss is linear in y.** The normalizing constants are the same and cancel: $L(y) = \ln \frac{e^{-y^2/2\sigma^2}}{e^{-(y-s)^2/2\sigma^2}} = \frac{(y-s)^2 - y^2}{2\sigma^2} = \frac{s^2 - 2sy}{2\sigma^2}$.
2. **A linear function of a Gaussian is Gaussian.** With $Y \sim \mathcal{N}(0, \sigma^2)$, the mean of L is the constant term $\frac{s^2}{2\sigma^2} = \frac{\mu^2}{2}$, and the variance is the squared slope times the variance of Y, $\frac{4s^2}{4\sigma^4}\sigma^2 = \mu^2$.
3. **Under Q, $Y \sim \mathcal{N}(s, \sigma^2)$** has mean s instead of 0, which moves the mean of L by the slope times s, $-\frac{2s \cdot s}{2\sigma^2} = -\mu^2$, so $L \sim \mathcal{N}(-\frac{\mu^2}{2}, \mu^2)$. Step 7 above predicts the same. Multiplying the density of $\mathcal{N}(m, v)$ by $e^{-\ell}$ and completing the square, $-\frac{(\ell - m)^2}{2v} - \ell = -\frac{(\ell - (m - v))^2}{2v} + \text{const}$, gives $\mathcal{N}(m - v, v)$; here $\frac{\mu^2}{2} - \mu^2 = -\frac{\mu^2}{2}$.
4. **Read off the tails.** For $L \sim \mathcal{N}(m, \mu^2)$, standardizing gives $\Pr[L > \varepsilon] = \Pr\left[Z > \frac{\varepsilon - m}{\mu}\right] = \Phi(\frac{m - \varepsilon}{\mu})$, because the standard normal is symmetric about 0. So $\Pr_P[L > \varepsilon] = \Phi(\frac{\mu^2/2 - \varepsilon}{\mu}) = \Phi(\frac{\mu}{2} - \frac{\varepsilon}{\mu})$, and $\Pr_Q[L > \varepsilon] = \Phi(\frac{-\mu^2/2 - \varepsilon}{\mu}) = \Phi(-\frac{\mu}{2} - \frac{\varepsilon}{\mu})$. Insert them in Equation 34.3. This is the exact $\delta(\varepsilon)$ of the Gaussian mechanism, and the (ε, δ) curve of μ-GDP in f-DP and Gaussian DP, where a mechanism is μ-GDP if telling its two outputs apart is never easier than telling $\mathcal{N}(0, 1)$ from $\mathcal{N}(\mu, 1)$.

34.3.4. Interpretation

The PLD is a complete summary for (ε, δ). Two pairs with the same PLD have the same $\delta(\varepsilon)$ at every ε, whatever their output spaces, because Equation 34.3 reads δ off the PLD and nothing else. A DP-SGD run with millions of parameters and a one-dimensional Gaussian pair can have the same PLD.

Not every distribution is a PLD, though. Fact 1 requires $\mathbb{E}_\omega[e^{-L}] \le 1$, since that average is the Q-mass where P is positive. The converse holds too: any ω with $\mathbb{E}_\omega[e^{-L}] \le 1$ is the PLD of some pair, and you can build the pair directly. Take $P = \omega$ on the real line, except that its atom at $+\infty$, if any, goes on an extra point y_+ where Q is zero. Take $Q(\mathrm{d}\ell) = e^{-\ell}\omega(\mathrm{d}\ell)$ on the finite losses, which has total mass at most 1 by assumption, and put the missing Q-mass $1 - \mathbb{E}_\omega[e^{-L}]$ on a second extra point y_- where P is zero. Then $\ln \frac{P}{Q}$ is ℓ at each finite ℓ and $+\infty$ at y_+, so the PLD is ω. Section 34.5 uses this to show that a rounded PLD still belongs to a real pair of distributions.

The weight $(1 - e^{\varepsilon - \ell})_+$ is non-decreasing in ℓ: it is 0 up to $\ell = \varepsilon$ and rises to 1. So $\delta(\varepsilon)$ is the PLD's upper tail beyond ε, down-weighted near ε (Figure 34.1). Because the weight is at most 1, $\delta(\varepsilon) \le \Pr_P[L > \varepsilon]$, and because losses just above ε get a weight close to 0, that tail bound is loose (Exercise 2 in the exercise book).

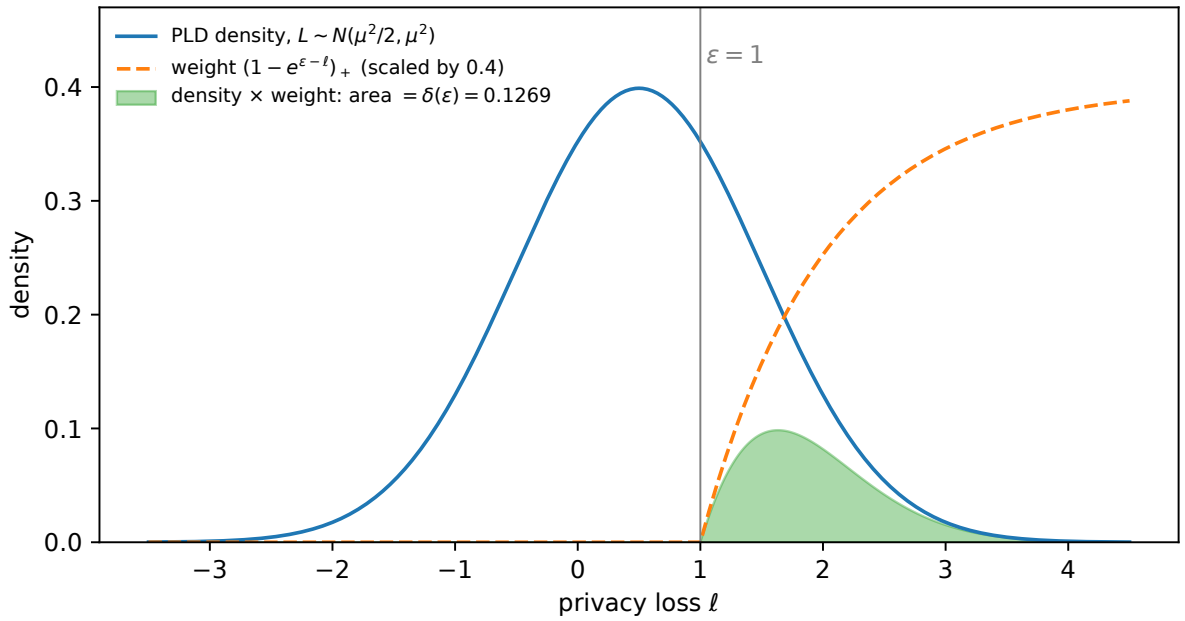

Figure 34.1.: The Gaussian PLD for $\mu = 1$ (blue), the weight $(1 - e^{\varepsilon - \ell})_+$ at $\varepsilon = 1$ (orange, scaled by 0.4 to fit), and their product (green). The green area is $\delta(1) = 0.1269$.

34.3.5. Example: the Gaussian mechanism with $\sigma = 1$

With sensitivity 1 and $\sigma = 1$, the shift is one noise standard deviation, $\mu = 1/1 = 1$, and the PLD is $\mathcal{N}(\frac{1}{2}, 1) = \mathcal{N}(0.5, 1)$. From a million samples of Y, the script finds a mean loss of 0.4990, a variance of 1.0013 and $\mathbb{E}[e^{-L}] = 1.0015$, against the exact 0.5, 1 and 1. The green area of

Figure 34.1 comes from Equation 34.4 at $\varepsilon = 1$: $\Phi(\frac{1}{2} - 1) - e\,\Phi(-\frac{1}{2} - 1) = \Phi(-0.5) - e\,\Phi(-1.5) = 0.3085 - 2.7183 \times 0.0668 = 0.3085 - 0.1816 = 0.1269$. At $\varepsilon = 0$ the second term has no factor e^{ε} and the formula is $\Phi(0.5) - \Phi(-0.5) = 0.6915 - 0.3085 = 0.3829$. Table 34.2 checks Equation 34.4 against numerical integration of $(1 - e^{\varepsilon - \ell})_+$ over the PLD density and against Monte Carlo.

Table 34.2.: $\delta(\varepsilon)$ of the Gaussian pair with $\mu = 1$, computed three ways.

ε	Closed form Equation 34.4	Quadrature over the PLD	Monte Carlo (10^6 draws)
0	0.382925	0.382925	0.382644
0.5	0.238422	0.238422	0.238748
1	0.126937	0.126937	0.126967
2	0.020924	0.020924	0.020922

The quadrature agrees to all six digits and Monte Carlo to within its sampling error. Since δ falls as ε grows, you can also go the other way and solve $\delta(\varepsilon) = 10^{-5}$ for ε: the mechanism is $(4.3772, 10^{-5})$-DP.

For a finite pair the two forms of Equation 34.3 can be checked by hand. Take $P = (0.1, 0.2, 0.3, 0.4)$ and $Q = (0.4, 0.3, 0.2, 0.1)$ at $\varepsilon = 0.5$, where $e^{0.5} = 1.6487$. Only the last output has $P > e^{0.5}Q$, so the sum is $\sum (P - e^{0.5}Q)_+ = 0.4 - 1.6487 \times 0.1 = 0.2351$. The losses are $\ln \frac{0.1}{0.4}$, $\ln \frac{0.2}{0.3}$, $\ln \frac{0.3}{0.2} = 0.405$ and $\ln \frac{0.4}{0.1} = 1.386$, so only the last exceeds 0.5, and $\Pr_P[L > 0.5] - e^{0.5} \Pr_Q[L > 0.5] = 0.4 - 1.6487 \times 0.1 = 0.2351$ as well.

34.3.6. Check yourself

- Why does an output with $Q(y) = 0$ count fully in δ, whatever ε is? *(Seeing it proves the dataset was D, not D'. No e^{ε} factor can cover a ratio of $P(y)/0$, so its whole probability goes into δ.)*
- A Gaussian mechanism with noise standard deviation 2 on a count (sensitivity 1), and a 1000-dimensional Gaussian mechanism with noise standard deviation 4 on a query of ℓ_2 sensitivity 2: do they have the same (ε, δ) curve? *(Yes. Both shift by half a noise standard deviation, $\mu = 1/2 = 2/4 = 0.5$, so both have PLD $\mathcal{N}(\frac{0.25}{2}, 0.25) = \mathcal{N}(0.125, 0.25)$, and by Equation 34.3 δ depends only on the PLD.)*

34.4. Composition is convolution

34.4.1. Context

DP-SGD releases T noisy gradients. More generally, a composition of k mechanisms outputs the tuple $(y_1, \ldots, y_k)$, and you want its $\delta(\varepsilon)$. The bounds of Composition (basic, advanced, and the optimal composition theorem of Kairouz, Oh and Viswanath, which is the best bound possible for steps known only by their $(\varepsilon_i, \delta_i)$) start from per-step $(\varepsilon_i, \delta_i)$ pairs, and so throw away the shape of each step's PLD. With PLDs, composition is exact.

34.4.2. Statement

Run k steps independently. The probability of the whole tuple of outputs is the product of the per-step probabilities, so the log-ratio of the whole tuple is the sum of the per-step log-ratios: the total privacy loss is the sum of the step losses. Those step losses are independent, and the distribution of a sum of independent variables is the **convolution** of their distributions. For independent steps with pairs (P_i, Q_i) and PLDs ω_i, the product pair $(P_1 \times \cdots \times P_k,\ Q_1 \times \cdots \times Q_k)$ therefore has PLD

$$\omega_{1..k} = \omega_1 * \omega_2 * \cdots * \omega_k, \qquad \omega^{*k} \text{ for } k \text{ identical steps,} \tag{34.5}$$

where $*$ is convolution of distributions (the law of a sum of independent variables), and the atom at $+\infty$ absorbs any sum that contains $+\infty$: once one step gives the dataset away completely, the whole run does. For k Gaussian steps, means and variances add, so $\mathcal{N}(\frac{\mu^2}{2}, \mu^2)^{*k} = \mathcal{N}(\frac{k\mu^2}{2}, k\mu^2)$, which is the PLD of a single Gaussian with $\mu_k = \sqrt{k}\,\mu$.

Adaptive composition. In DP-SGD each step's gradient depends on the model, which depends on the earlier outputs, so the steps are not independent. The way around this is to replace each step by a fixed pair that is at least as easy to tell apart, whatever happened before. To compare pairs at every level of strictness, use the hockey-stick divergence with a general weight γ in place of e^ε, $E_\gamma(P\|Q) = \sum_y \big(P(y) - \gamma Q(y)\big)_+$. A pair (P, Q) **dominates** a mechanism M if $E_\gamma(M(D)\|M(D')) \le E_\gamma(P\|Q)$ for all neighbours $D \sim D'$ and all $\gamma \ge 0$ (Zhu, Dong & Wang 2022, Definition 7). If (P_i, Q_i) dominates step i for every value of the earlier outputs, then $(P_1 \times \cdots \times P_k, Q_1 \times \cdots \times Q_k)$ dominates the adaptive composition (their Theorem 10; Section K.3 in the appendices derives it). So the convolution of the dominating PLDs gives a valid $\delta(\varepsilon)$ for the adaptive run.

34.4.3. Derivation

The derivation follows the probability of the tuple from a product, to a sum of losses, to a convolution.

1. **Densities multiply.** For independent steps the probability of a tuple is the product of the probabilities of its entries: $P(y_1, \dots, y_k) = \prod_i P_i(y_i)$, and likewise for Q.
2. **Losses add.** The ratio of two products is the product of the ratios, and the logarithm of a product is the sum of logarithms: $L(y_1, \dots, y_k) = \sum_i L_i(y_i)$, with $L_i = \ln(P_i/Q_i)$.
3. **The terms are independent.** Under P, the Y_i are independent with $Y_i \sim P_i$. Each $L_i(Y_i)$ is a function of its own Y_i only, so the $L_i(Y_i)$ are independent too, with laws ω_i.
4. **The law of a sum of independent variables is the convolution of their laws.** For two discrete variables, the chance that the sum is ℓ adds up, over all ways of splitting $\ell = a + b$, the chance of a times the chance of b, and that is what convolution computes. This is Equation 34.5.
5. **Gaussian check.** A sum of independent Gaussians is Gaussian, and means and variances add: $k\frac{\mu^2}{2}$ and $k\mu^2$. This is $\mathcal{N}(\frac{\mu_k^2}{2}, \mu_k^2)$ with $\mu_k^2 = k\mu^2$.
6. **Adaptivity breaks step 3, and domination repairs it.** If the second mechanism is chosen after seeing y_1, its pair depends on y_1, so its loss depends on the first output and the losses are no longer independent. The dominating-pair theorem bounds every pair the second mechanism could have by one fixed pair, and shows that the hockey-stick curves of

the product of the fixed pairs still lie above those of the adaptive run. Its proof is in Zhu, Dong & Wang (2022, Theorem 10), and Section K.3 in the appendices derives it step by step. Domination at every $\gamma \geq 0$ lets each branch's test be swapped for one on the fixed pair that fires at least as often under P and at most as often under Q, so the test's chance of firing under P, minus γ times its chance under Q, never goes down. It uses E_γ for all $\gamma \geq 0$, not only $\gamma \geq 1$ (which corresponds to $\varepsilon \geq 0$), which is why Definition 7 asks for all $\gamma \geq 0$.

34.4.4. Interpretation

Equation 34.5 has no slack at all. It is exact, so the only errors in a PLD accountant are the ones you introduce to compute the convolution: discretization (Section 34.5) and floating point (Section 34.6).

It also shows why the CLT is plausible. A k-fold convolution is the law of a sum of k independent terms, and the ordinary central limit theorem says that such a sum of anything with finite variance looks Gaussian for large k. That is the GDP central limit theorem of f-DP and Gaussian DP. The PLD accountant does not need that approximation; it computes the convolution.

The dominating pair is a choice, and the bound is only as tight as that choice. For the Gaussian mechanism with ℓ_2 sensitivity 1, the pair $\mathcal{N}(0, \sigma^2)$, $\mathcal{N}(1, \sigma^2)$ dominates and is attained by some neighbouring datasets, so the result is tight. For subsampled mechanisms you need one pair per direction (Section 34.7).

34.4.5. Example: ten Gaussian steps

One Gaussian step with $\sigma = 1$ has $\mu = 1$ and PLD $\mathcal{N}(0.5, 1)$. Ten steps add ten means and ten variances, so their PLD is $\mathcal{N}(5, 10)$, which is a single Gaussian with $\mu = \sqrt{10}$. Solving Equation 34.4 with that μ for $\delta = 10^{-5}$, the composition is $(17.8566, 10^{-5})$-DP. For 100 steps, $\mu = \sqrt{100} = 10$ and $\varepsilon = 91.8173$. Section 34.6 recovers both numbers from a discretized PLD.

34.4.6. Check yourself

- You compose a Gaussian step with $\mu = 1$ and one with $\mu = 2$. What is the PLD? *(Means $\frac{\mu^2}{2}$ and variances μ^2 add: $\mathcal{N}(\frac{1}{2} + 2, 1 + 4) = \mathcal{N}(2.5, 5)$, a single Gaussian with $\mu = \sqrt{5}$.)*
- Why is the convolution of PLDs exact while advanced composition is not? *(Advanced composition, and even optimal composition, see each step only through $(\varepsilon_i, \delta_i)$, so they must cover the worst PLD with those values. Convolution uses the actual PLDs.)*

34.5. Discretization: pessimistic and optimistic

34.5.1. Context

A computer cannot convolve continuous distributions. You must put the loss on a finite grid $\{ih : i \in \mathbb{Z}\}$ of spacing h. Any rounding changes δ. The question is whether you can round so

that the error has a known sign, for every number of compositions, so that the answer is still a guarantee.

34.5.2. Statement

The weight $(1 - e^{\varepsilon-\ell})_+$ that turns a loss into δ never decreases as the loss grows. So if you move every loss up, δ can only grow, and if you move every loss down, it can only shrink. That gives two ways to round, one for each direction. Given a PLD ω and a grid width h, define two discretizations.

- **Pessimistic** $\omega^{\uparrow}$: move every loss $\ell \in ((i-1)h, ih]$ up to ih. Truncate the top tail by moving its mass (at most a tiny τ) to $+\infty$, and the bottom tail by moving it up to the lowest kept grid point. Every move is upward.
- **Optimistic** $\omega^{\downarrow}$: move every loss $\ell \in [ih, (i+1)h)$ down to ih. Truncate the top tail by moving it down to the highest kept grid point, and drop the bottom tail. Every move is downward or removes mass.

Write $\delta_\omega(\varepsilon)$ for Equation 34.3 evaluated on ω. Rounding each step before convolving keeps the direction of every move in the total, so for every k and every ε,

$$\delta_{(\omega^{\downarrow})^{*k}}(\varepsilon) \;\le\; \delta_{\omega^{*k}}(\varepsilon) \;\le\; \delta_{(\omega^{\uparrow})^{*k}}(\varepsilon), \tag{34.6}$$

and the same holds for convolutions of different PLDs, each rounded the same way.

Two more things hold. First, the upper bound is not just a number but a real guarantee: $\omega^{\uparrow}$ is a valid PLD, $\mathbb{E}_{\omega^{\uparrow}}[e^{-L}] \le 1$, of a pair that dominates (P, Q), so the upper bound also holds for adaptive composition. Second, the sandwich is narrow. Write $\varepsilon^{\uparrow}(\delta)$ and $\varepsilon^{\downarrow}(\delta)$ for the values of ε at which the pessimistic and optimistic curves reach δ. Without truncation the two are at most kh apart, because each step's two roundings differ by at most h: $\varepsilon^{\uparrow}(\delta) \le \varepsilon^{\downarrow}(\delta) + kh$.

34.5.3. Derivation

1. **Build both roundings of one step from the same draw.** Draw $L \sim \omega$ and set $L^{\uparrow} = h\lceil L/h \rceil$ (round up) and $L^{\downarrow} = h\lfloor L/h \rfloor$ (round down). Then $L^{\uparrow}$ has law $\omega^{\uparrow}$, $L^{\downarrow}$ has law $\omega^{\downarrow}$, and, since a number lies between its two roundings and they are at most one grid step apart, $L^{\downarrow} \le L \le L^{\uparrow} \le L^{\downarrow} + h$ for every outcome. This is a coupling in the sense of Fact 2.
2. **Add up k steps.** Draw the k steps independently and apply step 1 to each. Adding the k inequalities gives $\sum L_i^{\downarrow} \le \sum L_i \le \sum L_i^{\uparrow} \le \sum L_i^{\downarrow} + kh$, and each sum has the convolved law of its rounded PLDs (Equation 34.5).
3. **Use that δ grows with the loss.** By Equation 34.3, $\delta(\varepsilon) = \mathbb{E}[g_\varepsilon(\text{total loss})]$ with $g_\varepsilon(\ell) = (1 - e^{\varepsilon-\ell})_+$, a non-decreasing function. Fact 2 applied to the inequalities of step 2 gives Equation 34.6.
4. **Truncation keeps the sign.** The pessimistic truncation moves mass up (to a higher grid point, or to $+\infty$ where $g_\varepsilon = 1$), so Fact 2 still applies. The optimistic truncation moves mass down, which Fact 2 covers in the other direction, or deletes it, which removes a non-negative term from δ. Both can be repeated after every convolution without breaking the inequality.

5. **The pessimistic PLD belongs to a real pair.** Rounding up raises every loss, so it lowers e^{-L}: $\mathbb{E}_{\omega^\uparrow}[e^{-L}] \le \mathbb{E}_{\omega}[e^{-L}] \le 1$ (mass moved to $+\infty$ contributes $e^{-\infty} = 0$). The Interpretation in Section 34.3 showed that any distribution with $\mathbb{E}[e^{-L}] \le 1$ is the PLD of some pair, by building the pair from it. So there is a pair $(P^\uparrow, Q^\uparrow)$ with PLD $\omega^\uparrow$ (Doroshenko et al. 2022, Lemma 4.2, prove it for this rounding).
6. **That pair dominates the original.** Step 3 with $k = 1$ says $E_{e^\varepsilon}(P\|Q) \le E_{e^\varepsilon}(P^\uparrow\|Q^\uparrow)$ for every real ε, that is, for every $\gamma = e^\varepsilon > 0$. At $\gamma = 0$ the divergence is $\sum_y P(y) = 1$ for both pairs. So $(P^\uparrow, Q^\uparrow)$ dominates (P, Q) at every $\gamma \ge 0$, and by the dominating-pair theorem of Section 34.4 (derived in Section K.3) the convolution of rounded-up PLDs bounds adaptive compositions too.
7. **The width.** By step 2, the pessimistic total is the optimistic total plus at most kh. Adding a constant c to the loss shifts its δ curve by c to the right, because g_ε only sees the difference $\varepsilon - \ell$: $\mathbb{E}[g_\varepsilon(X + c)] = \mathbb{E}[g_{\varepsilon - c}(X)]$. With Fact 2 this gives $\delta^\uparrow(\varepsilon) \le \delta^\downarrow(\varepsilon - kh)$. So wherever the optimistic curve has dropped to a given δ, the pessimistic curve has dropped to it at most kh further right, and the ε at which each crosses δ differ by at most kh.

34.5.4. Interpretation

The lower bound needs care about what it bounds. Rounding down lowers losses, which raises e^{-L}, so it can push $\mathbb{E}[e^{-L}]$ above 1, and then $\omega^\downarrow$ is not the PLD of any pair. That does not matter for a lower bound: $\delta^\downarrow$ is still below the δ of k non-adaptive copies of (P, Q), by the sandwich. It bounds the mechanism's δ from below only if some neighbouring datasets actually produce (P, Q). That holds for the Gaussian and the subsampled Gaussian.

The width is almost exactly kh, not just at most. A loss that is not on the grid is moved by exactly h between its two roundings, and a continuous PLD puts no mass on the grid points, so $L^\uparrow = L^\downarrow + h$ almost surely and the totals differ by exactly kh. The error therefore grows linearly in k. To keep the sandwich width fixed at 10^4 steps, you need a grid 10^4 times finer than for one step.

The midpoint of the two sides is a good estimate, but not a bound. A loss spread evenly inside a grid cell is moved up by about $h/2$ on average when rounded up, and down by the same amount when rounded down. So the pessimistic total is biased up by about $h/2$ per step and the optimistic one down by the same amount, and their midpoint is nearly unbiased. Only the two sides are guarantees.

Mass at $+\infty$ is cheap but not free. Each truncation of τ moves at most τ of mass to a place where its weight is 1, so it adds at most τ to δ. With $\tau = 10^{-15}$ and a few dozen truncations, this is far below any δ you would report.

34.5.5. Example: randomized response composed three times

Randomized response with $\varepsilon_0 = \ln 3$ reports the true bit with probability $\frac{3}{4}$ and the flipped bit with probability $\frac{1}{4}$ (see Randomized response). The true report is $\frac{3/4}{1/4} = 3$ times likelier under D than under D', so its loss is $\ln 3$, and the flipped one has loss $-\ln 3$. Its PLD therefore has two points: loss $+1.0986$ with probability 0.7500 and -1.0986 with probability 0.2500. On the grid $h = 0.5$, the loss 1.0986 lies between 1 and 1.5 and -1.0986 between -1.5 and -1, so

rounding up gives $\{-1, 1.5\}$ and rounding down gives $\{-1.5, 1\}$, with the same probabilities. The rounded-up PLD has $\mathbb{E}[e^{-L}] = 0.75\,e^{-1.5} + 0.25\,e^{1} = 0.1673 + 0.6796 = 0.8469 \le 1$, a valid PLD. The rounded-down PLD has $\mathbb{E}[e^{-L}] = 0.75\,e^{-1} + 0.25\,e^{1.5} = 0.2759 + 1.1204 = 1.3963 > 1$, which no pair of distributions can have.

Table 34.3 follows the four outcomes of three steps, indexed by the number j of steps with a positive loss. The probability of j is binomial, for instance $(\frac{1}{4})^3 = 0.0156$ for $j = 0$ and $3 \times \frac{3}{4} \times (\frac{1}{4})^2 = 0.1406$ for $j = 1$. The exact total is $j \ln 3 - (3 - j) \ln 3 = (2j - 3) \ln 3$, the rounded-up total is $1.5j - (3 - j)$, and the rounded-down total is $j - 1.5(3 - j)$.

Table 34.3.: Three-fold randomized response with $\varepsilon_0 = \ln 3$. Each outcome's total loss, exactly and after rounding each step's loss to the grid $h = 0.5$.

j	Probability	Exact total loss	Rounded up	Rounded down
0	0.0156	−3.2958	−3	−4.5
1	0.1406	−1.0986	−0.5	−2
2	0.4219	1.0986	2	0.5
3	0.4219	3.2958	4.5	3

Every rounded-up total sits above the exact total, and every rounded-down total below it. The gap between the two is $3 \times 0.5 = 1.5$ in every row, as derivation step 7 predicts. Feeding each column into Equation 34.3 gives the three δ curves. At $\varepsilon = 0$, for instance, only the two positive exact totals count, with weights $1 - e^{-3.2958} = 1 - \frac{1}{27}$ and $1 - e^{-1.0986} = 1 - \frac{1}{3}$, and each of them has probability $\frac{27}{64} = 0.4219$, so the exact $\delta(0) = \frac{27}{64} \times \frac{26}{27} + \frac{27}{64} \times \frac{2}{3} = \frac{26}{64} + \frac{18}{64} = \frac{44}{64} = 0.6875$. The resulting values of δ are bracketed accordingly (Table 34.4 and Figure 34.2).

Table 34.4.: $\delta(\varepsilon)$ of three-fold randomized response, exact and from the rounded PLDs on the grid $h = 0.5$.

ε	Exact δ	Pessimistic	Optimistic
0	0.6875	0.7820	0.5669
1	0.4190	0.6758	0.3648
2	0.3064	0.3872	0.2667

34.5.6. Check yourself

- Would it be safe to round each loss to the *nearest* grid point? *(Not as a guarantee. Some losses move down, so neither side of Equation 34.6 holds in general. Nearest rounding is a good estimate. The PRV accountant starts from it and then shifts the whole grid so that the mean loss is preserved (Section 34.6).)*
- If the grid happens to contain every possible loss, how wide is the sandwich? *(Zero. With $h = \ln 3/2$ every loss of randomized response, $\pm \ln 3 = \pm 2h$, is on the grid, and both roundings return the exact PLD; Exercise 3 in the exercise book checks it.)*

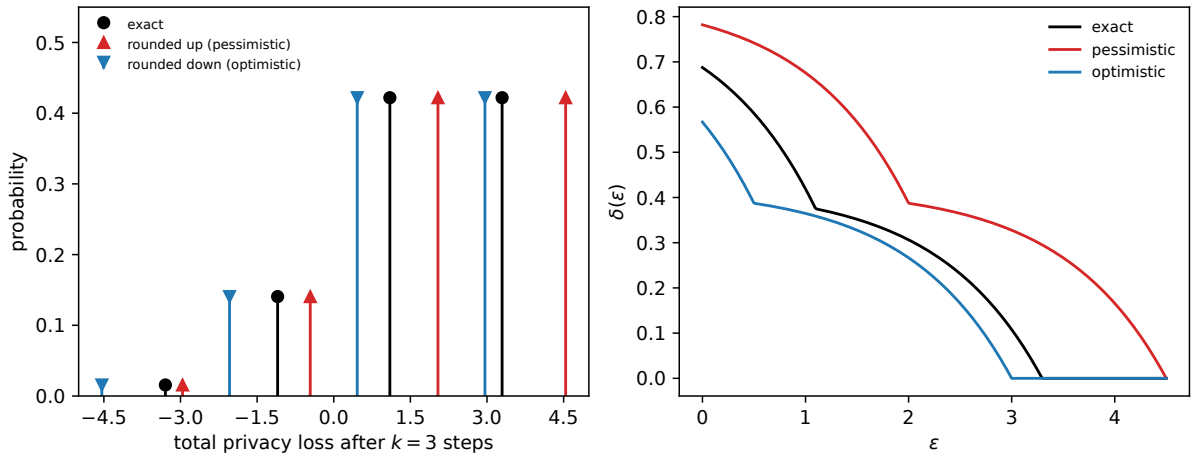

Figure 34.2.: Left: the PLD of three-fold randomized response with $\varepsilon_0 = \ln 3$ (black), rounded up (red) and rounded down (blue) on the grid $h = 0.5$; the rounded atoms are offset slightly sideways so that they do not overlap. Right: the three $\delta(\varepsilon)$ curves. The pessimistic curve lies above the exact one and the optimistic curve below it at every ε.

34.6. Composition by FFT

34.6.1. Context

A discretized PLD is a vector of masses $m_0, \dots, m_{n-1}$ at losses $(o + i)h$, where the integer offset o says where the vector starts on the grid, plus an atom at $+\infty$. Convolving two of them directly costs $O(n_a n_b)$ operations for vectors of lengths n_a and n_b. With a grid of $h = 10^{-5}$, a single DP-SGD step of the running example already has hundreds of thousands of bins (329590, Section 34.7), and after 10,000 steps the composed PLD has 2103251, a count the script prints along with the bins at every k it composes. The FFT makes this cheap. Koskela, Jälkö and Honkela (2020) introduced FFT-based PLD accounting.

34.6.2. Statement

On a common grid, adding two losses adds their grid indices, so the masses of the sum are the discrete convolution of the two mass vectors, and Fact 3 computes that convolution as a product of transforms, provided the window is long enough not to wrap. Let a and b be the mass vectors of two discretized PLDs with offsets o_a, o_b and atoms a_∞, b_∞ at $+\infty$, on the same grid. Their convolution has offset $o_a + o_b$, atom $a_\infty + b_\infty - a_\infty b_\infty$, and masses

$$c = \mathrm{IDFT}_N(\mathrm{DFT}_N(a) \cdot \mathrm{DFT}_N(b)), \qquad N \geq n_a + n_b - 1, \tag{34.7}$$

where DFT_N is the discrete Fourier transform of length N, IDFT_N its inverse, and the transforms are of the zero-padded vectors. For k identical steps, the transform of ω^{*k} is the k-th power of the transform, since each convolution multiplies by one more copy. The composed vector reaches index $k(n-1)$, so with $N \geq k(n-1)+1$,

$$\omega^{*k} = \mathrm{IDFT}_N(\mathrm{DFT}_N(m)^k). \tag{34.8}$$

If N is smaller, the result is the PLD of the total loss **modulo** Nh: mass that falls beyond the window wraps around to the other end.

34.6.3. Derivation

1. **Grid losses add as indices.** A loss $(o_a + i)h$ plus a loss $(o_b + j)h$ is $(o_a + o_b + i + j)h$. So the mass at index n of the sum collects every pair with $i + j = n$, $c_n = \sum_{i+j=n} a_i b_j$, which is the discrete convolution.
2. **The atom at $+\infty$.** The sum is finite only when both terms are finite, which has probability $(1 - a_\infty)(1 - b_\infty)$. The sum is $+\infty$ otherwise, with probability $1 - (1 - a_\infty)(1 - b_\infty) = a_\infty + b_\infty - a_\infty b_\infty$.
3. **Padding removes wraparound.** Pad a and b with zeros to length $N \geq n_a + n_b - 1$ and apply Fact 3. Since $i + j \leq n_a + n_b - 2 < N$, no index wraps, and the circular convolution is c.
4. **Powers.** Applying step 3 $k - 1$ times multiplies the transform by itself each time and gives $\mathrm{DFT}(m)^k$. The composed vector has $k(n - 1) + 1$ entries, because its largest index is k times the largest index $n - 1$, so that is the padding needed.
5. **Wraparound.** With N too small, Fact 3 still holds but indices add modulo N. Mass at total index $n \geq N$ lands at $n - N$: the total loss is reduced modulo Nh.

Repeated squaring. Taking the k-th power in one shot needs the full padded window, which is k times wider than one step. The script instead builds the power by squaring. It forms $\omega^{*2}, \omega^{*4}, \omega^{*8}, \ldots$ by convolving each with itself, and multiplies together the powers in the binary expansion of k; for $k = 10 = 8 + 2$, $\omega^{*10} = \omega^{*8} * \omega^{*2}$. After every convolution it truncates both tails at mass $\tau = 10^{-15}$, moving the mass in the safe direction of Section 34.5. The vector then grows like the spread of the composed PLD, not like the worst-case range $k(n - 1)$. The spread is the standard deviation of a sum of k independent losses, which grows like $\sqrt{k}$, and truncation at a fixed τ keeps a window of a roughly fixed number of standard deviations. Each convolution is padded to its two inputs, so nothing can wrap. In the example below, ten Gaussian steps take the vector from 15884 to 50257 bins, a ratio of $50257/15884 = 3.16$, which is $\sqrt{10}$. The script also cuts every loss below -100 or above 200 in the same safe direction, whatever its mass, because of floating-point noise (next paragraph): for a sharply peaked PLD, the noise in millions of bins can add up to more than τ, and then truncation by mass alone never trims the ends.

34.6.4. Interpretation

One FFT convolution of vectors of length N costs $O(N \log N)$. Repeated squaring needs at most $2 \log_2 k$ of them: about $\log_2 k$ squarings, and at most one multiplication for each binary digit of k.

The FFT is not exact in floating point. It computes each mass with an absolute error of order 10^{-16} times the largest mass, so tiny masses far in the tails come out as noise, sometimes negative. The script sets negative masses to zero. Summed over the two million bins of the 10,000-step PLD, this noise is many orders of magnitude below a δ of 10^{-5}, but it is not part of the certified bound. The PRV accountant of Gopi, Lee and Wutschitz (2021) also leaves it out of its error analysis, arguing that it is negligible for δ above 10^{-10}, the smallest δ its implementation accepts (their Section 6 and Appendix A).

To choose the grid, pick h from the sandwich width you can accept, which is kh (Section 34.5). Pick the range from the tails. The composed PLD has mean and variance k times those of one step, so a window of many standard deviations around the mean holds all but τ of the mass. Chebyshev's inequality, which says that a variable lands at least t away from its mean with probability at most its variance divided by t^2, bounds the mass outside a window from the variance alone. It is loose but needs nothing else (Exercise 4 in the exercise book).

Three variants of the same idea are in use. The **PRV accountant** (Gopi, Lee & Wutschitz 2021) also discretizes the privacy loss random variable and convolves with the FFT. It truncates the loss to a window chosen with tail bounds, rounds each loss to the nearest grid point, and then shifts the whole grid by one constant so that the discretized loss has the same mean as the truncated one. Rounding to the nearest point moves some losses up and some down; once the means match, the per-step errors have mean zero, so over k steps they partly cancel and their sum grows like $\sqrt{k}\,h$ instead of kh (their Lemma 5.3). That is why a mesh $h \approx 1/\sqrt{k}$ suffices instead of $h \approx 1/k$. It proves explicit error bounds on ε, and for k identical steps its running time is of order $\sqrt{k}$ up to logarithmic factors, against $k^{1.5}$ for the earlier FFT accountant of Koskela et al.

Connect the dots (Doroshenko, Ghazi, Kamath, Kumar & Manurangsi 2022) builds the pessimistic PLD on a given grid differently: from the values of $\delta(\varepsilon)$ at the grid points, interpolating the hockey-stick curve between them, instead of rounding each loss. They prove it is the best pessimistic PLD supported on that grid, and it allows much coarser grids than rounding up.

Characteristic-function accounting (Zhu, Dong & Wang 2022) skips the grid of masses and works with the Fourier transform of the PLD directly. The characteristic function $\mathbb{E}[e^{\mathrm{i}tL}]$ of a sum of independent losses is the product of the per-step ones, for the same reason as in Fact 3, and δ is recovered by numerical integration in the frequency domain. Google's `dp_accounting` library implements PLD accounting with pessimistic and optimistic rounding and connect-the-dots.

34.6.5. Example: Gaussian steps on a grid

Discretize the Gaussian PLD of $\mu = 1$, which is $\mathcal{N}(0.5, 1)$, on the grid $h = 10^{-3}$, truncated at $\tau = 10^{-15}$ per tail. It has 15884 bins. After ten steps by repeated squaring, the truncated vector has 50257 bins, while the one-shot k-th power needs a padded window of $10 \times (15884 - 1) + 1 = 158831$. Both give the same pessimistic $\delta(1) = 0.81891018$, against the exact 0.81851782 from Equation 34.4 with $\mu = \sqrt{10}$. Turning this into ε at $\delta = 10^{-5}$, Table 34.5 compares with the exact values from Section 34.4.

Table 34.5.: Composed Gaussian steps with $\mu = 1$ on the grid $h = 10^{-3}$: ε at $\delta = 10^{-5}$ from the pessimistic and optimistic PLDs against the exact value.

k	Exact ε	Pessimistic	Optimistic	Mean of the pessimistic PLD
10	17.8566	17.8616	17.8516	5.0050 (exact 5)
100	91.8173	91.8673	91.7673	50.0500 (exact 50)

The sandwich width is kh: $10 \times 10^{-3} = 0.01$ at $k = 10$ and $100 \times 10^{-3} = 0.1$ at $k = 100$. The exact value sits in the middle, $17.8616 - 17.8566 = 0.005 = kh/2$ at $k = 10$, because rounding up

moves each step's loss up by $h/2$ on average and rounding down moves it down by as much. The pessimistic means show the shift: $5 + 10 \times 0.0005$ and $50 + 100 \times 0.0005$.

Without padding, wraparound appears. Compute the tenth power on a circular window centred at the mean 5. A window of width 10, from loss 0 to 10, gives $\delta(1) = 0.83478562$, wrong in the second decimal, because losses below 0 wrap to the top of the window and losses above 10 wrap to the bottom. Width 20 gives 0.81890091, and width 40 gives 0.81891018, the padded value.

34.6.6. Check yourself

- Why does the circular window of width 10 *overestimate* $\delta(1)$? *(The two tails hold the same mass, 0.0569 each, because the window is centred on the mean: the composed PLD has standard deviation* $\sqrt{10}$*, so each tail beyond 5 from the mean has mass* $\Phi(-5/\sqrt{10}) = \Phi(-1.581) = 0.0569$*. Negative totals, which count nothing towards* $\delta(1)$*, wrap to just below 10, where they count almost fully. Totals above 10 wrap to between 0 and 10. Those that land below* $\varepsilon = 1$ *lose their weight, but about half of them (a share of 0.51) land above 1 and keep part of it. So the window gains more than it loses. In general the sign of the wraparound error is unknown, so it cannot be part of a certified bound.)*
- You double k. How much longer does one squaring step take, roughly? *(The composed PLD's spread grows like* $\sqrt{k}$*, so the vectors grow by about* $\sqrt{2}$ *and the FFT cost by a bit more than that, because of the* $\ln N$ *factor.)*

34.7. The subsampled Gaussian

34.7.1. Context

One DP-SGD step with Poisson sampling at rate q and noise multiplier σ includes each record independently with probability q, sums the clipped gradients of the sampled records, and adds Gaussian noise. Look at it from the point of view of one record, the one that may or may not be in the dataset. Without it, the noisy sum (in the worst-case direction, scaled by the clipping norm) is a Gaussian centred at 0. With it, the record is sampled with probability q and then shifts the centre by 1, the sensitivity; otherwise it changes nothing. So the output is a mixture: centred at 1 with probability q, at 0 with probability $1 - q$. Amplification by subsampling derives this reduction and computes its RDP. Here you need its PLD, in closed form, so that the discretization can be exact up to rounding.

34.7.2. Statement

Under the add/remove relation, neighbouring datasets differ by removing one record or by adding one, and each direction gives its own pair. Write $D' = D \cup \{x\}$ for the dataset that holds the record, as in the rest of the part; a guarantee must cover both orders of the pair. The **remove** direction puts the dataset with the record first, $P = M(D')$ and $Q = M(D)$, so P is the mixture and Q the plain Gaussian; its neighbour is obtained by removing x. The **add** direction is the

order $P = M(D)$, $Q = M(D')$, and the roles swap. The two pairs that matter are (Zhu, Dong & Wang 2022, Theorem 11 and the paragraph after it; Section L.2 in the appendices derives both)

$$\text{remove: } P = (1-q)\,\mathcal{N}(0,\sigma^2) + q\,\mathcal{N}(1,\sigma^2),\quad Q = \mathcal{N}(0,\sigma^2); \qquad \text{add: } P = \mathcal{N}(0,\sigma^2),\quad Q = (1-q)\,\mathcal{N}(0,\sigma^2) + q\,\mathcal{N} \tag{34.9}$$

Each dominates one direction of neighbouring datasets (Theorem 11 states the remove pair with the mixture component at 0 and the base at 1; the reflection $y \mapsto 1-y$ turns it into the form above and changes no divergence), and the T-step guarantee is the larger of the two δ curves, each composed T times.

The privacy loss of the remove pair is the log of the mixture density over the base density. The mixture over the base is $(1-q)$ plus q times the ratio of the shifted Gaussian to the base, and that ratio is an exponential in y, as in the Gaussian PLD of Section 34.3. The add pair is the remove pair with P and Q swapped, which flips the sign of the log-ratio. So

$$L_{\text{rem}}(y) = \ln\Big((1-q) + q\,e^{(2y-1)/(2\sigma^2)}\Big), \qquad L_{\text{add}}(y) = -L_{\text{rem}}(y), \tag{34.10}$$

with $Y \sim P$ of the respective pair. L_{rem} is increasing in y, ranges over $(\ln(1-q), \infty)$, and so can be inverted: the output that produces loss ℓ is

$$y(\ell) = \sigma^2 \ln\frac{e^\ell - 1 + q}{q} + \frac{1}{2}. \tag{34.11}$$

Because the loss is increasing in the output, a bin of losses is an interval of outputs, and its mass is the probability of that interval under the mixture, a weighted difference of normal distribution functions:

$$P[L_{\text{rem}} \in (a,b]] = (1-q)\Big[\Phi\Big(\tfrac{y(b)}{\sigma}\Big) - \Phi\Big(\tfrac{y(a)}{\sigma}\Big)\Big] + q\Big[\Phi\Big(\tfrac{y(b)-1}{\sigma}\Big) - \Phi\Big(\tfrac{y(a)-1}{\sigma}\Big)\Big], \tag{34.12}$$

and $\Pr_P[L_{\text{add}} \in (a,b]] = \Phi(y(-a)/\sigma) - \Phi(y(-b)/\sigma)$ with $Y \sim \mathcal{N}(0,\sigma^2)$.

34.7.3. Derivation

1. **Divide the mixture by the base.** Write φ for the standard normal density, so that $\mathcal{N}(c,\sigma^2)$ has density proportional to $\varphi((y-c)/\sigma)$ with the same constant for both centres. Dividing each part of the mixture by the base gives $\frac{(1-q)\varphi(y/\sigma)+q\varphi((y-1)/\sigma)}{\varphi(y/\sigma)} = (1-q) + q\,\frac{\varphi((y-1)/\sigma)}{\varphi(y/\sigma)}$.
2. **Compute the ratio of two Gaussians.** The densities are exponentials of minus a square, so their ratio is the exponential of the difference of the squares: $\frac{\varphi((y-1)/\sigma)}{\varphi(y/\sigma)} = \exp\big(\frac{y^2-(y-1)^2}{2\sigma^2}\big) = e^{(2y-1)/(2\sigma^2)}$. Taking logs of step 1 gives L_{rem}. Swapping P and Q flips the sign of the log-ratio, which gives L_{add}.
3. **The loss is increasing.** $e^{(2y-1)/(2\sigma^2)}$ is increasing in y and positive, so L_{rem} is increasing. As $y \to -\infty$ the exponential vanishes and the loss tends to $\ln(1-q)$; as $y \to \infty$ it tends to ∞.
4. **Invert it.** Solve $e^\ell = (1-q) + q\,e^{(2y-1)/(2\sigma^2)}$ for y: subtract $1-q$, divide by q, take logs, multiply by σ^2 and add $\frac{1}{2}$.

5. **Turn loss bins into output intervals.** Because the map is increasing, $\{L_{\text{rem}} \in (a, b]\} = \{Y \in (y(a), y(b)]\}$. Its probability under the mixture is $1 - q$ times the probability under $\mathcal{N}(0, \sigma^2)$ plus q times that under $\mathcal{N}(1, \sigma^2)$, which is the stated sum. For the add pair, $L_{\text{add}} \in (a, b]$ exactly when $L_{\text{rem}} \in [-b, -a)$, that is, exactly when $Y \in [y(-b), y(-a))$, with $Y \sim \mathcal{N}(0, \sigma^2)$. Where $-b \le \ln(1 - q)$, no output has that loss, and $y(-b) = -\infty$.
6. **Single-step δ in closed form, as a check.** For the remove pair, $L > \varepsilon$ exactly when $Y > y(\varepsilon)$, so by Equation 34.3, $\delta(\varepsilon) = \Pr_P[Y > y(\varepsilon)] - e^{\varepsilon} \Pr_Q[Y > y(\varepsilon)]$, two normal tail probabilities. The add pair is the same with $Y < y(-\varepsilon)$.
7. **Why two directions.** Under add/remove, the neighbour of a dataset can be that dataset with one record removed or with one added, so both orders of the pair, $(M(D'), M(D))$ and $(M(D), M(D'))$, must be covered. The two cases give different pairs, and neither one's PLD is a rounding of the other, so bounding one does not bound the other. Zhu, Dong & Wang (2022) prove each pair dominates its case, and Section L.2 in the appendices derives it step by step from two exact hockey-stick identities. A T-step run's guarantee is $\max\{\delta_{\text{rem},T}(\varepsilon), \delta_{\text{add},T}(\varepsilon)\}$, and the corresponding ε is the larger of the two values of ε.

The script computes the bin masses in step 5 from whichever of Φ and $1 - \Phi$ is smaller, so masses deep in either tail keep their relative precision.

34.7.4. Interpretation

The two directions have very different losses (Figure 34.3). The remove loss is bounded below by $\ln(1 - q)$ and has an unbounded upper tail: a rare large output betrays that the record was used. The add loss is its mirror image, bounded above by $-\ln(1 - q)$. Since δ only counts losses above ε, a single add step has $\delta(\varepsilon) = 0$ once $\varepsilon \ge -\ln(1 - q)$.

Which direction dominates? In the running example the remove direction gives the larger ε at every T in Table 34.7: the add direction's upper bound is only 0.0091 at $T = 1$ and 5.6615 at $T = 10{,}000$. That is an observation, not a theorem; the accountant computes both and takes the larger, as `pld_epsilon_subsampled_gaussian` does. The remove pair alone is not enough in general: Zhu, Dong & Wang (2022) point out that PLD accountants that use only the remove pair cover only the "remove" half of the add/remove relation.

34.7.5. Example: one DP-SGD step

For $q = 0.01$ and $\sigma = 1$, the lowest possible remove loss is $\ln(0.99) = -0.0101$. The remove loss is in $[-0.0101, 3.2858]$ except for 10^{-15} of mass, and the add loss is in $[-2.8926, 0.0101]$. On the grid $h = 10^{-5}$, that is 329590 and 290268 bins; for the remove direction, $3.2858 - (-0.0101) = 3.2959$ divided by 10^{-5}. The rounded-up remove PLD has $\mathbb{E}[e^{-L}] = 0.999995$, below 1 and so a valid PLD, as derivation step 5 of Section 34.5 requires. Table 34.6 compares the pessimistic PLD's δ with the closed form of step 6.

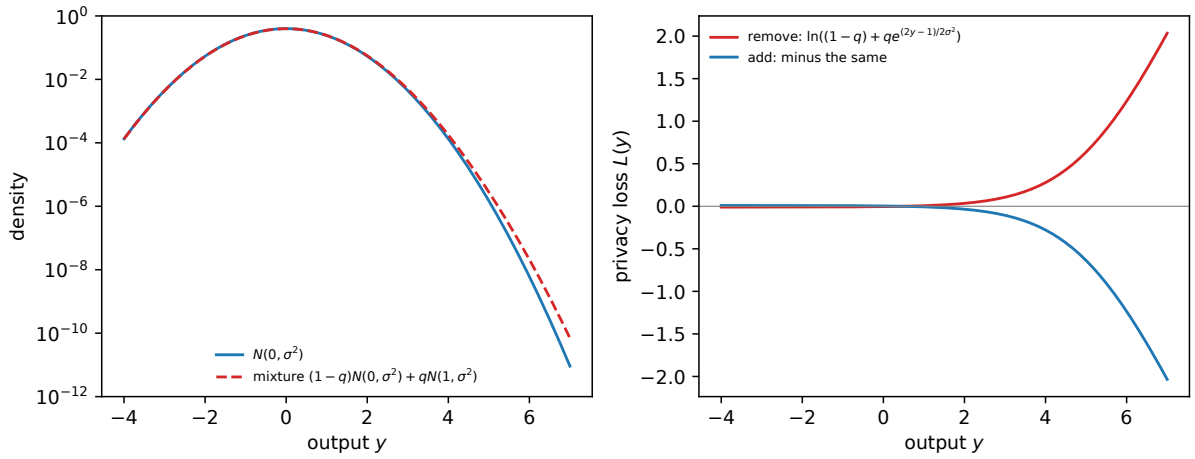

Figure 34.3.: Left: the densities of $\mathcal{N}(0, \sigma^2)$ and of the mixture $(1-q)\mathcal{N}(0, \sigma^2) + q\mathcal{N}(1, \sigma^2)$ for $q = 0.01$, $\sigma = 1$, on a log scale. They differ only in the far right tail. Right: the privacy loss as a function of the output for the remove pair (red) and the add pair (blue). Both are nearly flat near zero and steep in the right tail.

Table 34.6.: One subsampled-Gaussian step ($q = 0.01$, $\sigma = 1$): $\delta(\varepsilon)$ in closed form and from the pessimistic PLD on the grid $h = 10^{-5}$.

ε	Remove: exact δ	Remove: pessimistic	Add: exact δ	Add: pessimistic
0	3.829249e-03	3.830792e-03	3.829249e-03	3.832688e-03
0.5	2.214519e-07	2.214633e-07	0	0
1	2.732009e-09	2.732117e-09	0	0

The pessimistic values are slightly above the exact ones, as they must be. At $\varepsilon = 0$ both directions have the same δ, and the reason is a symmetry. At $\varepsilon = 0$, δ is $\sum_y (P(y) - Q(y))_+$, the total variation distance. Since P and Q both sum to 1, the total amount by which P exceeds Q equals the total amount by which Q exceeds P, so the value does not change when the two are swapped, and the add pair is the remove pair swapped. Beyond $\varepsilon = 0.0101$ the add direction's δ is 0, as the Interpretation explains. At $\delta = 10^{-5}$, one step has $\varepsilon = 0.1995$ in the remove direction and 0.0091 in the add direction (exact, by bisection on the closed form).

34.7.6. Check yourself

- What is $\delta(\varepsilon)$ of one add step at $\varepsilon = 0.02$? *(Zero, since the add loss never exceeds* $-\ln(0.99) = 0.0101$*, and* δ *only counts losses above* ε*.)*
- Why is the closed-form δ of one step not enough for T steps? *(The composed PLD is a* T*-fold convolution of a non-Gaussian distribution, which has no closed form. Only the per-step PLD is explicit.)*

34.8. The running example: DP-SGD

34.8.1. Context

The question from the start of the chapter: DP-SGD with $q = 0.01$, $\sigma = 1$, at $\delta = 10^{-5}$, after T steps. Every other chapter of this part gives its own number for the same run. This section gives the PLD bounds and compares them with two accountants from earlier chapters.

34.8.2. Statement

Putting the pieces together, discretize each direction's subsampled-Gaussian PLD up and down, compose it T times by FFT, and read off ε; the true value lies between the optimistic and the pessimistic answer. On the grid $h = 10^{-5}$ with tails truncated at 10^{-15}, Table 34.7 gives ε from the pessimistic PLD (an upper bound, valid for adaptive composition) and the optimistic PLD (a lower bound for the non-adaptive run), each the larger over the two directions. It compares them with the RDP accountant with the improved conversion and with the GDP central-limit approximation.

Table 34.7.: DP-SGD with $q = 0.01$, $\sigma = 1$: ε at $\delta = 10^{-5}$ after T steps, from the pessimistic and optimistic PLDs on the grid $h = 10^{-5}$ (the larger of the two directions; the width is their difference, Th), the pessimistic PLD of the add direction alone, the RDP accountant, and the GDP central-limit approximation.

T	PLD upper	PLD lower	Width	Add direction, upper	RDP	GDP CLT
1	0.1995	0.1994	1.0e-05	0.0091	0.9555	0.0368
10	0.3800	0.3799	1.0e-04	0.0655	1.0353	0.1304
100	0.7185	0.7175	1.0e-03	0.3387	1.2141	0.4575
1000	1.8332	1.8232	1.0e-02	1.4217	2.1014	1.6177
10000	6.2377	6.1377	1.0e-01	5.6615	6.7127	6.0071

34.8.3. Derivation

1. **PLD columns.** Discretize each direction's PLD (Section 34.7) up and down, compose T times by FFT (Section 34.6), and solve $\delta(\varepsilon) = 10^{-5}$ on each result. The solve can be exact. For ε between two grid points, the set of grid losses above ε does not change, so by Equation 34.3 $\delta(\varepsilon) = m_\infty + A - e^\varepsilon B$, where m_∞ is the atom at $+\infty$, A the total mass of the grid points above ε, and B the sum of those masses times $e^{-\ell}$. Setting this equal to 10^{-5} and solving for e^ε gives the root directly. Take the larger ε of the two directions.
2. **RDP column.** RDP tracks, for each order $\alpha > 1$, the Rényi divergence $\frac{1}{\alpha-1} \ln \mathbb{E}_Q[(P/Q)^\alpha]$, a log-moment of the likelihood ratio; these divergences add up over composed steps, and a conversion turns the total into (ε, δ). As in Amplification by subsampling, for the remove pair the moment is $A_\alpha = \mathbb{E}_{y\sim\mathcal{N}(0,\sigma^2)}\big[\big((1-q) + q\, e^{(2y-1)/(2\sigma^2)}\big)^\alpha\big]$, the likelihood ratio of step 1 of Section 34.7 raised to the power α and averaged under the base $Q = \mathcal{N}(0, \sigma^2)$.

The RDP of one step at order α is $\frac{1}{\alpha-1}\ln A_\alpha$. For integer α, expanding the power with the binomial theorem and using $\mathbb{E}_Q[e^{j(2y-1)/(2\sigma^2)}] = e^{(j^2-j)/(2\sigma^2)}$ (the Gaussian moment generating function at j/σ^2) gives $A_\alpha = \sum_{j=0}^{\alpha}\binom{\alpha}{j}(1-q)^{\alpha-j}q^j e^{(j^2-j)/(2\sigma^2)}$. For fractional α the script computes the expectation by numerical integration. Multiply by T, convert with $\varepsilon = \varepsilon(\alpha)+\ln\frac{\alpha-1}{\alpha}-\frac{\ln\delta+\ln\alpha}{\alpha-1}$ (From Rényi DP to (ε, δ) and to tests), where $\varepsilon(\alpha)$ is the composed RDP at order α, and minimize over the part's grid of orders. As a check, integration and the binomial sum agree at $\alpha = 2$ ($\ln A_2 = 0.00017181$) and $\alpha = 10$ ($\ln A_{10} = 0.34443377$).

3. **CLT column.** The GDP central limit theorem replaces the T composed steps by one Gaussian pair with shift $\mu = q\sqrt{T(e^{1/\sigma^2}-1)}$ (f-DP and Gaussian DP). One way to see where the formula comes from: one Gaussian step with shift 1 has χ^2-divergence $e^{1/\sigma^2}-1$ (the average squared deviation of the likelihood ratio from 1), subsampling at rate q scales the ratio's deviation from 1 by q and so this divergence by q^2, and for Gaussians μ^2 adds over composed steps, which gives the factor T. Then ε comes from Equation 34.4. At $T = 10{,}000$, $\mu = 0.01\times\sqrt{10^4\times(e-1)} = 0.01\times 100\times 1.3108 = 1.3108$.

34.8.4. Interpretation

The PLD pins down the truth (Figure 34.4). At $T = 1000$ the true ε is between 1.8232 and 1.8332. At $T = 10{,}000$ the bracket is $[6.1377, 6.2377]$, wider because the width is Th.

RDP is a valid bound, but loose. It exceeds the PLD upper bound by $0.9555-0.1995 = 0.7560$ at $T = 1$, $2.1014-1.8332 = 0.2682$ at $T = 1000$ and $6.7127-6.2377 = 0.4750$ at $T = 10{,}000$. The single step shows why most clearly: it gives 0.9555 against 0.1995, because the conversion from RDP pays a term of about $\frac{\ln(1/\delta)}{\alpha-1}$ whatever the curve, the price of turning one moment of the loss into a tail bound.

The CLT is not a bound, and here it is too optimistic. It falls below the PLD *lower* bound at every T, by $1.8232-1.6177 = 0.2055$ at $T = 1000$ and $6.1377-6.0071 = 0.1306$ at $T = 10{,}000$. The subsampled PLD has a heavy right tail (Figure 34.5), and at $\delta = 10^{-5}$ you are reading exactly that tail, where the Gaussian approximation is worst. Reporting the CLT number would understate the privacy loss.

Pick h for the largest T you will run. The width is Th, and $h = 10^{-5}$ makes it $10^4\times 10^{-5} = 0.1$ at $T = 10{,}000$. Each tenfold refinement of h makes the vectors ten times longer, because the same range of losses is cut into ten times as many bins: after 1000 steps the pessimistic remove PLD has 7687, 76894 and 767721 bins for $h = 10^{-3}$, 10^{-4} and 10^{-5}. Time and memory grow at least as fast.

34.8.5. Example: sandwich width against grid size

The sandwich width should be Th, so at a fixed T it should shrink tenfold with each tenfold finer grid. Table 34.8 repeats $T = 1000$ on three grids.

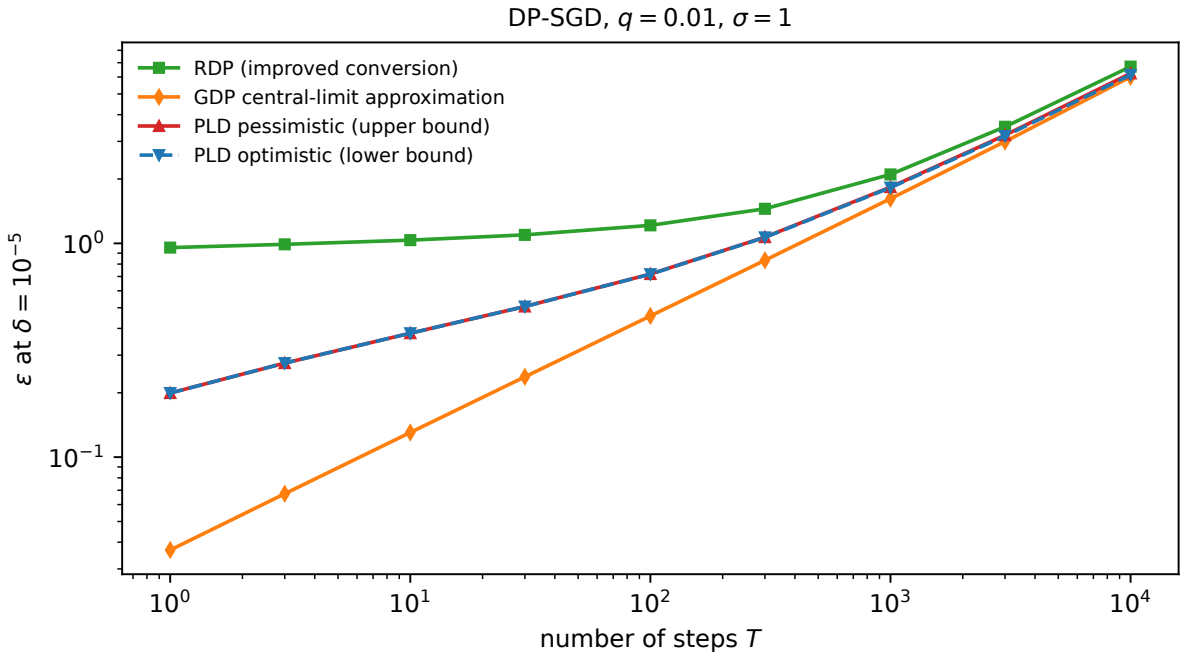

Figure 34.4.: ε at $\delta = 10^{-5}$ against the number of steps T for DP-SGD with $q = 0.01$, $\sigma = 1$: the RDP accountant (green), the GDP central-limit approximation (orange), and the pessimistic (red) and optimistic (blue) PLD bounds on the grid $h = 10^{-5}$. The two PLD curves overlap at this scale; RDP lies above them and the CLT below them.

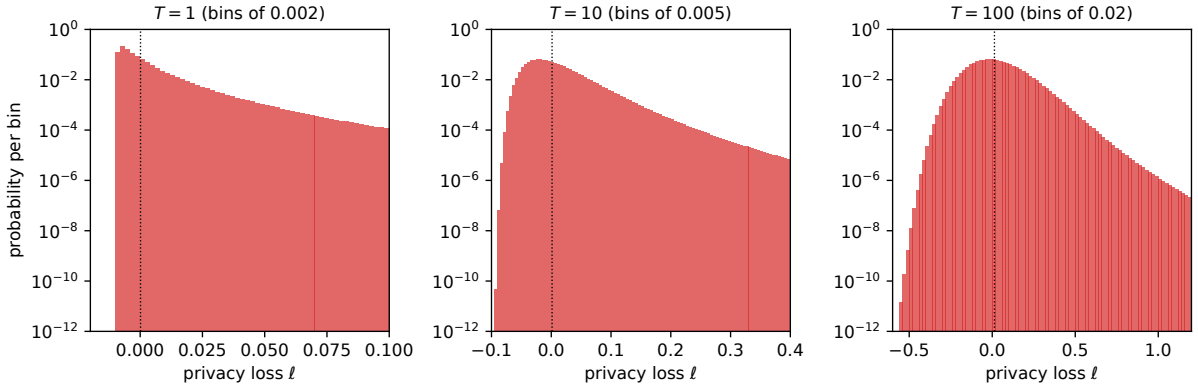

Figure 34.5.: The pessimistic remove-direction PLD of DP-SGD with $q = 0.01$, $\sigma = 1$ after 1, 10 and 100 steps (grid $h = 10^{-4}$, re-binned for display; log scale). The dotted line is the mean. One step piles its mass just above its lower limit $\ln(1 - q) = -0.0101$ and has a long right tail; convolution moves the bulk towards a bell shape, but the right tail stays heavier than the left.

Table 34.8.: DP-SGD after $T = 1000$ steps: the PLD bounds on ε at $\delta = 10^{-5}$ for three grid widths.

h	Upper	Lower	Width	Th
10^{-3}	2.3279	1.3279	1.0000	1.0000
10^{-4}	1.8782	1.7782	0.1000	0.1000
10^{-5}	1.8332	1.8232	0.0100	0.0100

The width equals Th to four decimals, as derivation step 7 of Section 34.5 predicts. On the coarsest grid the upper bound 2.3279 is worse than RDP's 2.1014. A PLD accountant is only as good as its grid.

34.8.6. Check yourself

- A colleague reports $\varepsilon = 1.62$ for 1000 steps from the CLT. What do you tell them? *(That is below the PLD lower bound 1.8232, so the run is not* $(1.62, 10^{-5})$*-DP. The CLT is an approximation and underestimates here.)*
- You need the upper bound at $T = 10{,}000$ within 0.01 of the truth. What grid do you need? *(A width of at most 0.01 needs* $Th \leq 0.01$*, so* $h \leq 0.01/10^4 = 10^{-6}$*, ten times finer than the script's grid.)*

34.9. Code

The script code/numerical_accounting.py implements the whole accountant in NumPy: the PLD dataclass, pessimistic and optimistic discretization, FFT convolution with padding and truncation, repeated squaring, the exact solve for ε, the subsampled-Gaussian PLD in both directions, and, for comparison, the RDP accountant and the CLT. The public functions are `gaussian_pld_delta`, `discretize_subsampled_gaussian_pld`, `compose_pld`, `pld_delta`, `pld_epsilon` and `pld_epsilon_subsampled_gaussian`. From the repository root:

```
uv run python code/part04-privacy-accounting/numerical_accounting.py
```

It takes from half a minute to a few minutes, depending on the machine. Nearly all of that is the four $T = 10{,}000$ compositions on the grid $h = 10^{-5}$. **Output** (seed 0), summarized in Table 34.9:

Table 34.9.: The script's output with the default seed.

Experiment	Result
Gaussian PLD, $\mu = 1$	Monte Carlo mean 0.4990, variance 1.0013, $\mathbb{E}[e^{-L}]$ 1.0015; $\delta(\varepsilon)$ in Table 34.2; $\varepsilon = 4.3772$ at $\delta = 10^{-5}$
Finite pair, $\varepsilon = 0.5$	Both forms of Equation 34.3 give 0.2351

Experiment	Result
Randomized response, three steps, $h = 0.5$	Table 34.3 and Table 34.4; $\mathbb{E}[e^{-L}]$ 0.8469 (up), 1.3963 (down)
Gaussian steps on $h = 10^{-3}$	Table 34.5; squaring and one-shot power agree, $\delta(1) = 0.81891018$
Wraparound, $k = 10$	Window 10: 0.83478562; window 20: 0.81890091; window 40: 0.81891018
One subsampled step	Table 34.6; exact ε 0.1995 (remove) and 0.0091 (add)
RDP check	$\ln A_2 = 0.00017181$ and $\ln A_{10} = 0.34443377$ by both methods
DP-SGD	Table 34.7 and Table 34.8

tests/test_numerical_accounting.py checks that the output still matches.

What to take from it. First, the pieces are right: the Gaussian PLD reproduces the closed form, the FFT squaring reproduces the one-shot power to eight digits, and the subsampled discretization brackets the closed-form single-step δ. Because each piece is checked against something exact, you can trust the composed numbers where nothing exact exists. Second, the sandwich is certified and its width is at most kh: nothing else in the accountant introduces a one-sided error you cannot see, so the two PLD columns of Table 34.7 are an honest error bar. Third, RDP is safe but loose, and the CLT is neither safe nor, here, accurate in the tail. The gap between them and the PLD bounds is what a loose accountant costs you.

34.11. Cheat sheet

$L(y) = \ln \frac{P(y)}{Q(y)}$; the PLD ω is the law of $L(Y)$ with $Y \sim P$; q is the sampling rate; h the grid width; k the number of composed steps (T for a DP-SGD run). Table 34.10 collects the results.

Table 34.10.: The results of this chapter.

Result	Formula	Note
δ from the PLD	$\delta(\varepsilon) = \mathbb{E}_\omega[(1 - e^{\varepsilon - L})_+] = \Pr_P[L > \varepsilon] - e^\varepsilon \Pr_Q[L > \varepsilon]$	Atom at $+\infty$ counts fully
Law under Q	$e^{-\ell}\omega(\mathrm{d}\ell)$, rest at $-\infty$	A PLD needs $\mathbb{E}_\omega[e^{-L}] \le 1$
Gaussian PLD	$\mathcal{N}(\mu^2/2, \mu^2)$; $\delta = \Phi(\frac{\mu}{2} - \frac{\varepsilon}{\mu}) - e^\varepsilon \Phi(-\frac{\mu}{2} - \frac{\varepsilon}{\mu})$	k steps: $\mu \to \sqrt{k}\mu$
Composition	$\omega_1 * \cdots * \omega_k$	Adaptive: convolve dominating pairs
Pessimistic / optimistic	Round losses up (tail to $+\infty$) / down (bottom tail dropped)	$\delta^\downarrow \le \delta \le \delta^\uparrow$ for every k
Sandwich width	$\varepsilon^\uparrow - \varepsilon^\downarrow \le kh$	Equality for continuous PLDs without truncation
FFT	$\mathrm{IDFT}(\mathrm{DFT}(a)\,\mathrm{DFT}(b))$, pad to $n_a + n_b - 1$	Too short a window wraps losses modulo Nh
Subsampled Gaussian loss	$\pm \ln\left((1-q) + qe^{(2y-1)/(2\sigma^2)}\right)$	Remove: $+$, $Y \sim$ mixture; add: $-$, $Y \sim \mathcal{N}(0, \sigma^2)$; take the max

Rules of thumb

- Report the pessimistic ε, and the optimistic one next to it as the error bar.
- Choose h so that kh is the error you can accept; check the sandwich width rather than trusting the grid.

- Compute both directions of add/remove for subsampled mechanisms; do not assume one dominates.
- Pad or truncate; never let an FFT wrap around silently.
- Use RDP and the CLT as quick estimates. RDP over-reports; the CLT can under-report in the tail that $\delta = 10^{-5}$ looks at.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

35. Amplification by shuffling and by iteration

35.1. Why this matters

Amplification by subsampling showed that uncertainty is worth privacy. If an adversary cannot tell **whether** your record was used in a step, the step costs far less than its noise alone suggests: a step that touches your record only with probability q leaks roughly q times as much. That is not the only uncertainty an algorithm can create. Two others matter in practice, and each has its own accountant.

The first is uncertainty about **which report is yours**. In the shuffle model, n users each randomize their own data on their own device and send the noisy report through a shuffler, a trusted component that strips identities and mixes the order. The analyst sees a bag of n anonymous reports. Each report on its own satisfies local differential privacy (DP) with some level ε_0: whoever sees that one report, even the collector, learns little about its sender, and the smaller ε_0, the less. To keep the reports useful, ε_0 is usually large, which makes this a weak guarantee. But the analyst does not know which report in the bag is yours, so your report hides among the others. The result is central DP, the guarantee about everything the analyst sees, with an ε that falls like $1/\sqrt{n}$. This is shuffling of anonymous, locally randomized reports. It is not the shuffle-and-partition batching used to train a model privately in the central model, where each record is used in exactly one batch per epoch and the shuffle only hides which one: Amplification by subsampling shows that no comparable amplification theorem covers that case, and that the Poisson number is wrong for it.

The second is uncertainty about **when your record was used**. Noisy gradient descent (GD) on a convex loss forgets. Each later step adds fresh noise and pulls nearby parameters together, so the effect of your record on the final model is washed out step by step. If only the final model is released, a record used early in training is much better hidden than the composition accounting of Rényi DP says, because composition charges every step as if the adversary had seen every intermediate model. For some problems, the privacy loss stops growing with the number of steps.

35.1.1. The one idea: the adversary's view is a post-processing of something simpler

Every result in this chapter has the same shape. You show that what the adversary sees can be **generated from a much simpler pair of distributions** by a procedure that does not depend on your record. Anything the adversary can learn from the real output, it could then have learned from the simple pair, by running that procedure itself. This is the data-processing inequality, and it means the simple pair's privacy holds for the real output. For shuffling, the simple pair is a pair of **counts**: how many reports look like each of your two possible values. For iteration, it is a pair of **Gaussians**, or a pair of distributions that a short chain of noisy steps keeps close. The work is

in finding the simple pair and computing how far apart its two distributions are. Table 35.1 lists the results.

Table 35.1.: The results of this chapter and where each is used.

Result	Where it is used
Exact $\delta(\varepsilon)$ of shuffled binary randomized response	Ground truth for any shuffling bound; deploying randomized-response surveys
The clone reduction and bound of Feldman, McMillan & Talwar	Central guarantees for any local randomizer behind a shuffler
Shifted Rényi divergence, shift reduction, contraction	Privacy of the last iterate of contractive noisy iterations
Amplification by iteration for one-pass noisy gradient descent	Per-record guarantees that depend on when the record was used
Hidden-state bounds that plateau	Convex training run for many epochs, releasing only the final model
Exact last-iterate privacy of noisy GD on a quadratic	A worked case in which every quantity is in closed form

How to read this chapter. The first two sections are about shuffling and the last three about iteration; the two halves are independent. In each half, read the exact computation first (shuffled randomized response; the quadratic loss), because it shows what the general bounds approximate. The derivations of the shift-reduction lemma and of the bounded-domain bound can wait for a second pass.

What you need. The Toolkit below restates every outside fact the derivations use, with a short reason for each, so you can read this chapter on its own. For more detail: the hockey-stick divergence E_γ, the Rényi divergence D_α and the data-processing inequality are in Divergences. The non-expansiveness of a gradient step is Fact 4 of Stability and generalization, and projection onto a convex set is Fact 3 of Optimization. Randomized response is in the definition of differential privacy, and the shuffle model in Trust models. Rényi differential privacy (RDP) and its composition are in Rényi DP, and its conversion to (ε, δ) in From RDP to (ε, δ). Gaussian differential privacy (GDP) is in f-DP and Gaussian DP.

Conventions. Throughout this chapter the neighbouring relation is replace-one: D and D' have the same size and differ in the value of one record, yours. Both shuffling theorems and both iteration theorems below are stated for it. P and Q are the distributions of the adversary's view on D and on D'. A mechanism is (ε, δ)-DP when $P(S) \le e^\varepsilon Q(S) + \delta$ and $Q(S) \le e^\varepsilon P(S) + \delta$ for every set S of outputs: no event becomes more than e^ε times likelier when your record changes, up to a small slack δ. In the iteration sections, some symbols differ from the part's notation table. σ is the noise standard deviation in parameter units, and $\tilde{\sigma}$ the noise multiplier. The parameters are θ and the loss of a record is ℓ. G is the Lipschitz constant of the loss (not L, which stays the privacy loss) and β its smoothness constant. d_K is the diameter of the convex set K that the parameters live in, so that D always means a dataset.

35.2. Toolkit: three facts every derivation uses

35.2.1. Fact 1 — $\delta(\varepsilon)$ of a discrete pair is a sorted tail sum

For a fixed ε, the smallest δ that makes $P(S) \le e^{\varepsilon}Q(S) + \delta$ true for every set S is the largest gap $P(S) - e^{\varepsilon}Q(S)$ over all sets. That largest gap is the **hockey-stick divergence** $E_{e^{\varepsilon}}(P\|Q)$. To find it, look at what each outcome y contributes to the gap: $P(y) - e^{\varepsilon}Q(y)$. This is positive exactly when $P(y)/Q(y) > e^{\varepsilon}$, that is, when the **privacy loss** $L(y) = \ln \frac{P(y)}{Q(y)}$, the log of how much likelier y is under D than under D', exceeds ε. So the best set collects every outcome with $L(y) > \varepsilon$ and nothing else, and for distributions P, Q on a finite set

$$\delta(\varepsilon) = E_{e^{\varepsilon}}(P\|Q) = \sum_{y:\, L(y)>\varepsilon} (P(y) - e^{\varepsilon}Q(y)). \tag{35.1}$$

This form makes the computation cheap. Sort the outcomes by $L(y)$ once and keep running sums of P and Q from the top. Then $\delta(\varepsilon)$ for any ε is one lookup: find where L drops below ε and read off the two running sums. The ε for a target δ is a bisection over these lookups. The script works this way, and builds the binomial probabilities in log space so that values of 10^{-300} cause no trouble.

The definition of (ε, δ)-DP has two directions, because the adversary may try to tell D from D' or D' from D. It needs $E_{e^{\varepsilon}}(P\|Q) \le \delta$ and $E_{e^{\varepsilon}}(Q\|P) \le \delta$, so the exact $\delta(\varepsilon)$ of a pair is the larger of the two sums.

35.2.2. Fact 2 — Post-processing a simpler pair

Suppose there is a randomized map f, the same for both datasets, that turns a sample of $\tilde{P}$ into a sample of P and a sample of $\tilde{Q}$ into a sample of Q; write $P = f(\tilde{P})$ and $Q = f(\tilde{Q})$. Then the real pair can be no further apart than the simple one: every divergence of (P, Q) is at most that of $(\tilde{P}, \tilde{Q})$,

$$E_{\gamma}(P\|Q) \le E_{\gamma}(\tilde{P}\|\tilde{Q}) \qquad \text{and} \qquad D_{\alpha}(P\|Q) \le D_{\alpha}(\tilde{P}\|\tilde{Q}). \tag{35.2}$$

This is the **data-processing inequality**. The reason, for E_{γ}, is that a test on the output can be pulled back to a test on the input. Take any set S of outputs, and let $g(u) = \Pr[f(u) \in S]$, a number between 0 and 1 for each input u. Then $P(S) - \gamma Q(S) = \mathbb{E}_{\tilde{P}}[g] - \gamma\, \mathbb{E}_{\tilde{Q}}[g]$. The right side is a sum of $g(u)(\tilde{P}(u) - \gamma\tilde{Q}(u))$ over u, and it is largest when $g = 1$ wherever the bracket is positive and $g = 0$ elsewhere, which gives exactly $E_{\gamma}(\tilde{P}\|\tilde{Q})$. The Rényi divergence D_{α}, defined in Fact 3, satisfies the same inequality, by Jensen's inequality applied to the convex function $t \mapsto t^{\alpha}$ inside its sum (Divergences proves it).

In this chapter the shuffled view will be a post-processing of counts, and the final model a post-processing of a coupled pair of noisy iterates.

35.2.3. Fact 3 — Gaussian pairs

Gaussian pairs come up in both halves of the chapter, so it pays to know everything about them once. Suppose that on D the adversary sees $Y \sim \mathcal{N}(m, v)$ and on D' it sees $Y \sim \mathcal{N}(m', v)$: the same spread, a shifted centre. Subtracting m and dividing by $\sqrt{v}$ is an invertible map that is the same for both datasets, so by Fact 2 applied in both directions it changes no divergence. It turns the pair into $\mathcal{N}(0,1)$ against $\mathcal{N}(\mu, 1)$ with

$$\mu = \frac{|m - m'|}{\sqrt{v}}, \tag{35.3}$$

the shift measured in standard deviations. A pair like this is **μ-GDP**: exactly as hard to tell apart as two unit-variance normals μ apart. Everything else follows from the privacy loss of $\mathcal{N}(0,1)$ against $\mathcal{N}(\mu,1)$, which is the difference of the two log densities, $L(y) = \frac{(y-\mu)^2 - y^2}{2} = \frac{\mu^2}{2} - \mu y$. It is linear in y, so it is normal: when $y \sim \mathcal{N}(0,1)$ it has mean $\mu^2/2$ and variance μ^2, and when $y \sim \mathcal{N}(\mu,1)$ it has mean $-\mu^2/2$ and the same variance.

The $\delta(\varepsilon)$ curve comes from the continuous form of Fact 1, $\delta(\varepsilon) = \Pr_P[L > \varepsilon] - e^{\varepsilon} \Pr_Q[L > \varepsilon]$. Write Φ for the standard normal cumulative distribution function, $\Phi(x) = \Pr[\mathcal{N}(0,1) \le x]$. Under P, $L > \varepsilon$ means a $\mathcal{N}(\mu^2/2, \mu^2)$ variable exceeds ε, which has probability $\Phi((\mu^2/2 - \varepsilon)/\mu)$; under Q the mean is $-\mu^2/2$. So $\delta(\varepsilon) = \Phi(-\frac{\varepsilon}{\mu} + \frac{\mu}{2}) - e^{\varepsilon}\Phi(-\frac{\varepsilon}{\mu} - \frac{\mu}{2})$.

The RDP curve needs one more definition. The **Rényi divergence of order** $\alpha > 1$ measures how far apart two distributions are by a moment of the likelihood ratio: $D_\alpha(P\|Q) = \frac{1}{\alpha-1} \ln \mathbb{E}_Q[(P/Q)^\alpha] = \frac{1}{\alpha-1} \ln \mathbb{E}_P[e^{(\alpha-1)L}]$. A mechanism whose pair has $D_\alpha \le \varepsilon(\alpha)$ for all neighbours is $(\alpha, \varepsilon(\alpha))$-RDP. For a normal L with mean $\mu^2/2$ and variance μ^2, $\mathbb{E}[e^{(\alpha-1)L}] = \exp\left((\alpha-1)\frac{\mu^2}{2} + (\alpha-1)^2\frac{\mu^2}{2}\right) = \exp\left(\alpha(\alpha-1)\frac{\mu^2}{2}\right)$, using the fact that a normal variable X has $\mathbb{E}[e^{(\alpha-1)X}] = e^{(\alpha-1)\mathbb{E}[X] + (\alpha-1)^2 \operatorname{Var}(X)/2}$. So $\varepsilon(\alpha) = \alpha\mu^2/2$.

Two more properties are used throughout. Sums of independent Gaussians are Gaussian, with means and variances adding. Releasing k independent Gaussian pairs with parameters $\mu_1, \dots, \mu_k$ is like seeing a k-dimensional normal shifted by $(\mu_1, \dots, \mu_k)$; only the direction of the shift matters, and along it the shift is $\sqrt{\mu_1^2 + \cdots + \mu_k^2}$ standard deviations. So the composition is $\sqrt{\mu_1^2 + \cdots + \mu_k^2}$-GDP (f-DP and Gaussian DP proves this for adaptively chosen steps too).

In RDP terms, hiding a shift of size a under noise of standard deviation σ is a Gaussian pair with $\mu = a/\sigma$, so it costs $\alpha\mu^2/2$:

$$R_\alpha(a) = D_\alpha(\mathcal{N}(0,\sigma^2) \,\|\, \mathcal{N}(a,\sigma^2)) = \frac{\alpha a^2}{2\sigma^2}. \tag{35.4}$$

35.3. Shuffled binary randomized response, exactly

35.3.1. Context

Each of n users holds a bit and reports it with binary randomized response: the true bit with probability $p = e^{\varepsilon_0}/(1 + e^{\varepsilon_0})$ (written t in Part 3), the flipped bit otherwise. Each report on its own is ε_0-DP. A report of 1 has probability p if you hold 1 and $1 - p$ if you hold 0, and the reverse for a report of 0, so the likelihood ratio of any report is at most $p/(1-p) = e^{\varepsilon_0}$. A shuffler

permutes the reports before the analyst sees them. How private is the shuffled bag? For this one randomizer the question has an exact answer, and that answer is the yardstick for every general bound in the next section.

35.3.2. Statement

Once the order is gone, the only thing a bag of bits can tell the analyst is how many of them are 1. So the analyst's view is equivalent to the **number Y of 1-reports**. Your report moves that count by at most one, and the other users' reports add random noise to it. Fix the other users' bits, and let your bit be 0 in D and 1 in D'. If the other $n-1$ users all hold 0, each of them reports 1 only when their coin flips the bit, so their number of 1-reports is $S \sim \mathrm{Bin}(n-1, 1-p)$, with probability mass function b. The count $Y = y$ arises either when your report is 0 and the others sent y ones, or when your report is 1 and the others sent $y-1$. Weighting the two cases by the probability of your report gives

$$P(y) = p\,b(y) + (1-p)\,b(y-1), \qquad Q(y) = (1-p)\,b(y) + p\,b(y-1), \qquad y = 0, \dots, n. \quad (35.5)$$

The exact $\delta(\varepsilon)$ of shuffled randomized response for this pair is the larger of $E_{e^\varepsilon}(P\|Q)$ and $E_{e^\varepsilon}(Q\|P)$, computed by Fact 1.

35.3.3. Derivation

1. **The bag is the count.** A shuffled sequence of bits is a uniformly random arrangement of its 1s and 0s. Given the count Y, the arrangement carries no further information about anyone's data, because every arrangement with Y ones is equally likely under both D and D'. A summary with this property is a **sufficient statistic**. Fact 2 applies in both directions: the count is a function of the bag, and the bag can be rebuilt from the count by arranging Y ones and $n-Y$ zeros in a random order, which uses randomness that does not depend on the data. So the divergences of the bag equal those of Y.
2. **Split the count.** Write $Y = S + B$, where S is the number of 1-reports among the others and B is your report. S does not depend on your bit. $B \sim \mathrm{Bern}(1-p)$ under D, because you hold 0 and report 1 only when you flip, and $B \sim \mathrm{Bern}(p)$ under D'.
3. **The others' count.** A user holding 0 reports 1 with probability $1-p$, independently of everyone else, so the number of 1-reports among $n-1$ such users is $S \sim \mathrm{Bin}(n-1, 1-p)$.
4. **Condition on B.** By the law of total probability, split on the value of your report: $P(Y=y) = \Pr[B=0]\,b(y) + \Pr[B=1]\,b(y-1)$. With $\Pr[B=0] = p$ under D and $1-p$ under D', this is Equation 35.5.
5. **Other pairs.** The pair above assumes the other users all hold 0. If m of them hold 1, those m report 1 with probability p each, so S becomes $\mathrm{Bin}(m,p) + \mathrm{Bin}(n-1-m, 1-p)$, the distribution of a sum of two independent counts (a convolution). A guarantee has to hold for the worst m. You only need to check half of them. Swapping 0 and 1 for every user, in both the bits and the reports, is a relabelling that the analyst could undo. It turns "m others hold 1, you hold 0 or 1" into "$n-1-m$ others hold 1, you hold 1 or 0", the same pair with D and D' exchanged. Since $\delta(\varepsilon)$ already takes the larger of the two directions, m and $n-1-m$ give the same ε, and $m \le (n-1)/2$ covers every pair. The script scans every such m at $n = 1000$ and $\delta = 10^{-6}$. For $\varepsilon_0 = 1$ and 4 the largest ε is at $m = 0$. For $\varepsilon_0 = 2$ it is at $m = 2$: 0.323324 against 0.323279 at $m = 0$, because the discrete count makes ε ripple

slightly in m. Large m is much better (0.2858 at $m = 499$), because then about half the others report 1 and the count is at its noisiest. At $n = 10^4$ and 10^5 the script scans $m \le 30$, and the largest value it finds exceeds the $m = 0$ value by at most 4.1×10^{-6}. The rest of the chapter uses the pair $m = 0$ and calls its ε the exact one. Strictly, it is exact for that pair and a lower bound on the worst case, within 10^{-4} of the largest value found: every entry of Table 35.4 is the same to four decimals.

A walk-through with $n = 3$. Take $\varepsilon_0 = \ln 3$, so $p = \frac{3}{1+3} = \frac{3}{4}$. The two other users hold 0, so each reports 1 with probability $\frac{1}{4}$, and $S \sim \mathrm{Bin}(2, \frac{1}{4})$ has $b = ((\frac{3}{4})^2, 2 \cdot \frac{1}{4} \cdot \frac{3}{4}, (\frac{1}{4})^2) = (\frac{9}{16}, \frac{6}{16}, \frac{1}{16})$. Table 35.2 fills in Equation 35.5 outcome by outcome. For example, $Q(1) = \frac{1}{4} \cdot \frac{6}{16} + \frac{3}{4} \cdot \frac{9}{16} = \frac{6+27}{64}$.

Table 35.2.: Shuffled binary randomized response with $n = 3$ users and $\varepsilon_0 = \ln 3$; the two other users hold 0.

Count y	0	1	2	3
$b(y)$, others' 1-reports	9/16	6/16	1/16	0
$P(y)$, you hold 0	27/64	27/64	9/64	1/64
$Q(y)$, you hold 1	9/64	33/64	19/64	3/64
$P(y)/Q(y)$	3.0000	0.8182	0.4737	0.3333

Now apply Fact 1 at $\varepsilon = 0.5$, where $e^{0.5} = 1.6487$. Only $y = 0$ has a ratio P/Q above 1.6487, so only it enters the sum: $E_{e^{0.5}}(P\|Q) = \frac{27-9e^{0.5}}{64} = 0.1900$. In the other direction, the ratios Q/P are the reciprocals of the last row, and $y = 2$ and $y = 3$ exceed 1.6487, so $E_{e^{0.5}}(Q\|P) = \frac{(19-9e^{0.5})+(3-e^{0.5})}{64} = 0.0861$. The other direction is smaller, so $\delta(0.5) = 0.1900$. Compare a single unshuffled report, whose pair is $(\frac{3}{4}, \frac{1}{4})$ against $(\frac{1}{4}, \frac{3}{4})$: only one output has a ratio above $e^{0.5}$, and $\delta(0.5) = \frac{3}{4} - \frac{1}{4}e^{0.5} = 0.3378$. Even two other users nearly halve δ. At $\varepsilon = 1$ the two values are 0.0396 and 0.0704. A simulation of 200,000 shuffles under D gives count frequencies 0.4226, 0.4203, 0.1413, 0.0158 against the exact 0.4219, 0.4219, 0.1406, 0.0156; the largest gap, 0.0015, is within sampling error.

35.3.4. Interpretation

Shuffling never improves pure DP. Look at the count $y = 0$. Its ratio is $P(0)/Q(0) = pb(0)/((1-p)b(0)) = e^{\varepsilon_0}$ for every n, because $b(-1) = 0$ removes the second term of both P and Q. In words: if nobody reports a 1, you were probably the one holding 0, and no number of other users changes that ratio. What changes is how often it happens. That outcome has probability p^n under D (everyone, you included, reports 0), which is tiny for large n. So shuffling amplifies by moving the bad outcomes into δ, as the first column of Table 35.2 shows.

A central limit view. Why should the privacy fall like $1/\sqrt{n}$? Under both datasets Y is the sum of many independent bits, so by the central limit theorem it is close to normal, and Fact 3 says a pair of normals with equal variance is μ-GDP with μ equal to the mean difference divided by the standard deviation. The mean of Y differs between D and D' only through your report, by $\mathbb{E}[B'] - \mathbb{E}[B] = p - (1-p) = 2p - 1$, where B' is your report under D'. The variance is $np(1-p)$

under both, since every report, yours included, is a Bernoulli variable that is 1 with probability p or $1-p$, and either way has variance $p(1-p)$. Dividing,

$$\mu \approx \frac{2p-1}{\sqrt{np(1-p)}} = \frac{e^{\varepsilon_0}-1}{e^{\varepsilon_0/2}\sqrt{n}} = \frac{2\sinh(\varepsilon_0/2)}{\sqrt{n}}, \tag{35.6}$$

where the middle form uses $2p-1 = \frac{e^{\varepsilon_0}-1}{e^{\varepsilon_0}+1}$ and $\sqrt{p(1-p)} = \sqrt{\frac{e^{\varepsilon_0}}{(e^{\varepsilon_0}+1)^2}} = \frac{e^{\varepsilon_0/2}}{e^{\varepsilon_0}+1}$, so that the factors $e^{\varepsilon_0}+1$ cancel. The last form divides top and bottom by $e^{\varepsilon_0/2}$: $\frac{e^{\varepsilon_0}-1}{e^{\varepsilon_0/2}} = e^{\varepsilon_0/2}-e^{-\varepsilon_0/2} = 2\sinh(\varepsilon_0/2)$. The privacy of shuffled randomized response falls like $1/\sqrt{n}$, with an ε_0-dependent constant that grows like $e^{\varepsilon_0/2}$.

When the approximation fails. The normal approximation is good when there are many 1-reports to hide among. At $n = 10^5$ and $\varepsilon_0 = 2$ it gives $\varepsilon = 0.0244$ against the exact 0.0247 (Table 35.4). At $n = 1000$ and $\varepsilon_0 = 4$, each of the 999 others reports 1 with probability $1-p = 1/(1+e^4)$, so on average they send only $999/(1+e^4) = 18.0$ 1-reports. A count that small is far from normal, and the approximation gives 0.9667 against the exact 1.6910. Use the exact computation, which costs milliseconds.

Figure 35.1 draws the two count distributions and the exact $\delta(\varepsilon)$ curves.

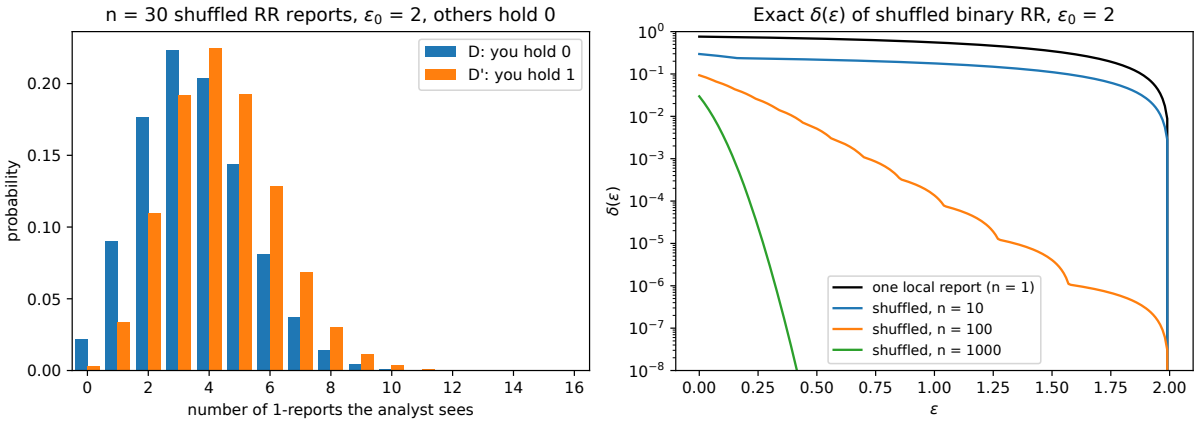

Figure 35.1.: Left: the distribution of the number of 1-reports among $n = 30$ shuffled randomized-response reports with $\varepsilon_0 = 2$, when you hold 0 (blue) and when you hold 1 (orange); the other users hold 0. Your report moves the count by at most one, against a spread of about $\sqrt{np(1-p)}$. Right: the exact $\delta(\varepsilon)$ for one unshuffled report and for $n = 10, 100, 1000$ shuffled reports. All curves reach 0 only at $\varepsilon = \varepsilon_0$, but for large n they are negligible far earlier.

35.3.5. Example: a survey of 10,000 people

A company asks 10,000 users whether they used a feature, through randomized response with $\varepsilon_0 = 2$ and a shuffler. Each user's report alone is 2-DP, a weak guarantee: the truth is reported with probability $p = e^2/(1+e^2) = 0.8808$, so a single report is the truth seven times out of eight. The shuffled bag is $(0.0870, 10^{-6})$-DP (Table 35.4). The shuffler bought central-model privacy without anyone seeing raw data.

35.3.6. Check yourself

- Why does the analysis of the count not depend on the order in which reports arrive? *(The shuffler outputs a uniformly random order, which carries no information. The count is sufficient for the bag.)*
- With $n = 3$ and $\varepsilon_0 = \ln 3$, what is the smallest ε for which $\delta(\varepsilon) = 0$? *(It is* $\ln 3$*: the outcome* $y = 0$ *has likelihood ratio 3, so for any smaller* ε *it contributes a positive amount to Fact 1's sum. Shuffling never lowers the pure-DP level.)*

35.4. The clone bound for any local randomizer

35.4.1. Context

Randomized response on bits is one randomizer. In practice users send histograms, k-ary responses or noisy vectors, and the shuffle is sometimes applied to adaptively chosen randomizers, as in shuffled stochastic gradient descent (SGD), where each user randomizes their own gradient before it is shuffled. You want one bound that holds for **every** ε_0-DP local randomizer, that is, every randomized map R from a user's data to a report whose output probabilities change by at most a factor e^{ε_0} when the input changes. Erlingsson et al. (2019) gave the first such bound; Balle et al. (2019) gave another with the "privacy blanket" idea, which writes each randomizer as a mixture of an input-independent part and the rest. The bound to use today is Feldman, McMillan & Talwar (2021), and its proof is short enough to follow.

35.4.2. Statement

The bound says that shuffling turns ε_0-local privacy into a central ε that shrinks like $1/\sqrt{n}$, with a constant that grows like $e^{\varepsilon_0/2}$ and a factor $\sqrt{\ln(1/\delta)}$ for the slack. It needs enough users relative to e^{ε_0}, for a reason the derivation makes clear.

Theorem 3.1 of Feldman, McMillan & Talwar (2021). Let each user apply an ε_0-DP local randomizer (possibly chosen adaptively from the previous outputs) to the data in a uniformly random order. For any $\delta \in [0, 1]$ with $\varepsilon_0 \le \ln\left(\frac{n}{16\ln(2/\delta)}\right)$, the output is (ε, δ)-DP with

$$\varepsilon \le \ln\left(1 + \frac{e^{\varepsilon_0} - 1}{e^{\varepsilon_0} + 1}\left(\frac{8\sqrt{e^{\varepsilon_0}\ln(4/\delta)}}{\sqrt{n}} + \frac{8e^{\varepsilon_0}}{n}\right)\right). \tag{35.7}$$

The theorem rests on a reduction, which is the useful part. Any ε_0-DP randomizer, run on any other user's data, produces with probability $e^{-\varepsilon_0}$ a report that looks exactly like yours could, a **clone**. Once the order is hidden, the adversary is left counting how many reports look like your D-version and how many look like your D'-version, and the clones blur that count. To state it, let C be the number of other users who act as clones, A the number of those clones that look like your D-version, and Δ a bit that says whether your own report points the right way.

Theorem 3.2 of the same paper (the reduction). Let $C \sim \mathrm{Bin}(n-1, e^{-\varepsilon_0})$, $A \sim \mathrm{Bin}(C, \frac{1}{2})$ and $\Delta \sim \mathrm{Bern}(\frac{e^{\varepsilon_0}}{e^{\varepsilon_0}+1})$, independent. The shuffled output on D and on D' is a post-processing, by one and the same randomized map, of

$$\tilde{P} = (A + \Delta,\ C - A + 1 - \Delta) \qquad \text{and} \qquad \tilde{Q} = (A + 1 - \Delta,\ C - A + \Delta). \tag{35.8}$$

In $\tilde{P}$ your report adds to the first count when $\Delta = 1$, and in $\tilde{Q}$ it adds to the second. By Fact 2, any (ε, δ) that holds for this pair of two-dimensional counts holds for the shuffled output. Computing the pair's $\delta(\varepsilon)$ exactly, with Fact 1, gives the **numeric clone bound**; Equation 35.7 is an analytic upper bound on it.

35.4.3. Derivation

Steps 1 to 4 prove the reduction, and step 1 carries the idea. Step 5 bounds the resulting pair.

1. **Every report contains a copy of yours.** Fix the two values x^0 (in D) and x^1 (in D') that you might hold, and let $R(x)$ be the distribution of the report of a user holding x. Being ε_0-DP means that no output is more than e^{ε_0} times likelier for one input than for another. Read from the other side, every output of $R(x)$ keeps at least a fraction $e^{-\varepsilon_0}$ of its probability under $R(x^0)$, and likewise for x^1: $R(x)(y) \geq e^{-\varepsilon_0} R(x^0)(y)$ and $R(x)(y) \geq e^{-\varepsilon_0} R(x^1)(y)$ for every output y. Average the two inequalities: $R(x) \geq \frac{e^{-\varepsilon_0}}{2}(R(x^0) + R(x^1))$ pointwise. The difference between the two sides is non-negative, and its total mass is $1 - \frac{e^{-\varepsilon_0}}{2}(1+1) = 1 - e^{-\varepsilon_0}$, so it is $(1 - e^{-\varepsilon_0})$ times a distribution $\mathrm{LO}(x)$, the **leftover**:
$$R(x) = \frac{e^{-\varepsilon_0}}{2} R(x^0) + \frac{e^{-\varepsilon_0}}{2} R(x^1) + (1 - e^{-\varepsilon_0})\mathrm{LO}(x). \tag{35.9}$$
2. **Read the mixture as a three-sided coin.** A mixture is sampled by first choosing a component with its weight, then drawing from that component. So sampling from Equation 35.9 means: flip a coin that says "0" with probability $e^{-\varepsilon_0}/2$, "1" with probability $e^{-\varepsilon_0}/2$, "leftover" otherwise; then report a draw from $R(x^0)$, $R(x^1)$ or $\mathrm{LO}(x)$. A user whose coin says "0" sends a report distributed exactly like yours on D: a **clone**. Each of the other $n-1$ users is a clone (face "0" or "1") with probability $e^{-\varepsilon_0}$, independently, so the number of clones is $C \sim \mathrm{Bin}(n-1, e^{-\varepsilon_0})$. Each clone is a 0-clone or a 1-clone with probability $\frac{1}{2}$, so $A \sim \mathrm{Bin}(C, \frac{1}{2})$ of them are 0-clones.
3. **After shuffling, only the counts of the coin faces matter.** Generate the output in two stages. First flip every other user's three-sided coin; then draw each report given its face. A user whose face is 0 or 1 draws from $R(x^0)$ or $R(x^1)$, which does not depend on who they are. A user whose face is "leftover" draws from $\mathrm{LO}(x_i)$, which depends only on that user's own data x_i, not on yours. Give yourself the face 0 on D and 1 on D', since your report is a draw from $R(x^0)$ or $R(x^1)$. After the shuffle nobody can tell whose report is whose. So someone who knows every other user's data, but not your bit, can produce the shuffled bag from just the number of 0-faces and 1-faces: draw that many reports from $R(x^0)$ and $R(x^1)$, draw a leftover report for every other user, and shuffle (Lemma 3.3 of the paper makes this precise, and Section L.3 writes the map out). Those numbers are $(A+1, C-A)$ on D and $(A, C-A+1)$ on D'. By Fact 2, the output is no more distinguishable than these counts.
4. **Your own report is a randomized response.** The counts of step 3 still give your face away exactly, by one. The last improvement uses the fact that your own report is itself noisy. Any ε_0-DP randomizer restricted to two inputs is a post-processing of binary

randomized response (Kairouz, Oh & Viswanath 2015, Lemma 3.4 of the paper). Concretely, $R(x^0)$ and $R(x^1)$ are mixtures of two distributions Q_0, Q_1 with weights $(\frac{e^{\varepsilon_0}}{e^{\varepsilon_0}+1}, \frac{1}{e^{\varepsilon_0}+1})$ and the reverse: your report is drawn from the distribution "on your side" with probability $\frac{e^{\varepsilon_0}}{e^{\varepsilon_0}+1}$ and from the other side otherwise, exactly like a randomized-response bit. Because $\frac{1}{2}(R(x^0)+R(x^1)) = \frac{1}{2}(Q_0+Q_1)$, every clone can be redrawn as a fair choice between Q_0 and Q_1. So replacing your face by that randomized-response bit Δ gives Equation 35.8 (Section L.3 in the appendices gives the full argument). This is where the factor $\frac{e^{\varepsilon_0}-1}{e^{\varepsilon_0}+1}$ in Equation 35.7 comes from: it is $\Pr[\Delta=1]-\Pr[\Delta=0]$, how much more often randomized response points the right way than the wrong way. Equivalently, randomized response passes on your bit only with that probability, and outputs a fair coin otherwise.

5. **Bound the pair.** The last step bounds $E_{e^\varepsilon}(\tilde{P}\|\tilde{Q})$ with binomial concentration (Chernoff bounds on C and on A given C; Lemma 3.5 and Appendix A of the paper). These bounds need many clones to hide among: the condition on ε_0 is the same as $ne^{-\varepsilon_0} \geq 16\ln(2/\delta)$, an expected number of clones large enough for C to be close to its mean except with probability about δ. Section L.3 in the appendices carries out a version of this calculation, with constants that match or beat the paper's. Here the script computes the pair's $\delta(\varepsilon)$ exactly instead.

Step 1 on a concrete randomizer. Binary randomized response with $\varepsilon_0 = \ln 3$ has $R(0) = (\frac{3}{4}, \frac{1}{4})$ and $R(1) = (\frac{1}{4}, \frac{3}{4})$ on outputs $(0,1)$, and $e^{-\varepsilon_0} = \frac{1}{3}$, so each clone weight is $\frac{e^{-\varepsilon_0}}{2} = \frac{1}{6}$ and the leftover weight is $1-\frac{1}{3} = \frac{2}{3}$. Take another user who holds $x=0$, with your values $x^0=0$, $x^1=1$. Table 35.3 decomposes this user's report.

Table 35.3.: The clone decomposition Equation 35.9 for binary randomized response with $\varepsilon_0 = \ln 3$, for a user holding 0. With probability $\frac{1}{6}$ the user's report is a draw from $R(0)$, with probability $\frac{1}{6}$ a draw from $R(1)$, and otherwise a draw from the leftover.

Output y	$R(0)(y)$	$\frac{1}{6}R(x^0)(y)$	$\frac{1}{6}R(x^1)(y)$	$\frac{2}{3}\mathrm{LO}(0)(y)$	$\mathrm{LO}(0)(y)$
0	3/4	1/8	1/24	7/12	7/8
1	1/4	1/24	1/8	1/12	1/8
Total	1	1/6	1/6	2/3	1

The fourth column is what remains of $R(0)$ after the two clone parts are taken out, and the last column rescales it by $\frac{3}{2}$ to a distribution. Each row adds up: $\frac{1}{8}+\frac{1}{24}+\frac{7}{12} = \frac{3}{4}$. The script prints the clone part $(0.1667, 0.1667)$ and $\mathrm{LO}(0) = (0.875, 0.125)$.

35.4.4. Interpretation

Why $1/\sqrt{n}$ and $e^{\varepsilon_0/2}$. The central limit view of the previous section explains the shape of the bound. Given $C=c$ clones, the first coordinates of $\tilde{P}$ and $\tilde{Q}$ are $A+\Delta$ and $A+1-\Delta$. Their means differ by $\mathbb{E}[\Delta]-\mathbb{E}[1-\Delta] = 2\Pr[\Delta=1]-1 = \frac{e^{\varepsilon_0}-1}{e^{\varepsilon_0}+1}$. The noise that hides this difference is the spread of $A \sim \mathrm{Bin}(c, \frac{1}{2})$, a standard deviation of $\sqrt{c\cdot\frac{1}{2}\cdot\frac{1}{2}} = \sqrt{c}/2$. The expected number of clones is $c \approx ne^{-\varepsilon_0}$, and dividing the mean difference by the spread, as Fact 3 does for a Gaussian pair, gives $\mu \approx \frac{e^{\varepsilon_0}-1}{e^{\varepsilon_0}+1}\cdot\frac{2}{\sqrt{ne^{-\varepsilon_0}}}$. That is the shape of Equation 35.7: $\varepsilon = O(\frac{e^{\varepsilon_0}-1}{e^{\varepsilon_0}+1}\sqrt{e^{\varepsilon_0}\ln(1/\delta)/n})$. For $\varepsilon_0 \leq 1$ the first factor is about $\varepsilon_0/2$ and e^{ε_0} is at most e, so this is of order $\varepsilon_0\sqrt{\ln(1/\delta)/n}$; above 1 the first factor tends to 1, leaving $\sqrt{e^{\varepsilon_0}\ln(1/\delta)/n}$.

What the general bound gives up. Divide the clone μ by the randomized-response μ of Equation 35.6, written as $\frac{e^{\varepsilon_0}-1}{e^{\varepsilon_0/2}\sqrt{n}}$. The factors $e^{\varepsilon_0}-1$ and $\sqrt{n}$ cancel, and what is left is $\frac{2e^{\varepsilon_0/2}}{e^{\varepsilon_0}+1}\cdot e^{\varepsilon_0}/2 = \frac{2e^{\varepsilon_0}}{e^{\varepsilon_0}+1} = \frac{2}{1+e^{-\varepsilon_0}}$. The ratio is above 1 for a clear reason. In binary randomized response every other report is a bit that could be yours, while the clone argument counts only the $e^{-\varepsilon_0}$ fraction of reports guaranteed to look like yours, split into two halves. The script gives this ratio as 1.46, 1.76 and 1.96 for $\varepsilon_0 = 1, 2, 4$; for instance $2e/(e+1) = 1.46$. The measured ratios of the numeric clone bound to the exact ε in Table 35.4 are 1.44 to 2.00 wherever the expected number of clones $(n-1)e^{-\varepsilon_0}$ is large, close to this prediction. At $n = 1000$ and $\varepsilon_0 = 4$ there are only about $999e^{-4} = 18.3$ expected clones, far from the central limit regime, and the ratio is 2.36. No general bound can go below the exact column, since binary randomized response is one of the randomizers it must cover.

The closed form is loose by another factor of 3 to 5. Equation 35.7 comes from Chernoff bounds with constant 8, which are safe but not sharp. Where its condition holds in Table 35.4, it is 3.10 to 4.75 times the numeric clone bound and 4.47 to 7.55 times the exact ε. Use it to reason about scaling; compute the numeric bound to deploy.

The condition matters. Below $ne^{-\varepsilon_0} = 16\ln(2/\delta)$ there may be too few clones, and Equation 35.7 says nothing. Solving for ε_0 gives the largest allowed level, $\ln\left(n/(16\ln(2/\delta))\right)$. At $\delta = 10^{-6}$, $16\ln(2\times 10^6) = 232.1$, so ε_0 must be at most $\ln(1000/232.1) = 1.460$ for $n = 1000$, 3.763 for $n = 10^4$ and 6.066 for $n = 10^5$.

The first bound was much weaker. Erlingsson et al. (2019, Theorem 7) prove $\varepsilon \le \varepsilon_1\sqrt{2n\ln(1/\delta)} + n\varepsilon_1(e^{\varepsilon_1}-1)$ with $\varepsilon_1 = 2e^{2\varepsilon_0}(e^{\varepsilon_0}-1)/n$, through a swap argument, subsampling and advanced composition. Substituting ε_1 into the first term, its leading term is $2e^{2\varepsilon_0}(e^{\varepsilon_0}-1)\sqrt{2\ln(1/\delta)/n}$, so its dependence on ε_0 is $e^{3\varepsilon_0}$ instead of $e^{\varepsilon_0/2}$, a factor $e^{2.5\varepsilon_0}$ worse. In Table 35.4 it is below ε_0, that is, it amplifies at all, only for $n = 10^5$ and $\varepsilon_0 = 1$, where it gives 0.4285.

Table 35.4.: Central ε at $\delta = 10^{-6}$ after shuffling n reports that are each ε_0-DP. "n/a" marks where the condition of Equation 35.7 fails; "—" marks where the bound of Erlingsson et al. is at least ε_0. The $n = 10^4$ rows agree with the table in Trust models.

n	ε_0	Exact, binary randomized response	Normal approx., Equation 35.6	Clones, numeric	Clones, closed form	Erlingsson et al.

Figure 35.2 draws the same comparison over n. All curves fall like $1/\sqrt{n}$ once n is large; the

constants are what separates them. Multiplying by $\sqrt{n}$ removes the common $1/\sqrt{n}$ and leaves the constant: the exact ε times $\sqrt{n}$ is 3.566, 8.702 and 31.464 at $n = 10^4$ for $\varepsilon_0 = 1, 2, 4$, growing with ε_0 roughly as $2\sinh(\varepsilon_0/2)$ in Equation 35.6 does.

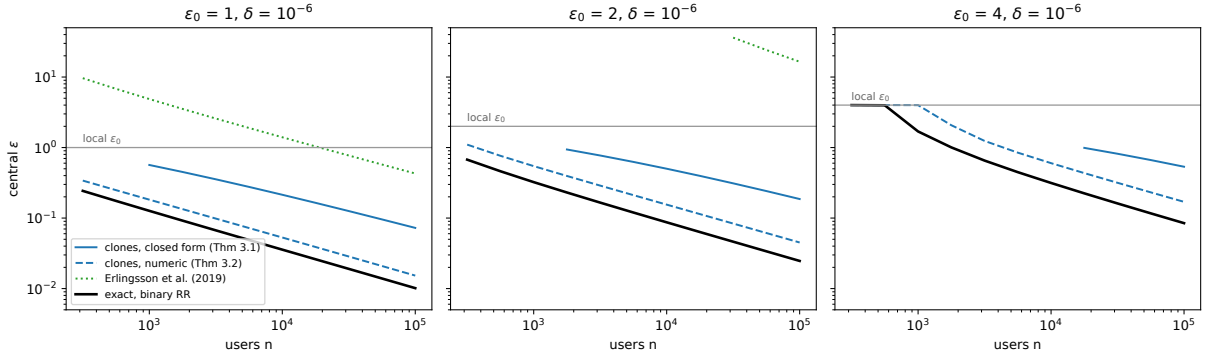

Figure 35.2.: Central ε at $\delta = 10^{-6}$ against the number of users n, for $\varepsilon_0 = 1, 2, 4$: the closed-form clone bound (drawn only where its condition holds), the numeric clone bound of Theorem 3.2, the bound of Erlingsson et al. (drawn where it is below 50, so it appears only for large n when $\varepsilon_0 = 2$ and not at all when $\varepsilon_0 = 4$, where it exceeds 7×10^6 for every n shown) and the exact ε of shuffled binary randomized response. The grey line is the local ε_0.

35.4.5. Example: how large may each user's ε_0 be?

You collect a bit from $n = 10^5$ users behind a shuffler and want central $\varepsilon \leq 0.2$ at $\delta = 10^{-6}$. Of the values in Table 35.4, the closed form allows $\varepsilon_0 = 2$ (0.1862), the numeric clone bound allows $\varepsilon_0 = 4$ (0.1698), and for binary randomized response the exact value at $\varepsilon_0 = 4$ is 0.0847. A larger ε_0 means less noise per report, so it matters what $\varepsilon_0 = 4$ buys. Each report is the truth with probability $p = e^4/(1 + e^4) = 0.9820$. Suppose the users are a random sample from a population in which a proportion π hold 1. A report is then 1 with probability $r = \pi p + (1-\pi)(1-p) = (1-p) + \pi(2p-1)$, so the fraction $\bar{Y}$ of 1-reports estimates r, and solving for π gives the debiased estimate $\hat{\pi} = (\bar{Y} - (1-p))/(2p-1)$. Its variance is $r(1-r)/(n(2p-1)^2)$, and expanding $r(1-r) = (2p-1)^2\pi(1-\pi) + p(1-p)$ gives $(\pi(1-\pi) + \frac{p(1-p)}{(2p-1)^2})/n$. The first term is the ordinary sampling variance, which you would pay without any privacy. The term added by the noise is $\frac{0.9820 \times 0.0180}{0.9640^2} = 0.0190$, against up to 0.25 for the sampling term $\pi(1-\pi)$, so the noise costs little accuracy. Which accountant you use decides whether a deployment is feasible.

35.4.6. Check yourself

- In step 1, why average the two inequalities instead of using just one? *(Using only x^0 would give clones of D's version of you but none of D''s. The analyst could then count reports that look like x^1. Splitting the clones evenly between the two makes the situation symmetric.)*
- Why does the analysis need a uniformly random order, rather than a fixed one? *(With a fixed order the analyst knows which report is yours, and the guarantee falls back to ε_0. The random order is what lets the faces be described by their counts.)*

35.5. Amplification by iteration

35.5.1. Context

Projected noisy SGD makes one pass over the data: at step t it takes a gradient step on record x_t, adds Gaussian noise, and projects back onto a convex set of allowed parameters. If every iterate is released, the record x_t is protected only by the noise of step t, as in one Gaussian mechanism: a value with bounded sensitivity plus Gaussian noise. If only the final iterate θ_n is released, the noise of steps $t+1, \dots, n$ also covers x_t. Feldman, Mironov, Talwar & Thakurta (2018) turned this into a guarantee. The obstacle is that the steps in between are arbitrary maps applied to random points, not additions, so you cannot just add up variances as for a sum of Gaussians. Their tool is a divergence that allows for a bounded shift.

35.5.2. Statement

The argument needs every step to be a map that never pushes two points further apart. A **contractive noisy iteration** is $X_t = \psi_t(X_{t-1}) + Z_t$, where each ψ_t is a **contraction**, $\|\psi_t(u) - \psi_t(v)\| \le \|u - v\|$, and $Z_t \sim \mathcal{N}(0, \sigma^2 I)$ is fresh noise. Two kinds of maps in noisy SGD have this property.

A gradient step $\theta \mapsto \theta - \eta\nabla\ell(\theta)$ on a convex β-smooth loss ℓ is a contraction when $\eta \le 2/\beta$ (Stability and generalization, Fact 4). The reason is that for such ℓ the gradient is **co-coercive** (proved in Section G.2 in the appendices): $\langle \nabla\ell(u) - \nabla\ell(v), u - v\rangle \ge \frac{1}{\beta}\|\nabla\ell(u) - \nabla\ell(v)\|^2$, so the gradients of two points differ in a direction that brings them together. Writing $g = \nabla\ell(u) - \nabla\ell(v)$ and expanding the square, $\|u - v - \eta g\|^2 = \|u - v\|^2 - 2\eta\langle g, u - v\rangle + \eta^2\|g\|^2 \le \|u - v\|^2 - \eta(\frac{2}{\beta} - \eta)\|g\|^2$, which is at most $\|u - v\|^2$ when $\eta \le 2/\beta$.

The projection Π onto a closed convex set K, which maps each point to the nearest point of K, is a contraction too. The proof of Fact 3 of Optimization shows that the nearest point makes an obtuse angle with every other point of K: $\langle u - \Pi u, \theta - \Pi u\rangle \le 0$ for every $\theta \in K$. Take $\theta = \Pi v$, then exchange u and v, and add the two inequalities: $\|\Pi u - \Pi v\|^2 \le \langle u - v, \Pi u - \Pi v\rangle \le \|u - v\|\,\|\Pi u - \Pi v\|$ by Cauchy–Schwarz, so $\|\Pi u - \Pi v\| \le \|u - v\|$. A composition of contractions is a contraction, so a projected gradient step is one too.

Now the divergence. The two runs, on D and on D', are driven apart at the step that uses your record, and after that the contractions keep the gap from growing while the noise blurs it. The quantity to track is therefore how far apart the two runs might be (a **shift**) and how much divergence would remain if you were allowed to move one of them by that shift. To move a random variable by at most z means to pair each of its values with a value at most z away; such a pairing of two random variables is a **coupling**. The **shifted Rényi divergence** allows the first distribution to be moved by at most z in this way before it is compared, with the Rényi divergence D_α of Fact 3:

$$D_\alpha^{(z)}(X\|X') = \inf\big\{D_\alpha(Y\|X') : \text{some coupling of } X \text{ and } Y \text{ has } \|X - Y\| \le z \text{ almost surely}\big\}. \tag{35.10}$$

With $z = 0$ no move is allowed, and it is D_α. Two lemmas drive everything (Feldman et al. 2018, Lemmas 20 and 21, both proved in Section L.4 in the appendices): noise lets you pay off part of the shift, and contractions only add the gap between the two maps to the shift, at no cost.

Shift reduction. Adding noise lets you buy down the shift. Let $R_\alpha(a)$ be the largest D_α between the noise and a copy of it shifted by at most a; for Gaussian Z it is Equation 35.4. Adding Z to both sides lowers the allowed shift by a at a price $R_\alpha(a)$: for any $a \geq 0$,

$$D_\alpha^{(z)}(X + Z \,\|\, X' + Z) \leq D_\alpha^{(z+a)}(X \| X') + R_\alpha(a). \tag{35.11}$$

Contraction. Applying contractions ψ, ψ' to the two sides cannot move points apart, but the two maps themselves may differ (they do at the step that uses your record). If they differ by at most s at every point, $\sup_u \|\psi(u) - \psi'(u)\| \leq s$, the shift needed grows by at most s and the divergence does not grow:

$$D_\alpha^{(z+s)}(\psi(X) \,\|\, \psi'(X')) \leq D_\alpha^{(z)}(X \| X'). \tag{35.12}$$

Chaining the two lemmas over T steps gives their Theorem 22. Let the two runs differ by $s_t = \sup_u \|\psi_t(u) - \psi_t'(u)\|$ at step t, and choose payments $a_1, \dots, a_T \geq 0$ such that the unpaid shift $z_t = \sum_{i \leq t}(s_i - a_i)$ never goes negative and is 0 at the end, $z_T = 0$. Then $D_\alpha(X_T \| X_T') \leq \sum_t R_\alpha(a_t)$: the divergence of the last iterate is at most the total price of the payments. For noisy SGD this becomes the following.

Theorem 23 of Feldman et al. (2018). Let the losses $\ell(\cdot\,; x)$ be convex, G-Lipschitz and β-smooth on a convex set K, and run projected noisy SGD $\theta_t = \Pi_K(\theta_{t-1} - \eta(\nabla \ell(\theta_{t-1}; x_t) + Z_t))$, $Z_t \sim \mathcal{N}(0, \sigma^2 I)$, $\eta \leq 2/\beta$, once over $x_1, \dots, x_n$. Releasing only θ_n is $(\alpha, \frac{2\alpha G^2}{\sigma^2(n-t+1)})$-RDP for the record x_t, for every $\alpha > 1$.

The guarantee is easier to read in terms of the **noise multiplier** $\tilde{\sigma} = \sigma/(2G)$, the noise per unit of the gradient's replace-one sensitivity. That sensitivity is $2G$ because a G-Lipschitz loss has gradients of norm at most G, so the gradients on x_t and x_t' differ by at most $2G$. Substituting $\sigma^2 = 4G^2\tilde{\sigma}^2$, the RDP of the record at step t reads

$$\varepsilon_t(\alpha) = \frac{\alpha}{2\tilde{\sigma}^2} \cdot \frac{1}{n - t + 1} : \tag{35.13}$$

one step's Gaussian RDP curve, divided by the number of noisy steps from t to the end.

35.5.3. Derivation

Shift reduction for one Gaussian step, concretely. The lemma is easiest to see on two point masses. Let $X = 0$ and $X' = z$, a distance z apart, and add $Z \sim \mathcal{N}(0, \sigma^2)$ to both.

1. With no shift allowed, the two outputs are $\mathcal{N}(0, \sigma^2)$ and $\mathcal{N}(z, \sigma^2)$, a Gaussian pair with $\mu = z/\sigma$, so $D_\alpha = \frac{\alpha z^2}{2\sigma^2}$ (Fact 3).
2. Now allow a shift of $z - a$, and use it: move the first output by $z - a$ towards the second. That is, $Y = X + Z + (z - a) \sim \mathcal{N}(z - a, \sigma^2)$, coupled to $X + Z$ at distance exactly $z - a$. Only a of the gap is left, so $D_\alpha(Y \| X' + Z) = \frac{\alpha a^2}{2\sigma^2}$ by Fact 3 again. Hence $D_\alpha^{(z-a)}(X + Z \| X' + Z) \leq R_\alpha(a)$.
3. Now read Equation 35.11 with shift $z - a$ on the left. Its right side is $D_\alpha^{(z)}(X \| X') + R_\alpha(a)$, and $D_\alpha^{(z)}(X \| X') = 0$ because moving X by z turns it into X'. So the lemma gives exactly the bound of step 2. The noise **pays for a of the shift at price** $\alpha a^2/(2\sigma^2)$; the rest of the shift is carried forward. The general proof (Lemma 20 of the paper, derived in Section L.4) splits each displacement of the coupling into a part carried forward and a part of length at most a that the noise pays for.

Spreading the shift. Now let the two runs differ only at step t, by s, and apply identity maps afterwards ($\psi_k(u) = u$, a contraction). You decide how much shift to pay at each later step, $a_t, \dots, a_T$ with $\sum_k a_k = s$. Since the price is quadratic in each payment, small equal payments should be cheapest.

1. By Equation 35.12 at step t, the shift grows from 0 to s. By Equation 35.11 at each step $k \geq t$ it shrinks by a_k at cost $R_\alpha(a_k)$. At step T it is 0, so the shifted divergence is the ordinary D_α.
2. The total cost is $\frac{\alpha}{2\sigma^2} \sum_k a_k^2$. Cauchy–Schwarz, applied to the vectors $(a_t, \dots, a_T)$ and $(1, \dots, 1)$ of length $T - t + 1$, gives $(\sum_k a_k)^2 \leq (T - t + 1) \sum_k a_k^2$, that is, $\sum_k a_k^2 \geq \frac{(\sum_k a_k)^2}{T-t+1}$, with equality for the even schedule $a_k = s/(T - t + 1)$.
3. So $D_\alpha(X_T \| X'_T) \leq \frac{\alpha s^2}{2\sigma^2(T-t+1)}$.
4. **The general induction (Theorem 22).** With arbitrary contractions in between, write $z_k = \sum_{i \leq k} (s_i - a_i)$ for the shift still unpaid after step k. The claim is that the divergence, with the unpaid shift allowed, is at most what has been paid so far: $D_\alpha^{(z_k)}(X_k \| X'_k) \leq \sum_{i \leq k} R_\alpha(a_i)$. It holds at $k = 0$, where both runs start at the same point. For the step from k to $k + 1$, write the new iterates as the maps plus noise, peel off the noise with shift reduction (paying a_{k+1}), rewrite the shift using $z_{k+1} + a_{k+1} = z_k + s_{k+1}$, and peel off the maps with the contraction lemma:

$$\begin{aligned} D_\alpha^{(z_{k+1})}(X_{k+1} \| X'_{k+1}) &= D_\alpha^{(z_{k+1})}(\psi_{k+1}(X_k) + Z \,\|\, \psi'_{k+1}(X'_k) + Z) \\ &\leq D_\alpha^{(z_{k+1}+a_{k+1})}(\psi_{k+1}(X_k) \,\|\, \psi'_{k+1}(X'_k)) + R_\alpha(a_{k+1}) && \text{(shift reduction)} \\ &= D_\alpha^{(z_k+s_{k+1})}(\psi_{k+1}(X_k) \,\|\, \psi'_{k+1}(X'_k)) + R_\alpha(a_{k+1}) && \text{(definition of } z_{k+1}) \\ &\leq D_\alpha^{(z_k)}(X_k \| X'_k) + R_\alpha(a_{k+1}) && \text{(contraction).} \end{aligned} \tag{35.14}$$

   Applying the claim for step k to the last line proves it for step $k + 1$. At $k = T$ the shift is $z_T = 0$, and the shifted divergence is the ordinary one. The contractions never enter the cost: they can only keep the shift from growing beyond $z_k + s_{k+1}$.
5. For noisy SGD, the steps on x_t and x'_t differ by $s = \eta \|\nabla \ell(\theta; x_t) - \nabla \ell(\theta; x'_t)\| \leq 2\eta G$, since each gradient has norm at most G (Lipschitz). The update subtracts ηZ_t, so the noise in parameter space has standard deviation $\eta\sigma$. Step 3, with the induction of step 4 in place of the identity maps and n in place of T, gives $\frac{\alpha(2\eta G)^2}{2\eta^2\sigma^2(n-t+1)} = \frac{2\alpha G^2}{\sigma^2(n-t+1)}$, which is Theorem 23. The learning rate η cancels, because it scales the shift and the noise alike.

Table 35.5 walks through steps 1 to 3 with $s = 1$, $\sigma = 1$, $\alpha = 2$ and $T - t + 1 = 4$ noisy steps. Each step pays $a = \frac{1}{4}$ at price $2 \cdot (\frac{1}{4})^2/2 = 0.0625$.

Table 35.5.: Paying off a shift of 1 over four Gaussian steps with $\sigma = 1$, at $\alpha = 2$. The total equals $D_2(\mathcal{N}(0, 4) \| \mathcal{N}(1, 4)) = 0.25$.

Step	1	2	3	4	Total
Shift before the step	1	0.75	0.5	0.25	
Shift paid, a_k	0.25	0.25	0.25	0.25	1
Cost $\alpha a_k^2/(2\sigma^2)$	0.0625	0.0625	0.0625	0.0625	0.2500

The total matches the exact divergence because four independent steps of variance 1 add up to variance 4, and by Fact 3 a shift of 1 under variance 4 costs $\frac{2\cdot 1^2}{2\cdot 4} = 0.25$. Uneven schedules cost more, because squares punish large payments: $(0.8, 0.2, 0, 0)$ costs $0.8^2 + 0.2^2 = 0.6800$ (with $\alpha/(2\sigma^2) = 1$), and paying everything at once costs 1. Figure 35.3 draws the schedule and its cost as the number of steps grows.

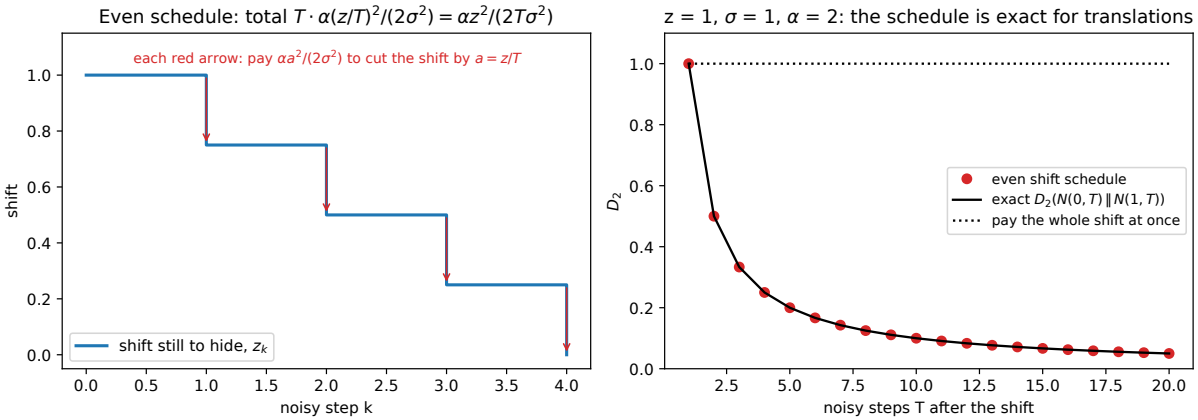

Figure 35.3.: Left: the even shift schedule over $T = 4$ noisy steps; each red arrow is a payment of $a = z/T$ at price $\alpha a^2/(2\sigma^2)$. Right: the total cost of the even schedule (dots) against the exact $D_2(\mathcal{N}(0,T)\|\mathcal{N}(1,T))$ (line), for a shift $z = 1$ and $\sigma = 1$; the dotted line is the cost of paying the whole shift in one step.

35.5.4. Interpretation

Exact for translations from a point. The even schedule loses nothing when the maps after step t are translations (they move every point by the same vector, so they keep the shift exactly as it is) and the two runs start from the same point at step t. Then the last iterate on D and D' is a pair of Gaussians shifted by s with variance $(T - t + 1)\sigma^2$ added after the shift, whose exact D_α is $\frac{\alpha s^2}{2(T-t+1)\sigma^2}$ by Fact 3. That is exactly the even schedule's cost, for every T (Figure 35.3, right; the script checks $T = 1, 2, 4, 10$).

Two things Theorem 23 ignores. Noise added **before** step t also hides the shift when the maps preserve it, and a **strict** contraction, one that brings points closer, shrinks the shift for free. Figure 35.4 compares the bound with the exact μ of a one-dimensional run, $\theta_k = c\,\theta_{k-1} + b_k + \mathcal{N}(0, \sigma^2)$, in which $c \le 1$ is the contraction factor and your record shifts only the offset b_t, by $s = \sigma$. Unrolling the run as in Section 35.7, the last iterate is Gaussian, your shift reaches the end damped to $c^{T-t}s$, and the noise has standard deviation $\sigma\sqrt{\sum_{j=0}^{T-1} c^{2j}}$; their ratio is the exact μ (Fact 3). For $c = 1$ the shift persists unchanged to the end and all T noise draws pile up on top of it, so the exact μ is $\frac{s}{\sigma\sqrt{T}} = 1/\sqrt{T} = 0.1000$ at every position, with $T = 100$. The bound, $1/\sqrt{T - t + 1}$, counts only the noise after step t and rises to 1 at $t = T$. For $c = 0.95$ the exact μ is far smaller (0.0240 at $t = 50$ against the bound's $1/\sqrt{51} = 0.1400$).

When it is exact. The bound is attained when step t first maps every point to a single point, which is a contraction, so that the earlier noise is erased. Then only the noise from step t on

hides the shift, and the exact μ is $s/(\sigma\sqrt{T-t+1})$, which matches Theorem 23 in its μ form. So Theorem 23 is exact in the worst case over contractions, and loose for typical ones.

Early records are safer, late ones are not. The last record is protected by one step only. A randomly chosen stopping time spreads this out: Theorem 26 of the paper gives $(\alpha, \frac{4\alpha G^2 \ln n}{n\sigma^2})$-RDP for every record when the number of steps is uniform on $\{1, \dots, n\}$, provided $\sigma \geq G\sqrt{2(\alpha-1)\alpha}$. (Section L.5 in the appendices derives the bound $2(e-1)\alpha G^2 H_n/(n\sigma^2)$, with H_n the n-th harmonic number, which implies this one for $n \geq 37$.) Substituting $\sigma^2 = 4G^2\tilde{\sigma}^2$, that is $\alpha \ln n/(n\tilde{\sigma}^2)$ in noise-multiplier form. The first record gets $\frac{\alpha}{2\tilde{\sigma}^2 n}$ from Equation 35.13 with $t = 1$, so the random stopping time gives every record $2 \ln n$ times the guarantee of the first record.

One pass, no sampling. Each record is used once, at a fixed position. Several passes need the general Theorem 22 with several shifts; with random sampling, Altschuler & Talwar (2022) combine iteration with subsampling.

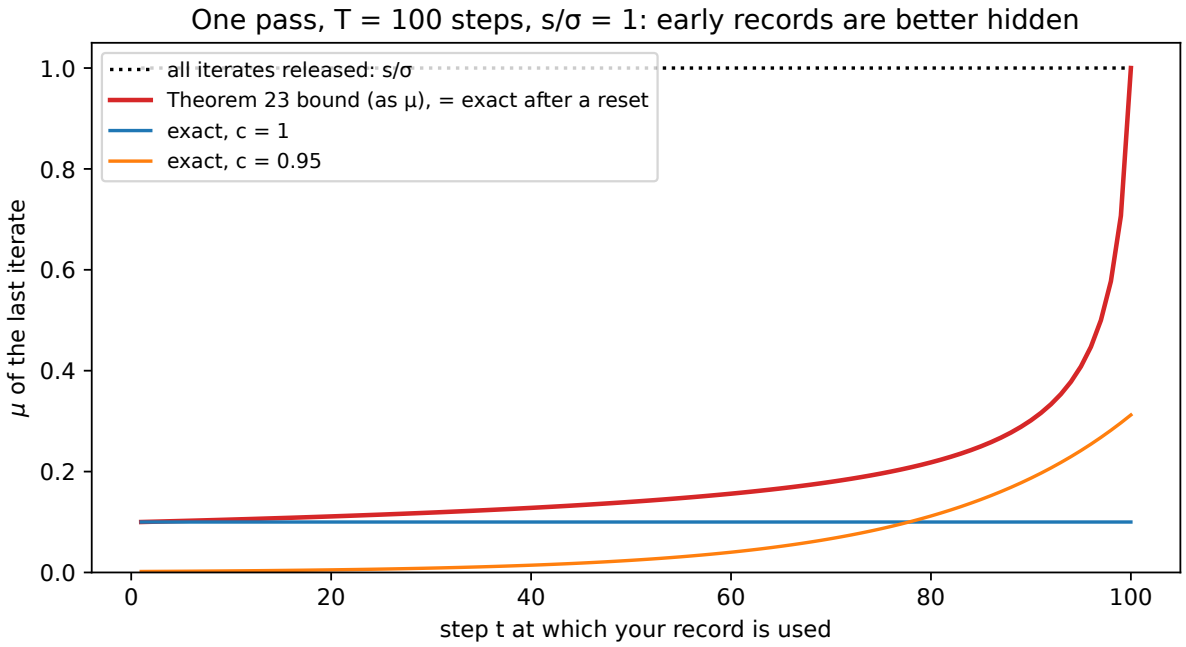

Figure 35.4.: The μ of the last iterate against the step t at which your record is used, for a one-pass run of $T = 100$ steps with per-step shift equal to the noise standard deviation ($s/\sigma = 1$). Releasing all iterates gives $\mu = 1$ for every record (dotted). Theorem 23 (red, as $\mu = 1/\sqrt{T-t+1}$) is exact when the run is reset just before step t; with $c = 1$ (blue) the earlier noise also helps, and with a strict contraction $c = 0.95$ (orange) the shift itself decays.

35.5.5. Example: a one-pass run over 10,000 records

Projected noisy SGD makes one pass over $n = 10{,}000$ records with noise multiplier $\tilde{\sigma} = 1$. An RDP curve becomes an (ε, δ) guarantee through Mironov's conversion: at each order α, the probability that the privacy loss exceeds ε is bounded by Markov's inequality applied to $e^{(\alpha-1)L}$, whose mean the RDP curve controls, and this gives $\varepsilon = \varepsilon(\alpha) + \frac{\ln(1/\delta)}{\alpha-1}$. The first term grows with

α and the second shrinks, so you minimize over the part's grid of orders. At $\delta = 10^{-5}$ the second term is $\ln(10^5)/(\alpha - 1) = 11.51/(\alpha - 1)$. Converting Equation 35.13 this way gives a different answer for each position.

The last record ($t = 10{,}000$) has $n - t + 1 = 1$ and gets $\varepsilon = 5.2985$. Its RDP curve is $\alpha/2$, the same as a single Gaussian mechanism with $\tilde{\sigma} = 1$, which is also what every record gets if all iterates are released. (That mechanism is a Gaussian pair with $\mu = 1$, and its exact ε, read from the $\delta(\varepsilon)$ curve of Fact 3, is 4.3772: the RDP conversion is not tight.) The record used 100 steps before the end ($t = 9901$) gets $\varepsilon = 0.4849$, and the record in the middle ($t = 5000$) gets $\varepsilon = 0.0707$. The first record gets $\varepsilon = 0.0481$, at the largest order $\alpha = 512$ of the grid. Its RDP curve is $\alpha/20{,}000$, so small ($\varepsilon(2) = 0.000100$) that the conversion term $\ln(1/\delta)/(\alpha - 1)$ stays as large as the RDP term even at the end of the grid: 0.0225 against $512/20{,}000 = 0.0256$ at $\alpha = 512$. A finer conversion from From RDP to (ε, δ) would give less.

The guarantee is per record and depends on position. A report must state the worst record's value, or randomize the order and the stopping time.

35.5.6. Check yourself

- Why does the theorem need the loss to be convex and smooth, with $\eta \leq 2/\beta$? *(So that each gradient step is a contraction. An expanding map could amplify a small shift faster than the noise can pay it off.)*
- If every iterate is released, what does the record at step 1 get? *(Only the noise of its own step: $\varepsilon(\alpha) = \alpha/(2\tilde{\sigma}^2)$, as for the last record. The later iterates reveal θ_1 directly.)*

35.6. Hidden state: privacy that stops growing

35.6.1. Context

Full-batch noisy GD uses every record at every step. Composition charges every step, so the RDP of T steps grows linearly in T. Amplification by iteration does not help by itself: with every step adding a fresh shift s, the payments of Theorem 22 must cover Ts in total, and the cheapest schedule pays s at every step, which is composition again. Yet if the parameters live in a bounded set, two runs can never be further apart than its diameter, however long they run. So the shift never has to exceed the diameter, and only the last stretch of steps can matter. Can the privacy loss of the last iterate then stop growing with T? Altschuler & Talwar (2022) show that it can.

35.6.2. Statement

The idea is to ignore everything that happened before some late step τ: at that point the two runs are somewhere inside the set, at most d_K apart, and only the steps after τ need to pay off that distance plus the new shifts. The cost then depends on how many steps are needed to pay, not on T.

Theorem 3.1 of Altschuler & Talwar (2022), in shape. For convex, G-Lipschitz, β-smooth losses on a convex set K of diameter d_K, learning rate $\eta \leq 2/\beta$, noise $\mathcal{N}(0, \sigma^2 I)$ added to the batch

gradient, any batch size B and T steps, noisy SGD releasing only the last iterate is (α, ε)-RDP with

$$\varepsilon \lesssim \frac{\alpha G^2}{n^2\sigma^2} \min\{T, \bar{T}\}, \qquad \bar{T} = \left\lceil \frac{d_K n}{G\eta} \right\rceil, \tag{35.15}$$

for α up to a threshold and $\sigma > 8\sqrt{2}G/B$; $\lesssim$ hides a constant, and $\lceil\cdot\rceil$ rounds up. Their Theorem 4.1 shows the shape is tight up to constants. The bound grows like composition until $\bar{T}$ and then stays flat.

The key lemma is their Proposition 3.2. It is Theorem 22 started at step τ instead of 0, with an initial shift of d_K instead of 0. In a contractive noisy iteration confined to a set of diameter d_K, with noise standard deviation σ_t at step t, for any $\tau < T$ and payments $a_{\tau+1}, \dots, a_T$ whose unpaid shift $z_t = d_K + \sum_{i=\tau+1}^{t}(s_i - a_i)$ stays non-negative and ends at $z_T = 0$,

$$D_\alpha(X_T \| X'_T) \le \sum_{t=\tau+1}^{T} \frac{\alpha a_t^2}{2\sigma_t^2}. \tag{35.16}$$

Specializing it to **full-batch noisy GD** with per-step shift s and per-step noise standard deviation σ (both in parameter units) gives the bound below. It takes the better of two strategies, starting the accounting at the beginning (cost Ts^2, composition) or m steps before the end (cost $(d_K + ms)^2/m$), each times $\frac{\alpha}{2\sigma^2}$. This specialization is our derivation, below; the paper proves Theorem 3.1 by a different route.

$$\varepsilon(\alpha) \le \frac{\alpha}{2\sigma^2} \min\left\{ Ts^2, \min_{m\in\{1,\dots,T\}} \frac{(d_K + ms)^2}{m} \right\} \le \frac{2\alpha d_K s}{\sigma^2} \quad \text{when } d_K/s \text{ is an integer.} \tag{35.17}$$

For other d_K/s the right-hand bound is $\frac{\alpha}{2\sigma^2}(4d_K s + s^2)$ (step 5).

35.6.3. Derivation

1. **Start the accounting late.** At step τ both runs lie in a set of diameter d_K, so they are at most d_K apart, and $D_\alpha^{(d_K)}(X_\tau \| X'_\tau) = 0$: shifting X_τ by at most d_K can turn it into X'_τ (couple the two runs and move each point onto its partner). This is the only place where boundedness enters.
2. **Run Theorem 22 from τ.** The induction of Theorem 22, started at τ with shift d_K and divergence 0 instead of shift 0, gives Proposition 3.2. Projections onto K are contractions (Section 35.5), so by Equation 35.12 they cost nothing.
3. **Pay evenly over the last $m = T - \tau$ steps.** The shift to pay off is the initial d_K plus s per step, $d_K + ms$ in total. The even schedule $a = (d_K + ms)/m$ pays s more than each step adds, so the unpaid shift falls linearly from d_K to 0 and $z_t \ge 0$ holds. It costs $m \cdot \frac{\alpha a^2}{2\sigma^2} = \frac{\alpha(d_K+ms)^2}{2m\sigma^2}$.
4. **Or start at the beginning.** With $\tau = 0$ both runs start at the same point, the starting shift is 0, and the even schedule over all T steps pays s per step: $\frac{\alpha T s^2}{2\sigma^2}$, exactly the composition of T Gaussian steps. Take the better of the two choices.
5. **Optimize m.** A short window means few payments, each large; a long window means more shift to pay. Expanding the square, $(d_K + ms)^2/m = d_K^2/m + 2d_K s + ms^2$, the sum of a term falling in m and one growing in m. Over real $m > 0$ it is minimized where the two balance, at $m = d_K/s$ (setting the derivative $-d_K^2/m^2 + s^2$ to 0), where it equals $d_K s + 2d_K s + d_K s = 4d_K s$. When d_K/s is an integer and $T \ge d_K/s$, that

m is allowed, so the bound never exceeds $\frac{\alpha}{2\sigma^2} \cdot 4d_K s = \frac{2\alpha d_K s}{\sigma^2}$, whatever T. Otherwise take $m = \lceil d_K/s \rceil$: writing $m = d_K/s + r$ with $0 < r < 1$, $d_K + ms = 2d_K + rs$, and $(d_K + ms)^2/m = 4d_K s + r^2 s^2/m < 4d_K s + s^2$. The bound reaches its plateau when the composition branch catches up with it, $Ts^2 = 4d_K s$, at $T = 4d_K/s$.

6. **Back to their parameters.** With $s = 2\eta G/n$ (the full-batch gradient is an average over n records, so replacing one moves it by at most $2G/n$) and noise $\eta\sigma$ in parameter space, the plateau is $\frac{2\alpha d_K \cdot 2\eta G/n}{\eta^2\sigma^2} = \frac{\alpha G^2}{n^2\sigma^2} \cdot \frac{4d_K n}{G\eta}$, the shape of Theorem 3.1 with $\bar{T} \propto d_K n/(G\eta)$.

35.6.4. Interpretation

Why the bounded domain caps the loss. Composition pays for every step because it assumes the adversary sees every iterate. The last iterate forgets: whatever happened before step $T - m$ is summarized by a starting point inside the set, and the starting points of the two runs differ by at most d_K. The last m noisy steps can hide that difference for a cost that does not depend on T.

The constant is loose. To see how loose, take a linear loss on $K = [0, 1]$, with $s = 0.01$ and $\sigma = 0.1$ per step. The two runs are then random walks drifting in opposite directions and projected onto the interval (the construction behind Altschuler & Talwar's lower bound). The script computes their D_2 on a grid of 1000 cells (500 cells give 0.3779 against 0.3786 at $T = 2000$, so the discretization error is small). Table 35.6 compares it with composition and with Equation 35.17. The walk's divergence flattens at 0.3786 after about 100 steps, the bound at 4.0000 after 400 steps (Figure 35.5, right). This walk is one pair of datasets with one starting point, so its divergence is a lower bound on the worst case: the shape of the bound is right, and its constant is at most $4.0000/0.3786 = 10.57$ times too large.

Strongly convex losses converge faster. A loss is λ-strongly convex when it curves upward at least as fast as $\frac{\lambda}{2}\|\theta\|^2$. Then each gradient step is a strict contraction by $1 - \eta\lambda$, so the shift shrinks by that factor every step even when nobody pays for it. The plateau is reached after about $1/(\eta\lambda)$ steps instead of $d_K n/(G\eta)$, with no diameter needed. Chourasia, Ye & Shokri (2021, Corollary 1) had shown earlier, by a different route, that for full-batch noisy GD (Langevin dynamics) the RDP of the last iterate is at most $\frac{\alpha S_g^2}{\lambda\sigma^2 n^2}(1 - e^{-\lambda\eta T/2})$ after T steps, where S_g is the sensitivity of the summed gradient and their noise is $\sqrt{2\eta}\sigma$ per step. As T grows the bracket tends to 1, so the bound levels off. Ye & Shokri (2022) extended this to mini-batch SGD, concurrently with Altschuler & Talwar. The next section checks their limit against an exact computation.

Only the last iterate. All these results need **only the last iterate to be released**. Checkpoints, logged intermediate models or a model released after each epoch break the argument, because the adversary then sees the run before it has forgotten, and you are back to composition.

Contractive steps. They also need **contractive steps**, which require convexity. For non-convex losses, Annamalai (2024) constructs a loss for which the last iterate of DP-SGD leaks as much as all iterates together, so no hidden-state amplification holds for all non-convex losses. Empirically, Nasr et al. (2021) found that their strongest attacks match the DP-SGD bound when the adversary sees every step or can craft gradients, and fall short of it when the adversary only sees the final model. That gap is an observation about their attacks, not a guarantee.

Do not report a hidden-state ε for deep learning.

Table 35.6.: D_2 of the last iterate of full-batch noisy GD on a linear loss over $K = [0, 1]$ ($d_K = 1$), with per-step shift $s = 0.01$ and noise $\sigma = 0.1$, by composition, by the bounded-domain bound, and computed numerically for the two projected random walks.

Steps T	10	100	400	1000	2000
Composition, $\alpha T s^2/(2\sigma^2)$	0.1000	1.0000	4.0000	10.0000	20.0000
Bounded-domain bound, Equation 35.17	0.1000	1.0000	4.0000	4.0000	4.0000
Projected random walks, numerical	0.0961	0.3693	0.3786	0.3786	0.3786

35.6.5. Example: two thousand steps on the unit interval

Take the setting of Table 35.6: diameter $d_K = 1$, $s = 0.01$, $\sigma = 0.1$, so $d_K/s = 100$ is an integer. Each composed step costs $\frac{\alpha s^2}{2\sigma^2} = \frac{2\times 0.0001}{2\times 0.01} = 0.01$ at $\alpha = 2$, so composition charges $0.01T$. Step 5 gives the plateau $2\alpha d_K s/\sigma^2 = 2\alpha \cdot \frac{0.01}{0.01} = 2\alpha$, which is 4.0000 at $\alpha = 2$, reached at $T = 4d_K/s = 400$ steps. After 2000 steps, composition charges 20.0000; the bounded-domain bound charges 4.0000, five times less, and for the hard instance of the projected random walks the value is below 0.4. Running ten times longer does not change the bound; under composition it would cost ten times more.

35.6.6. Check yourself

- Why does an unconstrained linear loss get no hidden-state amplification? *(Without a bounded set or a strict contraction, the runs drift apart by s per step forever: after T steps the means differ by Ts, the variances are $T\sigma^2$, and $\mu = Ts/(\sigma\sqrt{T}) = \sqrt{T}s/\sigma$, the same as composition. The next section computes this.)*
- A training pipeline saves a checkpoint every epoch and publishes the best one. Does the plateau apply? *(No. The adversary may see any of the checkpoints, so the analysis must cover all of them; the published model is selected using all of them.)*

35.7. An exact example: noisy GD on a quadratic

35.7.1. Context

All the results above are bounds. In one dimension, with a quadratic loss, each step of noisy GD is a linear map plus Gaussian noise, so the last iterate is Gaussian on both datasets and its privacy can be computed exactly with Fact 3. The computation shows the plateau directly, shows that it needs contraction, and gives a yardstick for the strongly convex bounds.

35.7.2. Statement

Consider the run $\theta_k = c\,\theta_{k-1} + b_k + \xi_k$, $\xi_k \sim \mathcal{N}(0, \sigma^2)$, for $k = 1, \dots, T$ from a fixed θ_0. Here c is the contraction factor, b_k is a data-dependent offset and ξ_k is the noise of step k. The offsets on D and D' differ by s at every step $k \geq t$ and agree before: your record enters at step t and stays. Unrolling the run, the last iterate is a weighted sum of all offsets and all noise draws, the step-k term weighted by c^{T-k}. So it is Gaussian with the same variance on both datasets, and by Fact 3 its μ is the weighted sum of the offset differences divided by the standard deviation of the weighted noise. The last iterate is exactly μ-GDP with

$$\mu_T = \frac{s}{\sigma} \cdot \frac{\sum_{k=t}^{T} c^{T-k}}{\sqrt{\sum_{j=0}^{T-1} c^{2j}}}, \qquad \text{and for } t = 1,\ c < 1: \qquad \lim_{T\to\infty} \mu_T = \frac{s}{\sigma}\sqrt{\frac{1+c}{1-c}}. \tag{35.18}$$

Releasing all iterates instead is $\sqrt{T-t+1}\,s/\sigma$-GDP. For $c = 1$ and $t = 1$ the two agree.

This is full-batch noisy GD on the quadratic loss $\ell(\theta; x) = \frac{\lambda}{2}(\theta - x)^2$, whose gradient is $\lambda(\theta - x)$. Averaged over the records, the gradient is $\lambda(\theta - \bar{x})$, where $\bar{x}$ is the mean of the records. So the step $\theta - \eta(\lambda(\theta - \bar{x}) + \text{noise})$ is $(1 - \eta\lambda)\theta + \eta\lambda\bar{x}$ plus noise: it has $c = 1 - \eta\lambda$ and offset $b = \eta\lambda\bar{x}$. Replacing one of n records by one that differs by Δx changes $\bar{x}$ by $\Delta x/n$, so $s = \eta\lambda\Delta x/n$. Starting the record at step $t > 1$ models a record that joins the training set late.

35.7.3. Derivation

1. **Unroll.** Substituting each step into the next, by induction on T, $\theta_T = c^T\theta_0 + \sum_{k=1}^{T} c^{T-k}(b_k + \xi_k)$: each step's offset and noise are multiplied by c once for every later step.
2. **The noise part** is a sum of independent Gaussians, so it is Gaussian with mean 0 and variance $\sigma^2 \sum_k c^{2(T-k)} = \sigma^2 \sum_{j=0}^{T-1} c^{2j}$, the same on D and D' (Fact 3).
3. **The mean part** differs between the datasets by $\sum_{k\geq t} c^{T-k} s$; the start θ_0 and the offsets before step t are the same in both runs and cancel.
4. **Gaussian pair.** By Fact 3 the pair is exactly μ-GDP with $\mu =$ (mean difference)/(standard deviation), which is Equation 35.18.
5. **The limit.** For $t = 1$ and $c < 1$, both sums are geometric: $\sum_{k=1}^{T} c^{T-k} = (1 - c^T)/(1 - c)$ and $\sum_{j=0}^{T-1} c^{2j} = (1 - c^{2T})/(1 - c^2)$. So $\mu_T = \frac{s(1-c^T)/(1-c)}{\sigma\sqrt{(1-c^{2T})/(1-c^2)}} \to \frac{s}{\sigma} \cdot \frac{\sqrt{1-c^2}}{1-c}$, since $c^T \to 0$. Writing $1 - c^2 = (1 - c)(1 + c)$, this is $\frac{s}{\sigma}\sqrt{\frac{(1-c)(1+c)}{(1-c)^2}} = \frac{s}{\sigma}\sqrt{\frac{1+c}{1-c}}$.
6. **Composition.** Releasing all iterates is $T - t + 1$ Gaussian mechanisms, each s/σ-GDP given the past (the offset shifts that step's output by s under noise σ), so by the composition rule of Fact 3 it is $\sqrt{T-t+1}\,s/\sigma$-GDP. For $c = 1$, every power of c is 1, and step 4 gives $\frac{(T-t+1)s}{\sigma\sqrt{T}}$, which for $t = 1$ is $\sqrt{T}s/\sigma$: hiding the state buys nothing without contraction.

35.7.4. Interpretation

Contraction is what forgets. With $c < 1$, the offset of step k reaches the end damped by c^{T-k}, while fresh noise keeps arriving. The signal saturates at the geometric limit $s/(1 - c)$ and the noise standard deviation at $\sigma/\sqrt{1 - c^2}$. With $c = 1$ both keep growing, the signal like T and the noise standard deviation like $\sqrt{T}$, so μ grows like $\sqrt{T}$ (Figure 35.5, left).

The plateau arrives after about $1/(1-c)$ steps. That is how long it takes c^T to become small. With $c = 0.9$, μ is 4.3588 at $T = 100$ and its limit is $\sqrt{1.9/0.1} = \sqrt{19} = 4.3589$; with $c = 0.99$ it is 9.6101 at $T = 100$, 14.1061 at $T = 1000$, and the limit is $\sqrt{1.99/0.01} = \sqrt{199} = 14.1067$. In general, a gradient step with $\eta = 1/\beta$ on a λ-strongly convex, β-smooth loss contracts by $c = 1 - \lambda/\beta$, so $1/(1-c)$ is the condition number β/λ, which is the threshold, up to logarithmic factors, that Altschuler & Talwar give for strongly convex losses.

Recent records are hardly hidden. A record that joins at step 41 of 50, with $c = 0.9$ and $s/\sigma = 1$, gets $\mu = 2.8391$ against $\sqrt{10} = 3.1623$ for releasing its 10 steps: only the last steps carry its signal, and a little earlier noise helps.

How tight is the strongly convex bound? In this example the limit of Chourasia, Ye & Shokri's Corollary 1, translated into the s, σ and c of this section, becomes $\frac{2\alpha s^2}{(1-c)\sigma^2}$, while the exact limiting RDP is $\alpha\mu^2/2$ (Fact 3) with the limiting μ of Equation 35.18, that is, $\frac{\alpha}{2} \cdot \frac{s^2}{\sigma^2} \cdot \frac{1+c}{1-c}$. Their ratio is $\frac{1+c}{4}$: at $c = 0.99$, $\alpha = 2$ and $s/\sigma = 1$ the exact value is $199 = 199.0000$ and the bound $4/0.01 = 400.0000$, a ratio of $1.99/4 = 0.4975$. The bound is within a factor of about 2.

A check by simulation. 200,000 runs with $c = 0.9$, $T = 50$ and $s/\sigma = 1$ give an estimated μ of 4.3381 against the exact 4.3365.

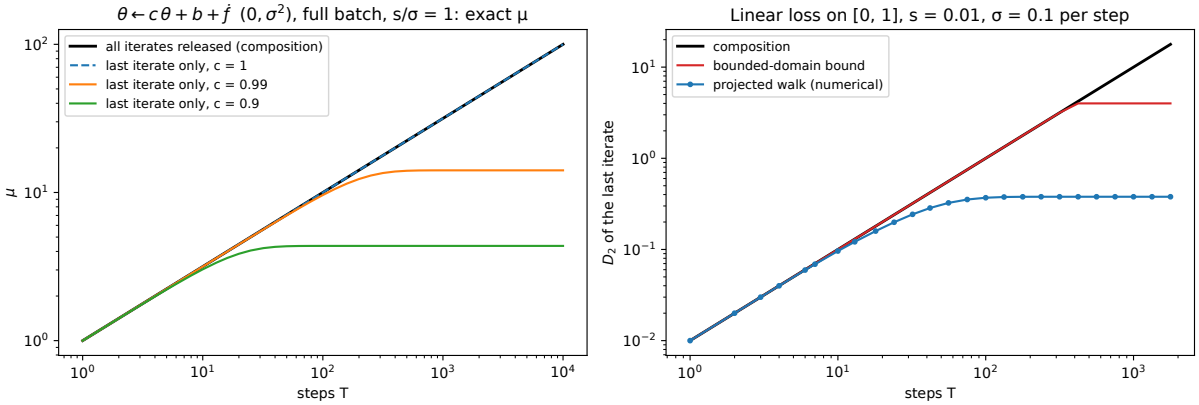

Figure 35.5.: Left: the exact μ of the last iterate of one-dimensional full-batch noisy GD with per-step shift equal to the noise standard deviation, against the number of steps T, for $c = 1$ (dashed, on top of the black composition line), $c = 0.99$ and $c = 0.9$. Right: D_∞ of the last iterate for a linear loss on $[0, 1]$ with $s = 0.01$ and $\sigma = 0.1$ per step: composition, the bounded-domain bound Equation 35.17, and the numerical value for two projected random walks.

35.7.5. Example: ten thousand steps with noise multiplier 10

Run $T = 10{,}000$ steps of full-batch noisy GD with noise multiplier $\sigma/s = 10$ on a quadratic with $c = 0.99$. Releasing every iterate is $\mu = \sqrt{10{,}000}/10 = 10.0000$-GDP, which is $\varepsilon = 91.8173$ at $\delta = 10^{-5}$ (from the $\delta(\varepsilon)$ curve of Fact 3): no guarantee at all. Releasing only the final model is, after this many steps, at the limit of Equation 35.18, $\mu = 0.1 \times 14.1067 = 1.4107$-GDP, $\varepsilon = 6.5534$. The noise is the same; the difference is entirely in what the adversary is allowed to see. Compare the DP-SGD running example of this part (under add/remove neighbours), where subsampling

rather than hidden state does the work: there each step uses only 1% of the data, which is why noise multiplier 1 suffices.

35.7.6. Check yourself

- In Equation 35.18, why does the start θ_0 not matter? *(It enters both runs as the same constant $c^T\theta_0$, so it cancels in the mean difference and adds no variance.)*
- Doubling the noise σ in this example: what happens to the plateau μ? *(It halves: μ is proportional to s/σ at every T.)*

35.8. Code: check every number by computation

The script code/shuffling_iteration.py computes every number in this chapter and draws every figure. Shuffled randomized response and the clone pair are computed exactly as discrete distributions in log space, with $\delta(\varepsilon)$ read from sorted prefix sums (Fact 1). The iteration results are closed forms for Gaussian pairs, checked by Monte Carlo, plus one grid computation for the projected random walks. From the repository root:

```
uv run python code/part04-privacy-accounting/shuffling_iteration.py
```

Output (seed 0), summarized in Table 35.7:

Table 35.7.: The script's output with the default seed.

Experiment	Result
Shuffled randomized response, $n = 3$, $\varepsilon_0 = \ln 3$	$\delta(0.5) = 0.1900$ against 0.3378 for one report; simulation within 0.0015 of the exact count distribution
Worst dataset pair, all m at $n = 1000$, $m \le 30$ at $n = 10^4, 10^5$	The pair where the others all hold 0 is the worst for $\varepsilon_0 = 1, 4$ at $n = 1000$, and within 4.5×10^{-5} of the largest ε found everywhere
Clone decomposition, $\varepsilon_0 = \ln 3$	Clone part $(0.1667, 0.1667)$, leftover $(0.875, 0.125)$
Shuffling at $\delta = 10^{-6}$	Table 35.4; numeric clone bound 1.44 to 2.36 times the exact value
Shift reduction, $z = 1$, $\sigma = 1$, $\alpha = 2$	Even schedule equals the exact D_2 at $T = 1, 2, 4, 10$
One pass over 10^4 records, $\tilde{\sigma} = 1$	ε from 0.0481 (first record) to 5.2985 (last) at $\delta = 10^{-5}$
Bounded domain, $d_K = 1$, $s = 0.01$, $\sigma = 0.1$	Table 35.6; plateau 4.0000 against 0.3786 for the projected random walks
Quadratic, $s/\sigma = 1$	Limits 4.3589 ($c = 0.9$) and 14.1067 ($c = 0.99$); Monte Carlo 4.3381 against 4.3365

tests/test_shuffling_iteration.py checks that the output still matches.

What to take from it. Shuffling amplifies like $1/\sqrt{n}$, and the constant matters: the exact value for binary randomized response is about half the best general bound and a quarter to an eighth of the closed form. Since **exact computations are cheap** (the count distributions have $n+1$ points, and even $n = 10^5$ takes milliseconds), do not settle for a closed form when the exact value is at hand. On the iteration side, **iteration amplifies only what is hidden**: the same noisy run is worth $\mu = 10$ or $\mu = 1.41$ depending on whether intermediate iterates are released. And **hidden-state gains need contraction or a bounded domain**; without either, the last iterate is as revealing as the whole trajectory.

35.10. Cheat sheet

Table 35.8 collects the results. ε_0 is the local level, n the number of users or records, $\tilde{\sigma}$ the noise multiplier, s and σ the per-step shift and noise in parameter units, c the contraction factor, d_K the diameter. All use replace-one neighbours.

Table 35.8.: The results of this chapter.

Result	Statement	Tightness
Shuffled binary randomized response	Count pair Equation 35.5; $\mu \approx 2\sinh(\varepsilon_0/2)/\sqrt{n}$	Exact for the pair where the others hold 0, within 10^{-4} of the worst pair found; normal approximation fails for few 1-reports
Clone reduction (Thm 3.2)	Output is a post-processing of $(A+\Delta, C-A+1-\Delta)$ vs $(A+1-\Delta, C-A+\Delta)$, $C \sim \mathrm{Bin}(n-1, e^{-\varepsilon_0})$	Numeric: 1.44–2.36 × exact for binary randomized response ($\approx 2/(1+e^{-\varepsilon_0})$ with many clones)
Clone bound (Thm 3.1)	Equation 35.7, needs $\varepsilon_0 \le \ln \frac{n}{16\ln(2/\delta)}$	4.47–7.55 × exact
Shift reduction	$D_\alpha^{(z)}(X+Z\Vert X'+Z) \le D_\alpha^{(z+a)}(X\Vert X') + \frac{\alpha a^2}{2\sigma^2}$	Exact for translations from a common point
One-pass noisy SGD (Thm 23)	$\varepsilon_t(\alpha) = \frac{\alpha}{2\tilde{\sigma}^2(n-t+1)}$ for the record at step t, last iterate only	Exact after a reset; loose for strict contractions
Bounded domain (from Prop. 3.2)	$\varepsilon(\alpha) \le \frac{\alpha}{2\sigma^2}\min\{Ts^2, \min_m(d_K + ms)^2/m\} \le \frac{2\alpha d_K s}{\sigma^2}$ (d_K/s an integer)	Right shape; constant at most about 10 × too large in the example
Quadratic, exact	μ_T of Equation 35.18; limit $\frac{s}{\sigma}\sqrt{\frac{1+c}{1-c}}$	Exact; strongly convex bound within a factor $\frac{4}{1+c}$

Rules of thumb

- Shuffling turns ε_0-local into central $\varepsilon \approx$ (a constant growing like $e^{\varepsilon_0/2}$) $\cdot \sqrt{\ln(1/\delta)/n}$. It never lowers the pure-DP level.

- For binary randomized response, compute the exact value. For other randomizers, compute the numeric clone bound; use the closed form only to reason.
- Amplification by iteration needs contractive steps (convex, smooth, $\eta \leq 2/\beta$) and a hidden state. The record used last gets no amplification.
- With a bounded domain or strong convexity, the last iterate's privacy plateaus; without them it grows like composition.
- Never claim hidden-state privacy for non-convex training or when checkpoints are released.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

36. Adaptive composition: filters, odometers and individual accounting

36.1. Why this matters

A composition theorem tells you how much privacy a sequence of steps loses in total, given what each step loses. Every composition theorem so far assumes that the privacy parameters of the steps are fixed before the run starts. The mechanisms themselves may be chosen adaptively, after seeing earlier outputs, as in Composition (Section 21.5), but the list of per-step budgets $\varepsilon_1, \dots, \varepsilon_k$, and the number of steps k itself, must be known in advance. Real systems break this assumption in three ways:

- **Data-dependent stopping.** You train until the validation loss stops improving, or an analyst keeps asking queries until the answer looks clear. The number of steps is a function of the outputs.
- **Adaptive noise.** You lower the noise when training stalls, or spend more on a query whose first answer was surprising. Each ε_t depends on the earlier outputs.
- **Records that contribute differently.** Training with differential privacy (DP) usually means stochastic gradient descent (SGD) with clipped per-record gradients and Gaussian noise, called DP-SGD. A record whose clipped gradient is small moves the noisy sum less than the clip allows. Its actual privacy cost per step is smaller than the worst case, and how much smaller depends on the current model, which depends on the earlier outputs.

In each case the per-step parameters are random variables: you only learn them as the run goes on. It is tempting to wait until the run ends, plug the values that actually occurred into a fixed-parameter theorem, and report the result. That does not work. Section 36.3 shows an analyst who makes the plug-in advanced composition bound fail with probability more than three times its nominal $\delta = 0.01$, just by choosing when to stop.

36.1.1. The one idea: a running budget needs a theorem about stopping

Once the parameters are adaptive, the question "what is the ε of these k steps?" no longer makes sense, because neither k nor the ε_t are known in advance. It splits into two questions, and each has its own object. A **privacy filter** answers "may I run one more step without exceeding the budget B?" It is a stopping rule, and its guarantee is a fixed (ε, δ) for whatever transcript the stopped run produces. A **privacy odometer** answers "how much have I spent so far?" It is a running bound, like the odometer of a car, and because you may stop whenever you like, it must hold at every step simultaneously.

Both need theorems of their own, and the tool behind all of them is the same. Track a quantity built from the privacy loss that, on average, never goes up from one step to the next: a

supermartingale, a process whose expected next value, given everything seen so far, is at most its current value. A fair betting game is the picture to keep in mind: your expected wealth after the next bet equals your wealth now. The key fact is that stopping such a process at a time of your choosing cannot raise its mean, so a clever stopping rule cannot manufacture privacy loss. In Rényi differential privacy (RDP), which measures each step by a curve $\varepsilon_t(\alpha)$ of Rényi divergences indexed by an order $\alpha > 1$, this is almost free. If the RDP spends at a fixed order α add up to at most B on every path, the run is (α, B)-RDP, exactly as if the parameters had been fixed. That one fact gives a filter with the constants of advanced composition, an odometer that costs only a union bound over orders, and per-record accounting in DP-SGD. Table 36.1 lists the results.

Table 36.1.: The results of this chapter and where each is used.

Result	Where it is used
Plugging realized ε_t into advanced composition fails under data-dependent stopping	Why "report advanced composition of what you spent" is not a valid odometer
Filters for pure DP: basic, Rogers et al., Whitehouse et al.	Interactive query systems with a global budget; choosing ε_t on the fly
The Rényi filter	Any RDP accountant with adaptive noise or adaptive stopping; the base of the next two rows
Odometers, and why they cost more	Early stopping; reporting the privacy spent so far
Individual (per-record) accounting in DP-SGD	Dropping records once their own budget is spent; per-record ε and its caveats

What you need. The privacy loss of an adaptive composition is a sum of conditional losses (Equation 21.4 in Composition), and advanced composition is Azuma's inequality applied to that sum (Equation 21.9). Azuma's inequality and martingales are in Concentration. From this part you need RDP, its composition and Mironov's conversion (Equation 29.10, Equation 29.17 in Rényi DP), the RDP curves of randomized response and the Gaussian mechanism (Equation 29.9, Equation 29.7), and two facts from Concentrated differential privacy: an ε-DP step is $(\alpha, \alpha\varepsilon^2/2)$-RDP for every α (Equation 31.6), and ρ-zero-concentrated differential privacy (ρ-zCDP) converts to $(\rho + 2\sqrt{\rho \ln(1/\delta)}, \delta)$-DP (Equation 31.10). Each is restated below where it is used.

Notation. Two datasets are **neighbours** if they differ in one person's record. A run has steps $t = 1, 2, ...$; step t releases an output y_t, using a mechanism chosen from the earlier outputs $y_{<t} = (y_1, \dots, y_{t-1})$. $P = M(D)$ and $Q = M(D')$ are the distributions of the whole transcript on two neighbours D and D'. The probability (or density) that step t outputs y_t after the history $y_{<t}$ is $P_t(y_t \mid y_{<t})$ on D and $Q_t(y_t \mid y_{<t})$ on D'. The **privacy loss** of an output is the log of how much likelier it is on D than on D': positive when it favours D, negative when it favours D'. The conditional loss of step t is therefore $L_t = \ln \frac{P_t(y_t|y_{<t})}{Q_t(y_t|y_{<t})}$, and the loss after t steps is $L_{1:t} = L_1 + \cdots + L_t$. The parameter ε_t (or $\varepsilon_t(\alpha)$ for RDP) may depend on the history $y_{<t}$ but not on the output y_t it is about to price: it is **predictable**, known just before the step runs. Probabilities and expectations are under P unless written otherwise. Randomized response at level ε reports a person's bit truthfully with probability $e^\varepsilon/(1 + e^\varepsilon)$ and flips it otherwise.

36.2. Toolkit: stopping a supermartingale

Each derivation below reuses three facts. The first says that stopping early does not change how you compute the loss. The second says that stopping early cannot raise the mean of a supermartingale. The third turns the second into a bound on the whole path of the process. The first is Lemma 21.2 of Composition, restated for a stopped run; the other two are proved here.

36.2.1. Fact 1 — The loss of a stopped run is the sum of the losses of the steps it ran

The probability of a whole transcript is built one step at a time: the probability of y_1, times the probability of y_2 given y_1, and so on. This is the chain rule of probability. So the transcript $(y_1, \dots, y_t)$ has density $\prod_{j \le t} P_j(y_j \mid y_{<j})$ under P and the same product of Q_j under Q. The ratio of the two products is the product of the step-by-step ratios, and the logarithm turns that product into a sum, so $L_{1:t} = \sum_{j \le t} L_j$ (Equation 21.4).

Now let the run stop at a random time T that is decided from the outputs alone. The stopped transcript $(y_1, \dots, y_T)$ still has density $\prod_{j \le T} P_j$. The reason is that the decision to stop after y_T is a function of $y_{\le T}$: given those outputs, it happens with probability 1 or 0, and that probability is the same under P and Q. A factor that is equal in the numerator and the denominator cancels from the ratio. So the loss of the stopped run is $L_{1:T}$, the sum of the losses of the steps it ran.

36.2.2. Fact 2 — Optional stopping: a stopped supermartingale keeps its mean at most where it started

Think of N_t as your wealth after t bets in a game that is fair or unfavourable to you. Each bet, on average, leaves your wealth where it was or lowers it. You may decide when to quit, looking at everything that has happened, but not at the future. The fact says that no such quitting rule can make your expected final wealth larger than your starting wealth.

In symbols, a process $N_0, N_1, \dots$ with N_t a function of $y_{\le t}$ is a **supermartingale** if $\mathbb{E}[N_t \mid y_{<t}] \le N_{t-1}$ for every t: given the history, the expected next value is at most the current one. It is a **martingale** if equality holds, the fair game. A **stopping time** T is a random step such that the event $\{T \ge t\}$, "the run takes step t", is decided by $y_{<t}$: you decide whether to take a step before seeing its result. If $T \le n$ for a fixed n, then

$$\mathbb{E}[N_T] \le \mathbb{E}[N_0]. \tag{36.1}$$

Proof. The idea is to write the stopped process as a running total of the increments it actually collects, and to show that each collected increment has non-positive mean. Write $T \wedge t = \min(T, t)$ for the time the stopped process has reached by step t.

1. **Write the stopped process as a sum of increments.** Up to step t, the stopped process gains the increment $N_t - N_{t-1}$ only if the run takes step t, that is if $T \ge t$. So $N_{T \wedge t} = N_{T \wedge (t-1)} + \mathbf{1}[T \ge t](N_t - N_{t-1})$, where the indicator $\mathbf{1}[T \ge t]$ is 1 when the run takes step t and 0 otherwise.

2. **Each collected increment has non-positive mean.** The indicator is decided by $y_{<t}$, so once you condition on $y_{<t}$ it is a known constant and comes out of the conditional expectation: $\mathbb{E}[\mathbf{1}[T \geq t](N_t - N_{t-1}) \mid y_{<t}] = \mathbf{1}[T \geq t](\mathbb{E}[N_t \mid y_{<t}] - N_{t-1}) \leq 0$, because the bracket is non-positive by the supermartingale property. This is where it matters that the stopping decision does not look at y_t.
3. **Add up the steps.** Take expectations and sum over $t = 1, \ldots, n$. Each step adds a non-positive amount to the mean, so $\mathbb{E}[N_{T \wedge n}] \leq \mathbb{E}[N_0]$. Since $T \leq n$, $T \wedge n = T$.

Within a fixed horizon, then, no rule for when to quit turns a fair coin game (N_t = your wealth) into a winning one; this is the reason a filter works. The horizon matters in general: with unlimited time and unlimited credit, "quit when you are one ahead" wins a fair coin game with probability 1, because the walk eventually reaches +1, at the price of arbitrarily deep debt along the way. For the non-negative processes used below ($N_t \geq 0$, so no debt) the horizon can be dropped. If T may be infinite, apply Equation 36.1 to $T \wedge n$ and let $n \to \infty$: $N_{T \wedge n} \to N_T$ on $\{T < \infty\}$, and Fatou's lemma (the mean of a limit of non-negative variables is at most the limit of the means) gives $\mathbb{E}[N_T \mathbf{1}[T < \infty]] \leq \mathbb{E}[N_0]$. The three-step table in Section 36.5 walks through the computation outcome by outcome.

36.2.3. Fact 3 — Ville's inequality: a supermartingale rarely ever gets large

Markov's inequality says that a non-negative variable with mean 1 is at least c with probability at most $1/c$. Applied to N_n at one fixed time n, it bounds the chance of being large at that time. Ville's inequality says the same bound holds for the chance of being large at *any* time up to n. The reason is Fact 2: stop the first time the process reaches c. That is a legitimate stopping rule, so the stopped value still has mean at most 1, and it is at least c on every path that ever got there. For example, in a fair game you start with wealth 1, so the chance that your wealth ever reaches 10 is at most 1/10, however long you play.

If $N_t \geq 0$ is a supermartingale with $N_0 = 1$, then for every $c > 0$ and every horizon n,

$$\Pr\left[\exists\, t \leq n : N_t \geq c\right] \leq \frac{1}{c}. \tag{36.2}$$

Proof.

1. **Stop at the first crossing.** Let T be the first t with $N_t \geq c$, or n if there is none. Whether $T \geq t$ depends only on $N_1, \ldots, N_{t-1}$ (it means none of them reached c), so T is a stopping time bounded by n.
2. **The stopped process keeps its mean.** By Fact 2 (Equation 36.1), $\mathbb{E}[N_T] \leq N_0 = 1$.
3. **Apply Markov's argument to the stopped value.** On the event that the process reaches c by time n, the run stopped there, so $N_T \geq c$; elsewhere $N_T \geq 0$. So N_T is at least c times the indicator of that event, and taking means, $c \Pr[\exists\, t \leq n : N_t \geq c] \leq \mathbb{E}[N_T] \leq 1$.

The events $\{\exists\, t \leq n : N_t \geq c\}$ grow with n, and their union is $\{\exists\, t : N_t \geq c\}$, so the same bound holds with no horizon at all. This is Markov's inequality, but for the whole path at once instead of one fixed time, and at no extra cost. It is the tool for odometers.

36.3. Why adaptively chosen parameters break the usual theorems

36.3.1. Context

Advanced composition says that k steps of ε-DP, with k and ε fixed, have privacy loss at most $\varepsilon\sqrt{2k\ln(1/\delta)} + k\varepsilon\tanh(\varepsilon/2)$ except with probability δ (Equation 21.17). The first term is the typical spread of a sum of k bounded losses, the second is their mean. A tempting shortcut for adaptive runs is to apply it **ex post**: stop whenever you like, then report advanced composition of the parameters you actually used. Rogers, Roth, Ullman & Vadhan (2016) showed that this shortcut is not valid, and that a correct running bound must be larger. The problem is the choice of the stopping time: a bound that fails with probability δ at each fixed time can fail far more often at a time chosen by looking at the outputs.

36.3.2. Statement

The two objects of this chapter are defined by Rogers et al. (2016); the form below follows Whitehouse, Ramdas, Rogers & Wu (2023). Let each step be ε_t-DP conditionally on the past, meaning that whatever the history $y_{<t}$, the mechanism run at step t is ε_t-DP, with ε_t predictable.

A **privacy filter** with budget (ε_g, δ) is a rule that, before each step, looks at the parameters $\varepsilon_1, \dots, \varepsilon_t$ so far, including the one about to run, and says *continue* or *halt*. It is valid if the stopped run $y_{1:T}$ is (ε_g, δ)-DP for every analyst, however the analyst picks the steps and their parameters.

A **privacy odometer** with confidence δ is a sequence of functions $U_t(\varepsilon_1, \dots, \varepsilon_t)$, a running bound computed from the parameters spent so far. It is valid if, for every analyst and every pair of neighbours, the probability that the loss ever exceeds the running bound is at most δ:

$$\Pr\left[\exists\, t : L_{1:t} > U_t\right] \le \delta. \tag{36.3}$$

The "there exists a t" is the point. Because you may stop at any time, the bound you report at the time you stop is only safe if it holds at all times at once.

The plug-in odometer fails. Let every step be randomized response with $\varepsilon = 0.1$ on the same person's bit, and let $U_t = t\varepsilon\tanh(\varepsilon/2) + \varepsilon\sqrt{2t\ln(1/\delta)}$, advanced composition of the realized parameters. For each fixed t, $\Pr[L_{1:t} > U_t] \le \delta$. But an analyst who stops the first time $L_{1:t} > U_t$ makes the bound fail with the probability in Table 36.2, which exceeds δ and keeps growing with the horizon.

Table 36.2.: Exact probability that randomized response with $\varepsilon = 0.1$ crosses the plug-in advanced composition bound by step n, computed by dynamic programming over the loss. The last column is the largest probability of exceeding the bound at a single fixed step, over every $t \le 1000$, and the step where it occurs.

Horizon n	10	100	1000	10,000	worst single fixed $t \le 1000$
$\delta = 0.05$: $\Pr[\exists\, t \le n : L_{1:t} > U_t]$	0.0110	0.0575	0.1004	0.1424	0.0110 ($t = 17$)
$\delta = 0.01$: $\Pr[\exists\, t \le n : L_{1:t} > U_t]$	0.0000	0.0090	0.0202	0.0318	0.0016 ($t = 21$)
$\delta = 10^{-5}$: $\Pr[\exists\, t \le n : L_{1:t} > U_t]$	0	3.12×10^{-6}	1.80×10^{-5}	3.69×10^{-5}	8.18×10^{-7} ($t = 758$)

36.3.3. Derivation

The argument has two halves. The first checks that the plug-in bound is a correct bound at every fixed time. The second shows that an analyst who stops on the data turns those correct fixed-time bounds into a wrong running bound.

The fixed-t bound holds.

1. **The loss is a walk.** Take a person whose bit is 1 in D and 0 in D'. Each randomized-response report of 1 has probability $e^\varepsilon/(1+e^\varepsilon)$ on D and $1/(1+e^\varepsilon)$ on D', so its loss is $\ln e^\varepsilon = +\varepsilon$, and a report of 0 has loss $-\varepsilon$. Under D the loss is $+\varepsilon$ with probability $e^\varepsilon/(1+e^\varepsilon)$, so its mean is $\varepsilon(\frac{e^\varepsilon}{1+e^\varepsilon} - \frac{1}{1+e^\varepsilon}) = \varepsilon\frac{e^\varepsilon-1}{e^\varepsilon+1} = \varepsilon\tanh(\varepsilon/2)$, which is $0.1 \times \tanh(0.05) = 0.004996$ for $\varepsilon = 0.1$ (step 3 of Section 21.1). The total loss $L_{1:t}$ is a random walk that moves up or down by ε at each step, with a slight upward drift.
2. **Centre it.** Subtract the drift: $M_t = L_{1:t} - t\varepsilon\tanh(\varepsilon/2)$. Each step adds a term with mean zero given the past, so M_t is a martingale, and its increments lie in an interval of length 2ε (from $-\varepsilon$ to $+\varepsilon$, shifted by the mean).
3. **Azuma.** Azuma's inequality (Concentration) says that a martingale with t increments, each confined to an interval of length ℓ, exceeds s with probability at most $\exp(-2s^2/(t\ell^2))$. With $\ell = 2\varepsilon$ this is $\Pr[M_t \ge s] \le \exp(-2s^2/(4t\varepsilon^2))$. Setting this to δ and solving, $s^2 = 2t\varepsilon^2\ln(1/\delta)$, so $s = \varepsilon\sqrt{2t\ln(1/\delta)}$. Adding the drift back, $\Pr[L_{1:t} > U_t] \le \delta$ at each fixed t. The exact probabilities are smaller still: over every $t \le 1000$ the largest is 0.0110 (at $t = 17$) for $\delta = 0.05$, because Azuma assumes the worst variance an increment in that interval could have.

Stopping when ahead breaks it.

4. **The analyst's rule.** Run steps until $L_{1:t} > U_t$, then stop. The analyst sees only outputs, and $L_{1:t}$ is a function of them (it is ε times the number of reports of 1 minus the number of reports of 0), so this is a legitimate stopping rule: it decides whether to continue from what has already been released.

5. **The event the odometer must control.** At the stopping time T, the claim "$L_{1:T} \le U_T$" fails exactly when the walk crossed the boundary at some $t \le n$, because that is when the analyst stops. So the failure probability is the crossing probability $\Pr[\exists\, t \le n : L_{1:t} > U_t]$, not the fixed-$t$ probability. The first is a probability over the whole path and can be much larger than the largest of the second.
6. **Compute it exactly.** $L_{1:t}/\varepsilon$ moves on the integers by ± 1. Propagate its distribution step by step, and at each t remove the probability mass that sits above U_t/ε, since those paths have crossed and stopped. The total removed mass is the crossing probability (Table 36.2).
7. **It tends to 1.** The boundary sits $\varepsilon\sqrt{2t\ln(1/\delta)}$ above the mean, a fixed multiple of $\sqrt{t}$. The centred steps take values $\pm\varepsilon$ minus the mean $\varepsilon\tanh(\varepsilon/2)$, so their variance is the mean square minus the squared mean, $\varepsilon^2 - \varepsilon^2\tanh^2(\varepsilon/2) = \varepsilon^2/\cosh^2(\varepsilon/2)$, and their standard deviation is $\varepsilon\,\mathrm{sech}(\varepsilon/2)$. The law of the iterated logarithm (a cited fact; see Durrett in the References) says how far a random walk reaches along its whole path: for any $\xi > 0$, the centred walk exceeds $(1-\xi)\,\varepsilon\,\mathrm{sech}(\varepsilon/2)\sqrt{2t\ln\ln t}$ infinitely often with probability 1. That curve grows slightly faster than any fixed multiple of $\sqrt{t}$, because of the slowly growing $\ln\ln t$. Since $\ln\ln t$ eventually exceeds $\ln(1/\delta)/\mathrm{sech}^2(\varepsilon/2)$, the walk crosses the boundary with probability 1, and the crossing probability by step n tends to 1 as $n \to \infty$.
8. **Every odometer pays for it.** Rogers et al. (2016, Theorem 6.1) turn this into a lower bound: no valid odometer can exceed the mean term by only $o(\sqrt{\sum_t \varepsilon_t^2\,\ln(\ln n/\delta)})$, that is, by an amount that becomes negligible next to that square root. Their construction is this one, stop when ahead, with n steps of $\varepsilon = 1/n$. So the price is an extra $\ln\ln n$ inside the logarithm, where a fixed-time bound has $\ln(1/\delta)$ alone.

36.3.4. Interpretation

The theorem was never wrong; its use was. Advanced composition bounds the loss at a time fixed in advance. A data-dependent time is a different random variable, and an analyst who stops when the loss happens to be high selects exactly the paths where the bound fails.

Fixed-t bounds have slack, but not enough to absorb this. At $\delta = 0.05$ the plug-in bound fails at a single time $t \le 1000$ with probability at most 0.0110, but over 10^4 steps with probability 0.1424. A valid odometer must pay for the union over times, which, by step 8, costs at least an extra $\ln\ln n$ inside the logarithm (Rogers et al., Theorem 6.1).

A small δ shrinks the price, but not the failure. Rogers et al. point out that for δ far below $1/n$, $\ln(\ln n/\delta) = \ln(1/\delta) + \ln\ln n$ is $\ln(1/\delta)$ plus a small additive term, so a valid odometer costs little more than the fixed-time bound. The plug-in bound is still invalid there: at $\delta = 10^{-5}$ it is crossed by step 10^4 with probability 3.69×10^{-5}, 3.69 times δ (Table 36.2).

Filters are different. A filter fixes the budget in advance and only asks whether the next step fits, so there is no running claim for the analyst to catch out at a bad moment. That question turns out to be answerable with no $\ln\ln$ loss (Section 36.4). So filters and odometers are genuinely different objects once parameters are adaptive, which they are not when parameters are fixed.

36.3.5. Example

With $\delta = 0.01$, the plug-in bound after $t = 100$ steps is the mean term plus the spread term: $100 \times 0.004996 + 0.1\sqrt{200\ln 100} = 3.534$. Figure 36.1 (left) shows typical runs. Most never come

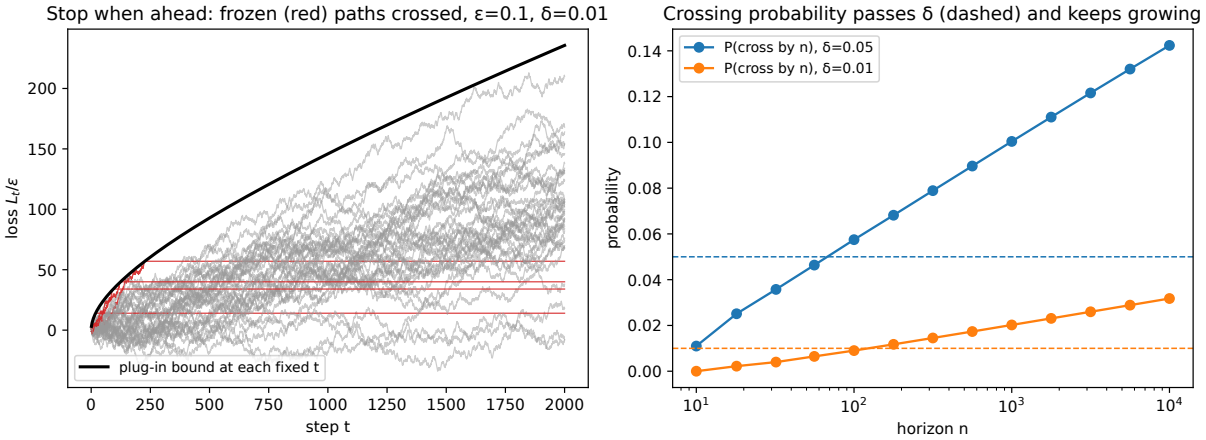

Figure 36.1.: Left: forty runs of randomized response with $\varepsilon = 0.1$, the loss in units of ε, and the plug-in advanced-composition bound at $\delta = 0.01$. An analyst who stops at the first crossing freezes the red paths there. Right: the exact probability that the bound is crossed by step n, for $\delta = 0.05$ and 0.01 (dashed lines); it passes δ and keeps growing.

near the boundary, but a few cross it early, where it is narrow because $\sqrt{t}$ is still small, and the analyst freezes them there. By $n = 10^4$, a fraction 0.0318 of runs have crossed (Table 36.2), so a report "$\varepsilon = U_T$ with $\delta = 0.01$" is wrong $0.0318/0.01 = 3.18$ times as often as it claims. At $\delta = 0.05$ the crossing probability reaches 0.1424, $0.1424/0.05 = 2.85$ times δ.

36.3.6. Check yourself

- Basic composition, $|L_{1:t}| \le \sum_{j \le t} \varepsilon_j$, does not suffer from this problem. Why? *(It holds for every output, not with high probability, so there is no bad event for the stopping rule to select. Summing realized parameters is a valid odometer and filter for pure DP, as Section 21.5 notes.)*
- Is the stop-when-ahead analyst unrealistic, since it needs the privacy loss? *(No. Here the loss is a function of the outputs, and in general an analyst can stop on any statistic correlated with it, such as "the answers look unusual". The definitions quantify over all analysts, so the bound must survive the worst one.)*

36.4. Filters for pure differential privacy

36.4.1. Context

You run an interactive system with a global budget (ε_g, δ). Each query comes with its own ε_t, chosen after seeing the earlier answers. Before each query you need a rule that says whether it may run. The simplest rule sums the ε_t; it is exact but its total grows like k, the number of steps. Advanced composition grows like $\sqrt{k}$ but, as Section 36.3 showed, cannot be applied ex post without care. Rogers et al. (2016) gave the first valid $\sqrt{k}$ filter, with worse constants than

advanced composition. Whitehouse et al. (2023), and independently the Rényi route of Feldman & Zrnic (2021), closed the gap.

36.4.2. Statement

All three filters below are valid for steps that are ε_t-DP conditionally on the past (pure DP, $\delta_t = 0$), with ε_t predictable. Each computes one statistic of $\varepsilon_1, \dots, \varepsilon_t$, including the step about to run, and says *continue* while it is at most ε_g. They differ in the statistic: the first adds the budgets, the other two add a mean term and a square-root spread term, as advanced composition does.

- **Basic filter** (Rogers et al. 2016, Theorem 3.4). The statistic is the plain sum of the budgets: continue while $\sum_t \varepsilon_t \le \varepsilon_g$. The stopped run is $(\varepsilon_g, 0)$-DP.
- **Rogers et al. filter** (2016, Theorem 5.1), for $\delta < 1/e$. The statistic is a mean term, the sum of each step's bound on its expected loss, plus a spread term like advanced composition's $\sqrt{2V\ln(1/\delta)}$, where $V = \sum_t \varepsilon_t^2$ plays the role of the variance. Because V is now random, the spread term is inflated: V is padded by $x = \varepsilon_g^2/(28.04\ln(1/\delta))$, and multiplied by a logarithmic factor in V/x. Continue while

$$K = \sum_t \frac{\varepsilon_t(e^{\varepsilon_t}-1)}{2} + \sqrt{2(V+x)\Big(1+\tfrac{1}{2}\ln\big(\tfrac{V}{x}+1\big)\Big)\ln(1/\delta)} \le \varepsilon_g. \tag{36.4}$$

- **Whitehouse et al. filter** (2023, Theorem 2). The statistic is advanced composition itself, spread term $\sqrt{2\ln(1/\delta)\sum_t \varepsilon_t^2}$ plus mean term $\frac{1}{2}\sum_t \varepsilon_t^2$, with no penalty for adaptivity. Continue while

$$\sqrt{2\ln(1/\delta)\textstyle\sum_t \varepsilon_t^2} + \tfrac{1}{2}\textstyle\sum_t \varepsilon_t^2 \le \varepsilon_g. \tag{36.5}$$

The last two give (ε_g, δ)-DP. Compare Equation 36.5 with advanced composition for unequal steps: it is the same formula with the tanh mean term $\varepsilon_t \tanh(\varepsilon_t/2)$ replaced by the slightly larger $\varepsilon_t^2/2$. It is larger because $\tanh x \le x$, so $\varepsilon_t \tanh(\varepsilon_t/2) \le \varepsilon_t \cdot \varepsilon_t/2$; the difference is about $\varepsilon_t^4/24$ per step, from the next term of the series $\tanh x = x - x^3/3 + \dots$. For fixed parameters it is exactly the bound you get by composing in zCDP, so adaptivity costs essentially nothing.

36.4.3. Derivation

Basic filter. The idea is that a pure-DP step bounds the loss of every single output, not just its typical size, so the sum of the budgets bounds the loss of every stopped transcript.

1. **Each step's loss is bounded on every output.** ε_t-DP says no output is more than e^{ε_t} times likelier on one neighbour than on the other, in either direction. Taking logarithms, $|L_t| \le \varepsilon_t$ for every output.
2. **So is the stopped run's loss.** By Fact 1 the stopped run has loss $L_{1:T} = \sum_{t \le T} L_t$, so $|L_{1:T}| \le \sum_{t \le T} \varepsilon_t \le \varepsilon_g$ on every path, because the filter never lets the sum pass ε_g.
3. **A bounded loss is pure DP.** A loss bounded by ε_g on every output means $P(y) \le e^{\varepsilon_g} Q(y)$ for every transcript y. Summing over the transcripts in any event gives $P(E) \le e^{\varepsilon_g} Q(E)$, which is $(\varepsilon_g, 0)$-DP.

Rogers et al. filter (what it needs; the proof is in their Section 5). It uses the centred loss of step 2 in Section 36.3, a martingale whose increments lie in intervals of length $2\varepsilon_t$; the difference is that these lengths are now random. Azuma's inequality needs the lengths fixed in advance, so Rogers et al. replace it with a **self-normalized** inequality (their Theorem 4.4, built on a result of de la Peña, Klass & Lai): a bound on the martingale divided by $\sqrt{V+x}$, where V, the sum of squared increment ranges up to a constant, may itself be random. Dividing by the realized spread is what lets the bound hold whatever V turns out to be, and the price is the extra x inside the square root and the factor $1+\frac{1}{2}\ln(V/x+1)$; the constant 28.04 is their choice of x. The mean term bounds each step's expected loss given the past, $\mathbb{E}[L_t \mid y_{<t}]$, by $\varepsilon_t(e^{\varepsilon_t}-1)/2$.

Whitehouse et al. filter, through the Rényi filter of the next section. The idea is to measure each pure-DP step in zCDP, where adaptive budgets add up for free at every order (the Rényi filter, Equation 36.6), and to convert to (ε,δ)-DP only at the end. Recall that a mechanism is $(\alpha,\varepsilon(\alpha))$-RDP if the Rényi divergence of order α between its outputs on any two neighbours is at most $\varepsilon(\alpha)$, and ρ-zCDP if it is $(\alpha,\alpha\rho)$-RDP at every order $\alpha>1$: its RDP curve is at most a line through the origin with slope ρ.

1. **Each step is zCDP.** An ε_t-DP step is $(\alpha,\alpha\varepsilon_t^2/2)$-RDP for every $\alpha>1$ (Equation 31.6), that is, $\varepsilon_t^2/2$-zCDP. The derivation is in Concentrated differential privacy; it uses that the step's loss lies in $[-\varepsilon_t,\varepsilon_t]$, so its exponential moments are controlled by its range.
2. **The rule is a Rényi filter at every order at once.** Let $\rho^*=(\sqrt{\ln(1/\delta)+\varepsilon_g}-\sqrt{\ln(1/\delta)})^2$ (Equation 31.12; step 3 shows where it comes from) and continue while $\frac{1}{2}\sum_t\varepsilon_t^2\le\rho^*$. For any fixed α, multiplying both sides by α shows this is the same as $\sum_t\alpha\varepsilon_t^2/2\le\alpha\rho^*$: a Rényi filter with budget $\alpha\rho^*$ on the spends of step 1. By Equation 36.6, the stopped run is $(\alpha,\alpha\rho^*)$-RDP. Since this holds for every α, the stopped run is ρ^*-zCDP.
3. **Convert.** ρ^*-zCDP gives $(\rho^*+2\sqrt{\rho^*\ln(1/\delta)},\delta)$-DP (Equation 31.10). This is Mironov's conversion (Equation 29.17), $\varepsilon(\alpha)+\ln(1/\delta)/(\alpha-1)$, at the best order: with $a=\alpha-1$ and $\ell=\ln(1/\delta)$ it reads $\rho+\rho a+\ell/a$, whose minimum over a is at $a=\sqrt{\ell/\rho}$, where it equals $\rho+2\sqrt{\rho\ell}$. The choice of ρ^* makes this exactly ε_g: $\rho+2\sqrt{\rho\ell}=\varepsilon_g$ is $(\sqrt{\rho}+\sqrt{\ell})^2=\varepsilon_g+\ell$, whose solution is $\sqrt{\rho}=\sqrt{\varepsilon_g+\ell}-\sqrt{\ell}$.
4. **Rewrite the rule.** $\rho\mapsto\rho+2\sqrt{\rho\ln(1/\delta)}$ is increasing, so "$\rho\le\rho^*$" is the same as "$\rho+2\sqrt{\rho\ln(1/\delta)}\le\varepsilon_g$". With $\rho=\frac{1}{2}\sum_t\varepsilon_t^2$, the square root is $2\sqrt{\frac{1}{2}\sum_t\varepsilon_t^2\ln(1/\delta)}=\sqrt{2\ln(1/\delta)\sum_t\varepsilon_t^2}$, so the left side is $\frac{1}{2}\sum_t\varepsilon_t^2+\sqrt{2\ln(1/\delta)\sum_t\varepsilon_t^2}$, which is Equation 36.5.

This is the theorem that Composition (Section 21.5) said a budget-spending rule needs. Whitehouse et al. prove the same filter directly, and also for steps with $\delta_t>0$, through approximate zCDP; Feldman & Zrnic (2021, Section 4.3) state the ρ^* form.

36.4.4. Interpretation

A plug-in filter on the Dwork–Rothblum–Vadhan form of advanced composition is valid after all. That form, Equation 21.9, written for unequal steps, has the statistic $\sqrt{2\ln(1/\delta)\sum_t\varepsilon_t^2}+\sum_t\varepsilon_t(e^{\varepsilon_t}-1)$. Since $e^x-1\ge x$, every step has $\varepsilon_t(e^{\varepsilon_t}-1)\ge\varepsilon_t^2\ge\varepsilon_t^2/2$, so this statistic is never below that of Equation 36.5. A filter that halts on it therefore halts no later than the Whitehouse filter, and stopping earlier is post-processing of the longer run: anything computed from a prefix of a private transcript is at least as private. The argument does not cover the tanh

form (Equation 21.17) used in Section 36.3, whose statistic is slightly below Whitehouse's. What fails there is the odometer use, not a filter.

Rogers et al. lose a constant factor. In Table 36.3 the Rogers filter needs 1.40 to 1.51 times the budget of the Whitehouse filter, and it lets through fewer than half as many steps (Table 36.4). The loss comes from the self-normalized inequality, which has to work for every value of the variance proxy V at once.

All of this is for pure DP. For steps with $\delta_t > 0$, Whitehouse et al. add a second rule, $\sum_t \delta_t \le \delta''$, and the guarantee becomes $(\varepsilon_g, \delta + \delta'')$. Rogers et al. (Lemma 3.3) instead run their pure-DP filter on the doubled parameters $2\varepsilon_t$ and halt once $\sum_t 2\delta_t/(\varepsilon_t e^{\varepsilon_t})$ exceeds δ'', with the same $(\varepsilon_g, \delta + \delta'')$.

36.4.5. Example

Take k steps of ε_0 each at $\delta = 10^{-6}$ and ask what global budget each rule needs to let them all through. For the basic filter that is $k\varepsilon_0$; for the others, it is the value of the statistic after k steps. Table 36.3 compares basic composition, advanced composition with k fixed in advance (Equation 21.9), and the two $\sqrt{k}$ filters; Figure 36.2 plots the same over k.

Table 36.3.: Global budget ε_g needed for k steps of ε_0 at $\delta = 10^{-6}$. For the Rogers filter, the smallest ε_g at which Equation 36.4 holds.

ε_0	k	Basic	Advanced (fixed k)	Rogers filter	Whitehouse filter	Rogers / Whitehouse
0.01	100	1.000	0.536	0.803	0.531	1.51
0.01	1000	10.000	1.763	2.570	1.712	1.50
0.01	10,000	100.000	6.262	8.450	5.757	1.47
0.1	100	10.000	6.308	8.472	5.757	1.47
0.1	1000	100.000	27.140	30.244	21.623	1.40

Turned around: with a budget of $\varepsilon_g = 1$, how many steps of ε_0 does each rule allow (Table 36.4)? For the Whitehouse filter, $\rho^* = (\sqrt{\ln(10^6) + 1} - \sqrt{\ln(10^6)})^2 = 0.017469$, and the rule $\frac{1}{2}k\varepsilon_0^2 \le \rho^*$ allows $\lfloor 2\rho^*/\varepsilon_0^2 \rfloor$ steps.

Table 36.4.: Number of steps of ε_0 allowed by a global budget $\varepsilon_g = 1$ at $\delta = 10^{-6}$.

ε_0	Basic	Advanced (fixed k)	Rogers filter	Whitehouse filter
0.01	100	337	154	349
0.001	1000	33,785	15,481	34,937

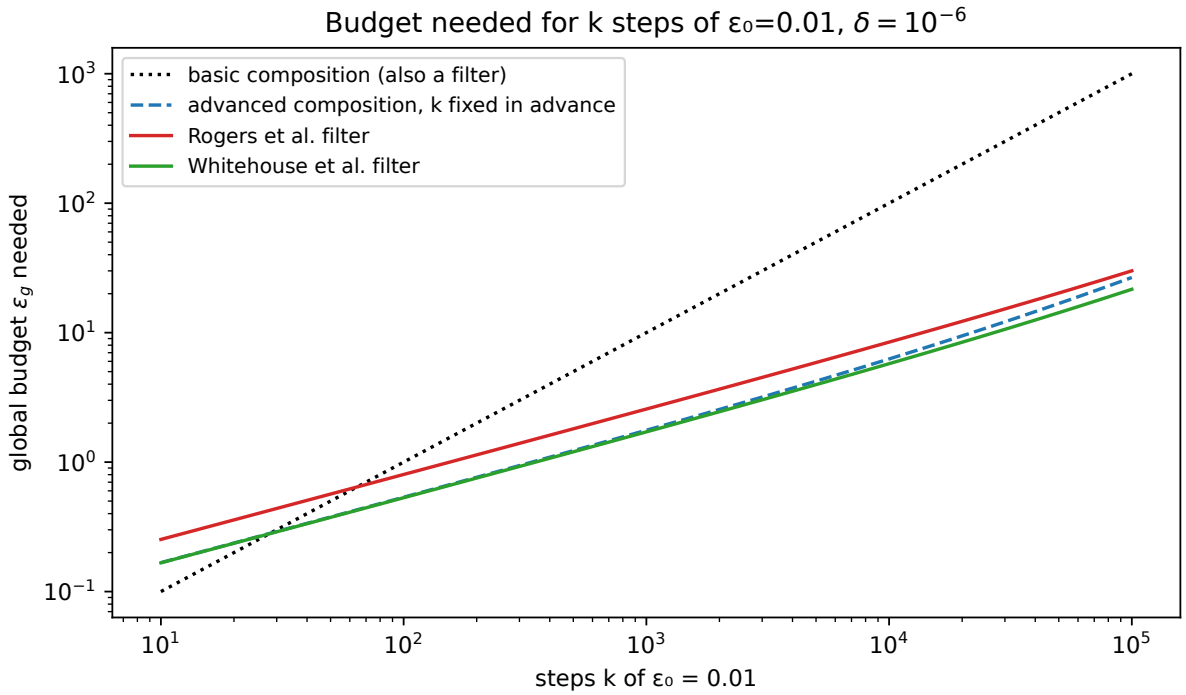

Figure 36.2.: Global budget needed to run k steps of $\varepsilon_0 = 0.01$ at $\delta = 10^{-6}$, on log–log axes: basic composition, advanced composition with k fixed in advance, and the Rogers et al. and Whitehouse et al. filters. The Whitehouse filter lies on or below fixed-k advanced composition; the Rogers filter sits a constant factor above.

36.4.6. Check yourself

- Why does the Whitehouse filter beat fixed-k advanced composition from Equation 21.9, even though it allows adaptivity? *(Its mean term is $\varepsilon_t^2/2$ instead of $\varepsilon_t(e^{\varepsilon_t}-1)$. It comes from the zCDP view of a pure-DP step, which is tighter than the Dwork–Rothblum–Vadhan mean bound. Against the* tanh *form Equation 21.17 the two are nearly equal, since $\varepsilon\tanh(\varepsilon/2)\approx\varepsilon^2/2$.)*
- In step 2 of the Whitehouse derivation, why is it important that the halting rule does not depend on α? *(Each Rényi filter is valid at one fixed order. Because $\frac{1}{2}\sum\varepsilon_t^2\le\rho^*$ is the same rule for every α, one run is a valid filter at all orders simultaneously, so the conversion may pick the best α afterwards.)*

36.5. The Rényi filter

36.5.1. Context

Rényi differential privacy describes a mechanism by a curve. The Rényi divergence of order $\alpha>1$ between the output distributions on two neighbours is $D_\alpha(P\|Q)=\frac{1}{\alpha-1}\ln\mathbb{E}_P\big[e^{(\alpha-1)L}\big]$, a log of an exponential moment of the privacy loss L, and a mechanism is $(\alpha,\varepsilon(\alpha))$-RDP if this is at most $\varepsilon(\alpha)$ for every pair of neighbours. RDP composition adds curves: if step t is $(\alpha,\varepsilon_t(\alpha))$-RDP with ε_t fixed in advance, the run is $(\alpha,\sum_t\varepsilon_t(\alpha))$-RDP (Equation 29.10). What if $\varepsilon_t(\alpha)$ depends on the earlier outputs, because the noise is adapted, because the run stops on a data-dependent rule, or because it is one record's individual spend? Feldman & Zrnic (2021) and Lécuyer (2021) showed that nothing is lost, at a fixed order.

36.5.2. Statement

Fix an order and a budget, add up the RDP spends as the run goes, and stop before the sum would pass the budget. The result is that the stopped run has the guarantee the budget names, exactly as if the spends had been fixed in advance.

Rényi filter (Feldman & Zrnic 2021, Section 4; Lécuyer 2021, Section 3). Fix an order $\alpha>1$ and a budget B. Let step t be $(\alpha,\varepsilon_t(\alpha))$-RDP conditionally on $y_{<t}$, with $\varepsilon_t(\alpha)$ predictable. Run step t only if the spends so far, including its own, fit in the budget:

$$\sum_{j\le t}\varepsilon_j(\alpha)\le B. \tag{36.6}$$

Then the stopped run is (α,B)-RDP. Equivalently: if $\sum_t\varepsilon_t(\alpha)\le B$ holds on every path, the adaptive composition is (α,B)-RDP.

36.5.3. Derivation

The plan is to build a supermartingale out of the privacy loss and the spends, stop it with the filter, and read the RDP bound off its mean. The quantity that works is $e^{(\alpha-1)L}$, because its

mean is exactly what the Rényi divergence measures, divided by what the spends allow it to be. Fix neighbours D, D' and the order α, and define

$$N_t = \exp\Big((\alpha-1)\Big(L_{1:t} - \sum_{j\le t}\varepsilon_j(\alpha)\Big)\Big), \qquad N_0 = 1. \tag{36.7}$$

1. **One step's exponential moment is the RDP parameter.** Given $y_{<t}$, step t is a fixed mechanism, so by the definition of D_α as a moment of the loss (Equation 31.1), $\mathbb{E}[e^{(\alpha-1)L_t} \mid y_{<t}] = e^{(\alpha-1)D_\alpha(P_t\|Q_t)}$. The RDP assumption $D_\alpha(P_t\|Q_t) \le \varepsilon_t(\alpha)$ then bounds it by $e^{(\alpha-1)\varepsilon_t(\alpha)}$. The moment form holds because $\mathbb{E}_P[e^{(\alpha-1)L}] = \sum_y P(y)(P(y)/Q(y))^{\alpha-1} = \sum_y P(y)^\alpha Q(y)^{1-\alpha}$, the sum inside the Rényi divergence.
2. **N_t is a supermartingale.** Going from $t-1$ to t adds L_t to the loss and $\varepsilon_t(\alpha)$ to the spend, so $N_t = N_{t-1}\, e^{(\alpha-1)(L_t - \varepsilon_t(\alpha))}$. Both N_{t-1} and $\varepsilon_t(\alpha)$ are functions of $y_{<t}$, so given $y_{<t}$ they are constants and come out of the conditional expectation. What remains is $\mathbb{E}[e^{(\alpha-1)L_t} \mid y_{<t}]\, e^{-(\alpha-1)\varepsilon_t(\alpha)} \le 1$ by step 1, so $\mathbb{E}[N_t \mid y_{<t}] \le N_{t-1}$. This is where predictability is used.
3. **Stop it.** The filter's last step T is a stopping time: whether step t runs is decided by $\varepsilon_1(\alpha), \dots, \varepsilon_t(\alpha)$, which are functions of $y_{<t}$. By Fact 2, $\mathbb{E}[N_T] \le N_0 = 1$.
4. **Use the budget on every path.** Undo the definition of N_T: $e^{(\alpha-1)L_{1:T}} = N_T\, e^{(\alpha-1)\sum_{j\le T}\varepsilon_j(\alpha)}$. The filter guarantees $\sum_{j\le T}\varepsilon_j(\alpha) \le B$ on every path, so this is at most $N_T\, e^{(\alpha-1)B}$. Take expectations: $\mathbb{E}\big[e^{(\alpha-1)L_{1:T}}\big] \le e^{(\alpha-1)B}\,\mathbb{E}[N_T] \le e^{(\alpha-1)B}$.
5. **Read off the divergence.** By Fact 1, $L_{1:T}$ is the privacy loss of the stopped transcript, so by the moment form again the left side is $e^{(\alpha-1)D_\alpha(P_{1:T}\|Q_{1:T})}$, and taking logs gives $D_\alpha \le B$. Swapping the roles of D and D' gives the other direction.

Step 4 is where "on every path" matters. If $\sum_j \varepsilon_j(\alpha) \le B$ held only on average, you could not pull $e^{(\alpha-1)\sum_j \varepsilon_j}$ out of the expectation as the constant $e^{(\alpha-1)B}$: paths with a large spend may also be paths with a large N_T, and the expectation of a product is not the product of expectations.

The supermartingale, outcome by outcome. Rényi DP (Table 29.5) already composed two adaptive randomized responses, $\ln 3$ and then $\ln 3$ or $\ln 1.5$ depending on y_1. With two steps, fixed-curve composition (Equation 29.10, charging step 2 its worst branch) gives the same bound as the filter, the largest path spend. Three steps whose branches swap costs show what the filter adds.

Take $\alpha = 2$, so $\alpha - 1 = 1$ and $N_t = e^{L_{1:t} - \text{spend}}$, and one person's bit, 1 in D and 0 in D'. Step 1 is randomized response with $\varepsilon = \ln 3$: it reports the true bit with probability $3/(1+3) = 3/4$. Its RDP at order 2, from the randomized-response curve (Equation 29.9) with $p = 3/4$, is $\varepsilon_1(2) = \ln\left(p^2/(1-p) + (1-p)^2/p\right) = \ln(2.25 + 0.0833) = 0.8473$. After $y_1 = 1$, steps 2 and 3 are randomized response with $\ln 3$ (strong) and then $\ln 1.5$ (weak, keep-probability $1.5/2.5 = 0.6$, RDP $\ln(0.36/0.4 + 0.16/0.6) = 0.1542$); after $y_1 = 0$, weak and then strong. Every path runs one strong step after the first, so every path spends $B = 2\varepsilon_1(2) + 0.1542 = 1.8487$ (computed before rounding), the filter's budget. Fixed-curve composition must charge each of steps 2 and 3 its worst branch, 0.8473, and gives $3 \times 0.8473 = 2.5419$.

Table 36.5 lists the eight transcripts. Read the first row as a template. On D the bit is 1, so the three reports of 1 have probabilities 0.75 (strong), 0.75 (strong) and 0.6 (weak), and $P = 0.75 \times 0.75 \times 0.6 = 0.3375$. On D' each report of 1 is a flip, so $Q = 0.25 \times 0.25 \times 0.4 = 0.0250$. The loss is $\ln(0.3375/0.0250) = \ln 13.5 = 2.6027$, and $N_3 = e^{2.6027 - 1.8487} = 2.1254$.

Table 36.5.: Three adaptive randomized-response steps at $\alpha = 2$. The first output decides the order of a strong ($\ln 3$) and a weak ($\ln 1.5$) step, so every path spends the same; $N_3 = e^{L_{1:3} - \text{spend}}$.

(y_1, y_2, y_3)	P	Q	$L_{1:3}$	spend $\sum_j \varepsilon_j(2)$	N_3	$P \times N_3$
(1, 1, 1)	0.3375	0.0250	+2.6027	1.8487	2.1254	0.7173
(1, 1, 0)	0.2250	0.0375	+1.7918	1.8487	0.9446	0.2125
(1, 0, 1)	0.1125	0.0750	+0.4055	1.8487	0.2362	0.0266
(1, 0, 0)	0.0750	0.1125	−0.4055	1.8487	0.1050	0.0079
(0, 1, 1)	0.1125	0.0750	+0.4055	1.8487	0.2362	0.0266
(0, 1, 0)	0.0375	0.2250	−1.7918	1.8487	0.0262	0.0010
(0, 0, 1)	0.0750	0.1125	−0.4055	1.8487	0.1050	0.0079
(0, 0, 0)	0.0250	0.3375	−2.6027	1.8487	0.0117	0.0003

The table checks two things. First, the mean of N_3 is 1. The mean is the sum of the last column, and the unrounded entries sum to 1.0000. You can also see the supermartingale step by step. After one step, $N_1 = e^{L_1 - 0.8473}$: given $y_1 = 1$ it is $e^{\ln 3 - 0.8473} = 1.2857$, and given $y_1 = 0$ it is $e^{-\ln 3 - 0.8473} = 0.1429$. Its mean is $0.75 \times 1.2857 + 0.25 \times 0.1429 = 1.0000$, and the conditional mean of N_3 on each branch equals that branch's N_1. For randomized response, step 1 of the derivation holds with equality, because the RDP parameter is the exact divergence, so N is a martingale rather than merely a supermartingale.

Second, the filter bound is attained, and it beats fixed curves. The joint D_2 of the transcript is $\ln \mathbb{E}_P[e^{L_{1:3}}] = \ln \sum P^2/Q = 1.8487$, exactly B, because N is a martingale and every path spends B. Fixed-curve composition gives 2.5419: it charges both later steps as if both were strong, though no path runs two strong steps after the first.

36.5.4. Interpretation

At a fixed order, the filter is free. Its bound is the largest path spend, which is never more than fixed-parameter composition gives, and less when branches trade costs (Table 36.5). When every path spends exactly B and every step's exponential moment equals its RDP parameter, as for Gaussian steps and randomized response, N is a martingale and the bound is attained. In Figure 36.3, adaptive Gaussian steps (shift 0.3 after a positive output, 0.6 otherwise, in units of the noise; $\alpha = 2$, $B = 1$) are stopped by the filter. Each path's $\ln N_t$ wanders, but the mean of N_t stays at 1. When the last step is shrunk to spend the remaining budget exactly, a Monte Carlo estimate over 10^6 paths gives $D_2 = 1.0004$, the budget up to sampling error. When the filter simply stops, paths end with a mean spend of 0.8998 and a largest spend of 0.9900, and $D_2 = 0.9305$: below the budget, because no path uses all of it.

The price is the order. The filter is valid at an order fixed before the run. You can track several orders and stop when any one of them is exhausted; then the budget held at every order on every path, and every one of them is certified. What you cannot do is let the run continue as long as *some* order still fits, with the order chosen after seeing the spends, without paying for it; Section 36.6 prices that choice with a union bound.

At the end you convert. The stopped run is (α, B)-RDP, so by Mironov's conversion (Equation 29.17) it is $(B + \ln(1/\delta)/(\alpha - 1), \delta)$-DP for every δ. That conversion is a Chernoff bound: the exponential moment $e^{(\alpha-1)B}$ bounds the probability that the loss exceeds $B + \ln(1/\delta)/(\alpha - 1)$ by δ, and outputs whose loss is below that threshold satisfy the e^{ε} ratio. A DP target (ε_g, δ) therefore fixes $B = \varepsilon_g - \ln(1/\delta)/(\alpha - 1)$ at the chosen order.

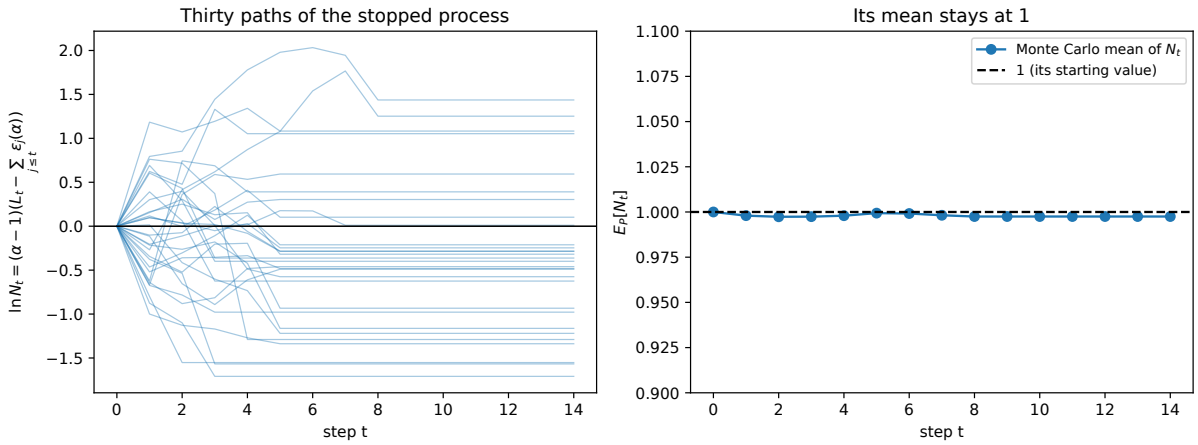

Figure 36.3.: Adaptive Gaussian steps under a Rényi filter with $\alpha = 2$ and $B = 1$. Left: $\ln N_t$ along thirty paths; each path freezes when the filter stops it. Right: the Monte Carlo mean of N_t over 2×10^5 paths stays at its starting value 1, as optional stopping says.

36.5.5. Example

You train with full-batch noisy gradient descent, noise multiplier σ, and you want to lower the noise when progress stalls. With a budget of $(\varepsilon_g, \delta) = (5.299, 10^{-5})$ and the order $\alpha = 5.8$, the RDP budget is $B = 5.299 - \ln(10^5)/4.8 = 2.900$ (these are the numbers of Section 36.7). A Gaussian step with noise multiplier σ_t spends $\alpha/(2\sigma_t^2)$ at order α (Equation 29.7), because two Gaussians one noise-width apart have Rényi divergence $\alpha/2$ in units of the noise, and dividing the shift by σ_t divides that by σ_t^2. With $\sigma_t = 10$ throughout each step spends $5.8/200 = 0.0290$, and you get $2.900/0.0290 = 100$ steps. If you switch to $\sigma_t = 5$ after a plateau at step 60, each step costs $5.8/50 = 0.1160$, and the filter allows $(2.900 - 60 \times 0.0290)/0.1160 = 1.160/0.1160 = 10$ more steps. Either way the run is $(5.8, 2.900)$-RDP, whatever rule decided the switch.

36.5.6. Check yourself

- In step 2 of the derivation, what goes wrong if $\varepsilon_t(\alpha)$ may depend on y_t, the output of step t itself? *(It no longer comes out of the conditional expectation given $y_{<t}$. A mechanism could then spend little exactly on the outputs that reveal the most, and N need not be a supermartingale.)*
- In Table 36.5 the joint D_2 equals the budget exactly, while in the two-step run of Table 29.5 it is 1.6766, below the largest path spend 1.6946. What makes the difference? *(In the two-step run the paths through the weak branch spend only 1.0014 and pull $\mathbb{E}_P[e^L]$ below e^B. Here every path spends B and N is a martingale, so $\mathbb{E}_P[e^{L_{1:3}}] = e^B\,\mathbb{E}_P[N_3] = e^B$.)*

36.6. Odometers

36.6.1. Context

Early stopping, "accuracy first" training and open-ended analyses do not have a budget to stop at. They need a running answer to "how much have I spent?" that stays valid however the stopping time is chosen. That is the odometer of Equation 36.3: a bound U_t such that the loss exceeds it at *some* time with probability at most δ. Section 36.3 showed that plugging the realized parameters into a fixed-time bound is not one. The cost of an odometer is a union over the times at which you might stop, or over the orders you might pick.

36.6.2. Statement

Each odometer below takes the running RDP spend at a few orders and turns it into a running ε. Let step t be $(\alpha, \varepsilon_t(\alpha))$-RDP conditionally on the past, for each order α in a finite grid Λ fixed in advance ($|\Lambda|$ is the number of orders), and write $S_t(\alpha) = \sum_{j \le t} \varepsilon_j(\alpha)$ for the spend so far at order α.

Ville odometer. Report, at every step, Mironov's conversion of the spend so far, at the best order in the grid, with δ replaced by $\delta/|\Lambda|$ to pay for choosing the order late. With probability at least $1 - \delta$, simultaneously for all t,

$$L_{1:t} \le U_t = \min_{\alpha \in \Lambda} \Big[S_t(\alpha) + \frac{\ln(|\Lambda|/\delta)}{\alpha - 1} \Big]. \tag{36.8}$$

Lécuyer odometer (Lécuyer 2021, Section 4). Instead of applying Ville's inequality to the spend directly, run a sequence of Rényi filters with doubling budgets, and report the budget of the first filter that has not yet run out, plus a conversion term at a confidence that shrinks with the filter's index. For each order, the budgets are $B_f(\alpha) = 2^{f-1} \ln(2|\Lambda|/\delta)/(\alpha - 1)$, $f = 1, 2, ...$, and $f(\alpha)$ is the first f whose budget covers $S_t(\alpha)$. Then with probability at least $1 - \delta$,

$$L_{1:t} \le \min_{\alpha \in \Lambda} \Big[B_{f(\alpha)}(\alpha) + \frac{\ln(2|\Lambda| f(\alpha)^2/\delta)}{\alpha - 1} \Big]. \tag{36.9}$$

Pure-DP odometers. Rogers et al. (2016, Theorem 6.5) give an advanced-composition odometer whose square-root term carries $\ln(\ln n/\delta)$ instead of $\ln(1/\delta)$, the $\ln\ln$ price of Section 36.3. Whitehouse et al. (2023, Theorem 3) give tighter ones, matching advanced composition at a preselected point or, up to a $\ln\ln$ factor, at all times.

36.6.3. Derivation

Ville odometer. The supermartingale of the Rényi filter does not need a filter to be a supermartingale; the filter only stopped it. Ville's inequality says it rarely ever gets large, and "N_t large" unpacks to "the loss is far above the spend".

1. **At a fixed order, N_t of Equation 36.7 is a non-negative supermartingale with $N_0 = 1$.** Steps 1–2 of the Rényi filter derivation showed this using only that the spends are predictable; no filter is needed.

2. **Ville** (Fact 3, Equation 36.2, with no horizon) with $c = |\Lambda|/\delta$: $\Pr[\exists\, t : N_t \geq |\Lambda|/\delta] \leq \delta/|\Lambda|$.
3. **Unpack.** Take logarithms and divide by $\alpha - 1$: $N_t \geq |\Lambda|/\delta$ is the event $L_{1:t} \geq S_t(\alpha) + \ln(|\Lambda|/\delta)/(\alpha - 1)$. So, at this order, the bound $S_t(\alpha) + \ln(|\Lambda|/\delta)/(\alpha - 1)$ holds for all t at once except with probability $\delta/|\Lambda|$.
4. **Union over the orders.** The probability that the bound fails at some order is at most the sum of the failure probabilities, $|\Lambda| \times \delta/|\Lambda| = \delta$ (the union bound). Outside the failure event the bound holds at every order and every time, so it holds at the minimizing order, chosen after the fact.

With a single order ($|\Lambda| = 1$) the Ville odometer is $S_t(\alpha) + \ln(1/\delta)/(\alpha - 1)$, which is Mironov's fixed-time conversion: at one fixed order, a running bound is free. The cost of an odometer is entirely the freedom to choose the order late.

Lécuyer odometer (what it needs). Each filter in the sequence certifies (α, B_f)-RDP of the run truncated at its halting time, and is converted with a tail bound at confidence $\delta/(2|\Lambda|f^2)$, which gives the term $\ln(2|\Lambda|f^2/\delta)/(\alpha - 1)$. The odometer reports at every time up to that halt, not only at the halt, so the tail bound must hold at all those times at once. Ville's inequality gives exactly that: apply it, as in step 2 above, to the supermartingale N_t stopped at the filter's halting time, which is still a non-negative supermartingale starting at 1. The confidences shrink with f so that their total stays below δ: the sum over f and α is $\delta \sum_f 1/(2f^2)$, and $\sum_f 1/(2f^2) = \pi^2/12 < 1$. Because the budgets double, the certified $B_{f(\alpha)}$ is at most twice the actual spend once the spend exceeds B_1, so rounding up to the next filter costs at most a factor 2 in that term.

36.6.4. Interpretation

At a single order, the Ville odometer is exactly tight for Gaussian steps. To see why, look at the loss in the right units. A Gaussian step with shift μ, in units of the noise, has privacy loss that is itself normal, with mean $\mu^2/2$ and variance μ^2, so after t steps the loss is normal with mean $t\mu^2/2$ and variance $t\mu^2$. Write $s = t\mu^2$ for the accumulated variance. Then $L_{1:t} = s/2 + W_s$, where W is a Brownian motion (the continuous-time limit of a random walk, with $W_s \sim \mathcal{N}(0, s)$ and independent increments) observed at the variance times s. The spend at order α is $\alpha\mu^2/2$ per step, so the Ville boundary is the line $\alpha s/2 + \ln(1/\delta)/(\alpha - 1)$. Subtracting the drift $s/2$, the walk crosses it when $W_s \geq a + bs$ with $a = \ln(1/\delta)/(\alpha - 1)$ and $b = (\alpha - 1)/2$.

Ville's inequality gives the crossing probability in continuous time too. The process $\exp(2bW_s - 2b^2 s)$ is a non-negative martingale with mean 1, because the Gaussian moment generating function gives $\mathbb{E}[e^{2bW_s}] = e^{(2b)^2 s/2} = e^{2b^2 s}$. On the event $W_s \geq a + bs$ its exponent is at least $2b(a + bs) - 2b^2 s = 2ab$, so that event is the event that the martingale reaches e^{2ab}, and the probability is at most e^{-2ab}. It is exactly e^{-2ab}: a continuous path meets the line exactly, where the martingale equals e^{2ab}, and on paths that never cross, the martingale tends to 0, so optional stopping holds with equality. Here $2ab = \ln(1/\delta)$, so $e^{-2ab} = \delta$. A Monte Carlo check with $\mu = 0.2$, $\alpha = 2$, $\delta = 0.05$ over 1000 steps gives a crossing probability of 0.0461, against the continuous-time limit 0.0500: checking only at whole steps misses crossings between them. At any single fixed time the same line is crossed with probability at most 0.0072. The slack that Mironov's conversion has at a fixed time is precisely what pays for time-uniformity. With more than one order the union bound adds slack, and the odometer is no longer tight.

A small grid is cheaper. The union costs $\ln|\Lambda|$ in the numerator: $\ln(1/\delta) = \ln(10^5) = 11.513$ against $\ln(|\Lambda|/\delta) = 11.513 + \ln 154 = 16.550$ for the part's 154 orders at $\delta = 10^{-5}$. Heuristically,

a coarse grid of a few orders per factor of two in spend is enough: if the spend may range over $[S_{\min}, S_{\max}]$, such a grid has $|\Lambda| \approx \log_2(S_{\max}/S_{\min})$ orders, and the union costs $\ln|\Lambda|$, a $\ln\ln$ of the range. This is the same shape as the $\ln\ln$ term in Rogers et al.'s lower bound.

Odometers are tail bounds, not DP guarantees. Equation 36.3 bounds the tail of the loss at whatever time you stop: reporting "$\varepsilon = U_T$" means "the loss of this run exceeds U_T with probability at most δ", with U_T itself random. To turn it into an ordinary (ε_g, δ)-DP guarantee, stop by a rule that keeps $U_T \le \varepsilon_g$, and split any event E by whether the loss is above ε_g: where it is not, $P(y) \le e^{\varepsilon_g} Q(y)$, and where it is, the probability is at most $\Pr[L > \varepsilon_g]$. That gives $\Pr[E] \le e^{\varepsilon_g} Q(E) + \Pr[L > \varepsilon_g]$ (steps 1–2 of Section 29.8). The second check-yourself question below does this.

36.6.5. Example

Take full-batch Gaussian steps with $\sigma = 10$, so $S_t(\alpha) = \alpha t/(2\sigma^2)$, $\delta = 10^{-5}$ and the part's grid of 154 orders. Table 36.6 compares the fixed-time conversion, valid only if t was chosen in advance, with the two odometers and with a Ville odometer at the single order 5.8, chosen in advance for $t = 100$. The last column is easy to check by hand: at order 5.8 each step spends $5.8/200 = 0.029$ and the conversion term is $\ln(10^5)/4.8 = 2.399$, so at $t = 10$ it is $0.29 + 2.399 = 2.689$ and at $t = 1000$ it is $29 + 2.399 = 31.399$. Figure 36.4 plots them over t.

Table 36.6.: Running ε at $\delta = 10^{-5}$ for t full-batch Gaussian steps with $\sigma = 10$. Only the last three columns are valid when t is chosen from the outputs.

Steps t	Fixed-time conversion	Ville odometer (154 orders)	Lécuyer odometer	Ville at $\alpha = 5.8$ only
10	1.568	1.869	1.916	2.689
100	5.299	6.253	6.507	5.299
300	9.812	11.465	11.892	11.099
1000	20.175	23.194	24.633	31.399

The Ville odometer costs 15–19% over the fixed-time value (ratios 1.15 to 1.19 across the rows): 6.253 against 5.299 at $t = 100$. The single-order odometer is free at its design point and poor elsewhere, 31.399 at $t = 1000$, because its order is far from the best one there. For the part's running example ($q = 0.01$, $\sigma = 1$, 10^4 steps, $\delta = 10^{-5}$, with the subsampled-Gaussian curve of Amplification by subsampling, where each step uses a random fraction q of the records), Mironov's fixed-time conversion gives 7.43; an odometer valid whenever the run stops costs 8.82 (Ville) or 9.08 (Lécuyer).

36.6.6. Check yourself

- Why is a filter cheaper than an odometer? *(A filter only certifies one budget fixed in advance, so it can use one order and one stopping time. An odometer must be correct at whatever time and order turn out best, and pays a union bound over them.)*

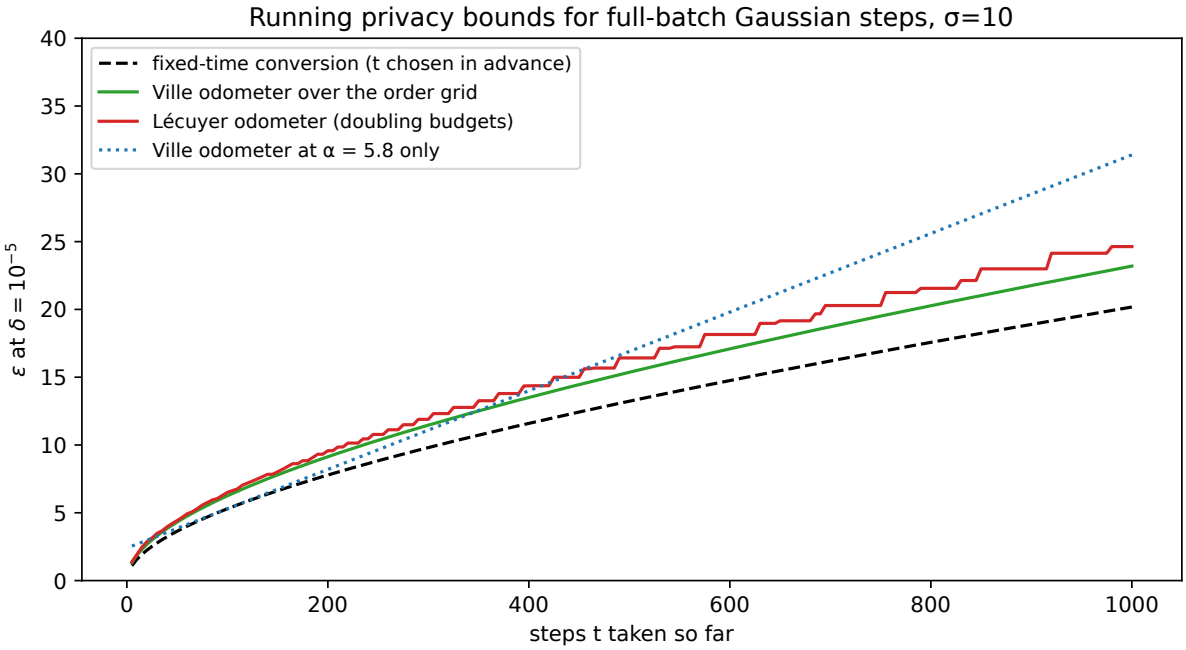

Figure 36.4.: Running privacy bounds at $\delta = 10^{-5}$ for full-batch Gaussian steps with $\sigma = 10$: Mironov's conversion at a time fixed in advance (dashed, not a valid odometer), the Ville odometer over the part's 154 orders, Lécuyer's odometer with doubling budgets, and a Ville odometer at the single order 5.8.

- Can you build a filter for a DP target (ε_g, δ) that continues while *some* order in Λ still fits, $\min_\alpha[S_t(\alpha) + \ln(|\Lambda|/\delta)/(\alpha - 1)] \le \varepsilon_g$? *(Yes: it stops before the Ville odometer passes ε_g, so the stopped loss exceeds ε_g with probability at most δ, and the tail split gives (ε_g, δ)-DP. The $|\Lambda|$ inside the logarithm is the price of choosing the order late.)*

36.7. Individual privacy accounting in DP-SGD

36.7.1. Context

A step of DP-SGD computes each record's gradient, **clips** it (scales it down, if needed, so that its norm is at most C), adds the clipped gradients, and adds Gaussian noise before releasing the sum. The usual analysis charges every record the worst case at every step, as if its clipped gradient always had norm C. Most records do not: once the model fits them, their gradients shrink. Feldman & Zrnic (2021) observed that a record's actual privacy cost is a random, predictable quantity, so the Rényi filter applies record by record. You can track each record's own spend and drop it from the gradient sum once its budget is used, while every record keeps the same guarantee. This section does the full-batch case, where every record is used at every step and every number is exact.

36.7.2. Statement

A record's privacy cost at a step depends on how far it moves the released sum, which is the norm of its clipped gradient. Measured at order α, that cost is the Gaussian RDP for that shift, at most the worst-case cost when the norm is C.

Individual RDP of a Gaussian step (Feldman & Zrnic 2021, Section 2). At step t, the mechanism releases $\sum_i \bar{g}_{i,t} + \mathcal{N}(0, \sigma^2 C^2 I)$, where $\bar{g}_{i,t}$ is record i's gradient at the current model, clipped to norm C. Removing record i moves the mean by $\bar{g}_{i,t}$, so record i's spend at order α is

$$\varepsilon_{i,t}(\alpha) = \frac{\alpha \|\bar{g}_{i,t}\|^2}{2\sigma^2 C^2} \leq \frac{\alpha}{2\sigma^2}. \tag{36.10}$$

Individual filter (Feldman & Zrnic 2021, Section 4.1). Fix α and B. At step t, record i takes part only if $\sum_{j \leq t} \varepsilon_{i,j}(\alpha) \leq B$, counting only the steps it took part in. Then the whole run is (α, B)-RDP.

36.7.3. Derivation

The plan is to compute a record's spend exactly, check that it is predictable, and then apply the Rényi filter separately to each pair of neighbours, which differ in a single record.

1. **The individual spend is a Gaussian Rényi divergence.** With record i present the output is $\mathcal{N}(m + \bar{g}_{i,t}, \sigma^2 C^2 I)$, without it $\mathcal{N}(m, \sigma^2 C^2 I)$, where m is the sum of the other records' clipped gradients. Rotate so $\bar{g}_{i,t}$ lies along one axis; the noise is the same in every direction, so the other coordinates have the same distribution in both cases and contribute nothing. The remaining one-dimensional pair is two normals with standard deviation σC whose means differ by $\|\bar{g}_{i,t}\|$, a shift of $\|\bar{g}_{i,t}\|/(\sigma C)$ in units of the noise. Two normals with shift μ in units of the noise have $D_\alpha = \alpha\mu^2/2$ (Equation 3.15), in both directions, which gives $\alpha\|\bar{g}_{i,t}\|^2/(2\sigma^2 C^2)$. Clipping makes $\|\bar{g}_{i,t}\| \leq C$, which gives the bound $\alpha/(2\sigma^2)$.
2. **It is predictable and does not depend on the other records.** $\bar{g}_{i,t}$ is a function of record i and the current model, and the model is a function of the earlier releases $y_{<t}$. So $\varepsilon_{i,t}(\alpha)$ is the RDP of step t for the pair (any dataset containing record i, the same dataset without it), conditionally on $y_{<t}$.
3. **Dropping a record costs it nothing.** Whether record i takes part at step t depends only on its own spends so far, which are functions of $y_{<t}$ and record i. If it is dropped, the outputs with and without it have the same law at that step, and its spend for the step is 0.
4. **Apply the Rényi filter per record.** For the pair (with i, without i), record i's spends are predictable and their sum never exceeds B, so by Equation 36.6 the transcript is (α, B)-RDP for this pair. Every pair of neighbours differs in one record, so the run is (α, B)-RDP.

36.7.4. Interpretation

The filter gives the same guarantee with more training. Every record ends with (α, B)-RDP, as in a worst-case run of $B/(\alpha/(2\sigma^2))$ steps. But records whose gradients shrink spend less per step, so they keep taking part long after the worst-case run would have stopped.

The guarantee is at one order. The filter certifies one order and one budget, (α, B), for every record; converted at that order it gives the run's (ε, δ). A per-record ε computed from the realized spend, at that order or with the order optimized afterwards, is an estimate, not a guarantee, for the reasons of Section 36.3: it is a fixed-time bound evaluated at a random quantity.

Individual ε is itself sensitive. A record's spend is a function of its gradient norms, so a small spend says "this record is well fitted". Feldman & Zrnic note that it can be shown to the record's owner without hurting anyone else, because it depends on the other records only through the private outputs, but publishing all of them leaks.

Without a filter, per-record numbers are ex post estimates. In an ordinary run of fixed length, a record's realized spend $\sum_t \varepsilon_{i,t}(\alpha)$ is random, and Equation 36.6 needs a bound on every path. Yu et al. (2023) study these ex post, output-specific guarantees for DP-SGD; Koskela, Tobaben & Honkela (2023) extend individual filtering from RDP to Gaussian differential privacy, which describes a mechanism by how hard it is to tell its two output distributions apart with a hypothesis test, for tighter accounting.

There is a fairness cost. Records that the model fits poorly, often from under-represented groups, keep large gradients, spend their budget first and are dropped first, so the model sees even less of them. Yu et al. (2023) find that the classes a model serves worst also get the weakest individual guarantees. This is one mechanism behind the disparate impact of DP training on accuracy, discussed in a later part.

The argument extends to subsampling. For Poisson-subsampled DP-SGD, where each record joins each step's batch independently with probability q, the individual spend of a record with clipped norm $\|\bar{g}_{i,t}\|$ is the RDP of the subsampled Gaussian with noise multiplier $\sigma C/\|\bar{g}_{i,t}\|$ (Amplification by subsampling), since the record's shift is $\|\bar{g}_{i,t}\|$ against noise of standard deviation σC. The filter argument is unchanged, because that norm, and so the spend, is still predictable. Feldman & Zrnic (2021, Section 5) note that the gain then needs every record's gradient at every step, sampled or not; Koskela, Tobaben & Honkela (2023) carry out individual accounting for subsampled DP-SGD.

36.7.5. Example

A simulation with an explicit model of gradient norms. There are 10,000 records, clip $C = 1$, $\sigma = 10$ and full-batch steps. Two kinds of record differ in whether the model learns them. **Typical records** (90%) have gradient norms $\|g_{i,t}\| = s_i e^{-t/40} e^{0.25 Z_{i,t}}$, with a per-record scale $s_i \sim U(0.3, 2)$ (uniform between 0.3 and 2) and $Z_{i,t}$ standard normal noise. The factor $e^{-t/40}$ makes them shrink as training proceeds, as the model fits them. **Hard records** (10%; 962 in this draw) have $\|g_{i,t}\| = s_i e^{0.25 Z_{i,t}}$ with $s_i \sim U(0.7, 1.5)$, with no shrinking factor: they are never fitted.

Gradients are then clipped at $C = 1$. The worst-case run has $T_0 = 100$ steps. Each Gaussian step with noise multiplier σ is $1/(2\sigma^2)$-zCDP, so 100 steps are $\rho = 100/(2 \cdot 10^2) = 0.500$-zCDP, and converting gives $\varepsilon = 5.299$ at $\delta = 10^{-5}$, best at order $\alpha^* = 5.8$, where the spend is $B = 2.900$. Every per-step spend is at most $\alpha^*/(2\sigma^2) = 0.0290$.

Individual ε after the same 100 steps. At the fixed order $\alpha^* = 5.8$, record i's ε is Mironov's conversion of its own spend, $\sum_t \varepsilon_{i,t}(5.8) + \ln(10^5)/4.8$. The second term does not depend on the

record, so an individual ε can never fall below the floor $\ln(10^5)/4.8 = 2.399$, even for a record that spends nothing. Table 36.7 and Figure 36.5 show the distribution.

Table 36.7.: Individual ε at $\delta = 10^{-5}$ after 100 full-batch steps with $\sigma = 10$, at the fixed order $\alpha^* = 5.8$ and, in the last column, with the order optimized per record over the part's grid. The worst case is 5.299.

Records	10th percentile	Median	90th percentile	Median, order chosen per record
All	2.56	3.25	3.81	2.75
Typical	2.55	3.17	3.67	2.61
Hard	4.23	5.02	5.26	5.01

The typical median is 3.17, against 5.299 for the worst case; 16.3% of all records are below half the worst case. Hard records sit just under the worst case, 5.02 at the median, because their gradients are usually near or above the clip. These realized values are ex post estimates (Yu et al. 2023): the filter certifies only its budget, $\varepsilon = 5.299$, for every record. Optimizing the order per record lowers the typical median further, to 2.61, because a small spend is best converted at a larger order, where the floor term is smaller.

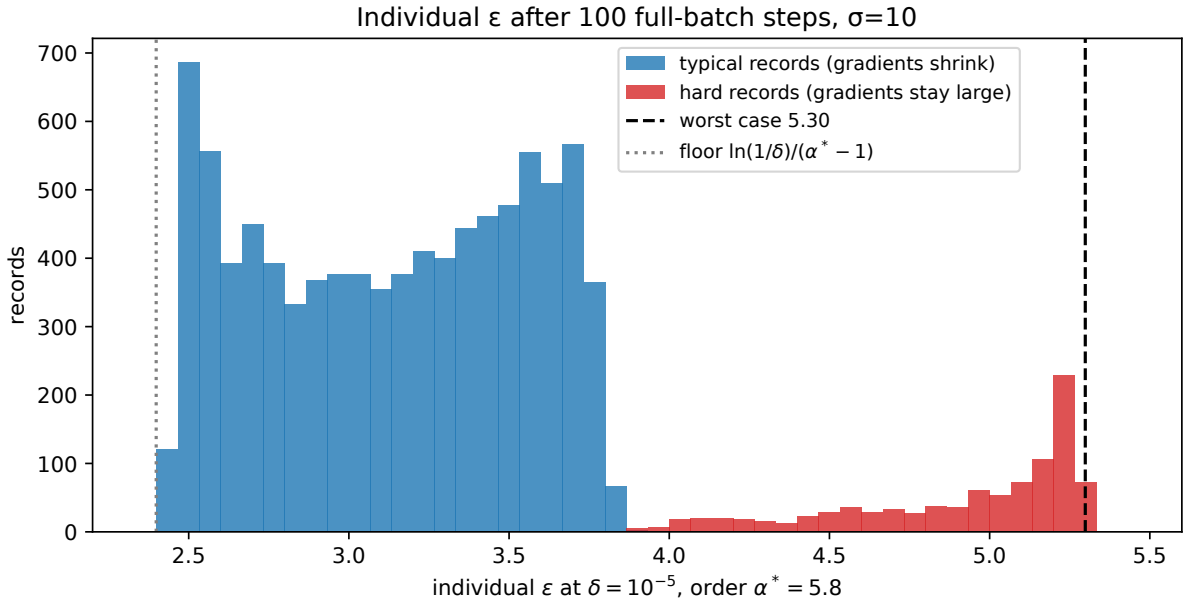

Figure 36.5.: Individual ε at $\delta = 10^{-5}$ and order $\alpha^* = 5.8$ after 100 full-batch steps with $\sigma = 10$. Typical records (blue) spend far less than the worst case (dashed); hard records (red) pile up just below it. The dotted line is the floor $\ln(1/\delta)/(\alpha^* - 1)$ that a fixed order cannot go below.

The individual filter over 300 steps. With budget $B = 2.900$ at $\alpha^* = 5.8$, everyone takes part in the first 100 steps, since no step costs more than 0.0290 and $100 \times 0.0290 = 2.900$. After that, hard records run out: the first is excluded at step 101, the median one at step 111, and by step 200 none takes part (0.1% are back in at step 300, on steps where their gradient happened to

be small enough to fit in what was left of the budget). No typical record is ever excluded; at step 300 their median spend is 0.778, about a quarter of the budget. Every record, typical or hard, has the same $(5.8, 2.900)$-RDP guarantee, the same as the 100-step worst-case run (Figure 36.6).

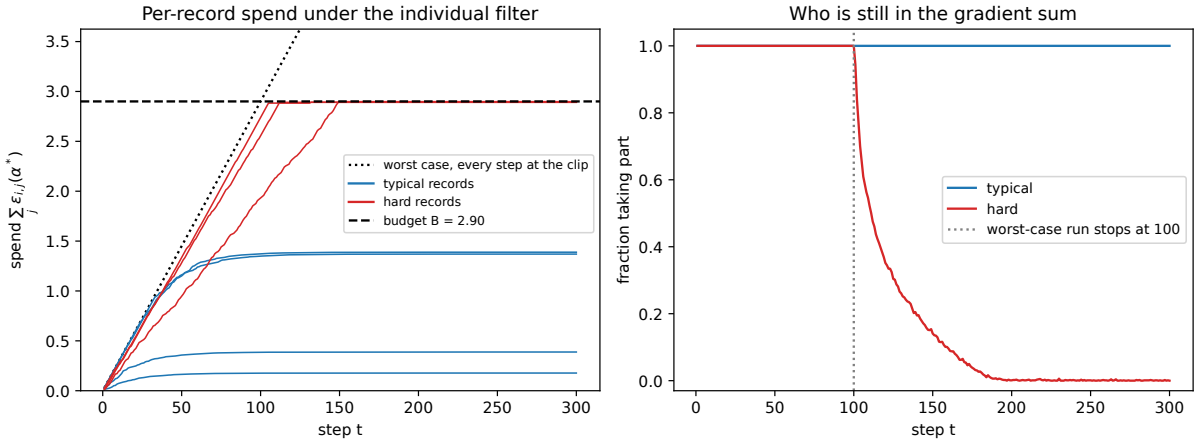

Figure 36.6.: Left: cumulative spend at order 5.8 under the individual filter, for four typical records (blue) and three hard records (red), against the worst case (dotted) and the budget $B = 2.90$ (dashed). Hard records reach the budget and stop; typical records level off far below it. Right: the fraction of each group that takes part in the gradient sum at each step.

36.7.6. Check yourself

- Why must a record's spend be computed from that record and the past outputs alone, and not from the whole dataset? *(If record j's spend depended on the whole dataset, removing record i would change the spends of other records and so which of them take part. The outputs with and without i would then differ even at steps where i itself is dropped, and step 3 fails. Feldman & Zrnic make this point about the per-instance definition, relative to the fixed dataset. For a clipped-gradient sum the issue does not arise, since $\bar{g}_{i,t}$ depends only on record i and the model.)*
- If every gradient is clipped, is the individual filter ever worse than the worst-case analysis? *(No. Each per-step spend is at most $\alpha/(2\sigma^2)$, so every record survives at least $B/(\alpha/(2\sigma^2))$ steps, the length of the worst-case run, and the guarantee is the same.)*

36.8. Code: filters, odometers and per-record spend

The script code/adaptive_composition.py computes every number in this chapter and draws every figure. The plug-in failure is computed exactly by dynamic programming over the randomized-response walk. The filters are short functions of the realized parameters; the Rogers et al. budget is found by bisection. The Rényi filter is checked on the three-step table and by Monte Carlo on adaptive Gaussian steps; the Ville odometer's tightness is checked against the Brownian line-crossing formula. The individual-accounting simulation uses the explicit gradient-norm model above. From the repository root:

```
uv run python code/part04-privacy-accounting/adaptive_composition.py
```

Output (seed 0), summarized in Table 36.8:

Table 36.8.: The script's output with the default seed.

Experiment	Result
Plug-in advanced composition, randomized response $\varepsilon = 0.1$	Crossing by $n = 10^4$: 0.1424 at $\delta = 0.05$, 0.0318 at $\delta = 0.01$, 3.69×10^{-5} at $\delta = 10^{-5}$; at a single fixed $t \leq 1000$ at most 0.0110, 0.0016 and 8.18×10^{-7}
Budget for $k = 1000$ steps of 0.01, $\delta = 10^{-6}$	Basic 10.000; advanced (fixed k) 1.763; Rogers filter 2.570; Whitehouse filter 1.712
Steps allowed at $\varepsilon_g = 1$, $\varepsilon_0 = 0.01$	Basic 100; advanced 337; Rogers 154; Whitehouse 349
Three-step randomized response, $\alpha = 2$	$\mathbb{E}[N_3] = 1.0000$; joint $D_2 = 1.8487 =$ budget; fixed-curve bound 2.5419
Adaptive Gaussian filter, $\alpha = 2$, $B = 1$, 10^6 paths	With top-up $D_2 = 1.0004$; without, $D_2 = 0.9305$
Odometers, $\sigma = 10$, $t = 100$, $\delta = 10^{-5}$	Fixed time 5.299; Ville 6.253; Lécuyer 6.507
Odometers, running example ($q = 0.01$, $\sigma = 1$, 10^4 steps)	Fixed time 7.43; Ville 8.82; Lécuyer 9.08
Ville crossing, Gaussian steps, $\delta = 0.05$	Monte Carlo 0.0461; Brownian limit 0.0500
Individual ε, 100 steps, $\sigma = 10$	Worst case 5.299; median typical 3.17, hard 5.02
Individual filter, 300 steps	Hard records excluded from step 101 (median 111); typical never; typical median spend 0.778 of 2.900

tests/test_adaptive_composition.py checks that the output still matches.

Four things stand out. First, stopping is the whole difficulty: the same bound that is valid at every fixed time fails about three times as often as claimed (2.85 times at $\delta = 0.05$, 3.18 at 0.01) once the analyst may choose when to stop. Second, filters cost nothing in RDP: the Rényi filter's bound is attained in the Monte Carlo check, and the derived DP filter matches fixed-parameter zCDP composition. Third, odometers cost a union bound, about 15–19% in ε here, which is the price of choosing the order after the fact. Fourth, per-record spend varies widely: most records spend far less than the worst case, while the minority that the model never fits spend all of it and are the first to be dropped.

36.10. Cheat sheet

Steps have predictable parameters ε_t (pure DP) or $\varepsilon_t(\alpha)$ (RDP at a fixed order); $V = \sum_t \varepsilon_t^2$; $S_t(\alpha) = \sum_{j \le t} \varepsilon_j(\alpha)$. Table 36.9 collects the results.

Table 36.9.: Filters, odometers and individual accounting.

Object	Rule or bound	Guarantee	Source
Basic filter / odometer	$\sum_t \varepsilon_t \le \varepsilon_g$; $U_t = \sum_{j \le t} \varepsilon_j$	$(\varepsilon_g, 0)$-DP; holds on every path	Rogers et al., Thm 3.4
Rogers filter	Equation 36.4 $\le \varepsilon_g$	(ε_g, δ)-DP, $\delta < 1/e$	Rogers et al., Thm 5.1
Whitehouse filter	$\sqrt{2\ln(1/\delta)V + V/2} \le \varepsilon_g$, i.e. $V/2 \le \rho^*$	(ε_g, δ)-DP	Whitehouse et al., Thm 2

Object	Rule or bound	Guarantee	Source
Rényi filter	$S_T(\alpha) \le B$ on every path	(α, B)-RDP	Feldman & Zrnic; Lécuyer
Ville odometer	$U_t = \min_{\alpha\in\Lambda}[S_t(\alpha) + \ln(\lvert\Lambda\rvert/\delta)/(\alpha-1)]$	$\Pr[\exists\, t : L_{1:t} > U_t] \le \delta$	Fact 3 + union bound
Lécuyer odometer	Equation 36.9	same	Lécuyer, Section 4
Individual spend, Gaussian sum	$\varepsilon_{i,t}(\alpha) = \alpha\lVert\bar{g}_{i,t}\rVert^2/(2\sigma^2C^2)$	per-record filter gives (α, B)-RDP	Feldman & Zrnic

Rules of thumb

- Never report a fixed-time bound evaluated at a data-dependent time. Use a filter if you have a budget, an odometer if you do not.
- In RDP, a filter at a fixed order costs nothing. Fix the order before the run; track a few orders if you want the best one, and stop when any is exhausted.
- An odometer costs a union over the orders you might choose: replace $\ln(1/\delta)$ by $\ln(\lvert\Lambda\rvert/\delta)$, and keep the grid small.
- For pure-DP steps, the Whitehouse filter is advanced composition with the mean term $\varepsilon_t^2/2$, and it is valid for adaptive parameters.
- Individual accounting gives every record the same guarantee and lets well-fitted records keep training; the records it drops first are the ones the model already serves worst.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

37. Choosing an accountant

37.1. Why this matters

You have trained a model with differential privacy (DP). The training loop was stochastic gradient descent (SGD) with per-example clipping and Gaussian noise, called DP-SGD. At each step every record joins the batch independently with probability q (Poisson sampling), each record's gradient is clipped to norm at most C, and Gaussian noise of standard deviation σC is added to the sum, so σ, the **noise multiplier**, says how large the noise is compared with one record's largest possible contribution. Your run used $q = 0.01$, $\sigma = 1$ and $T = 10{,}000$ steps. You must now write one sentence in a paper or a model card: "the model is $(\varepsilon, 10^{-5})$-DP". That sentence means: for any two datasets that differ in one record, and for any event about what training released, the probability of the event on one dataset is at most e^{ε} times its probability on the other, plus $\delta = 10^{-5}$. A small ε means one record barely changes what anyone can see; δ is a small allowance for that promise to fail.

The run is fixed, so its true ε is one number. But nobody can compute it exactly, and a procedure that bounds or estimates it is called an **accountant**. The chapters of this part give you six of them. Composing per-step guarantees gives 11296.93. Rényi differential privacy (RDP) gives 7.4287 or 6.7127, depending on the conversion. The Gaussian differential privacy (GDP) central limit theorem (CLT) gives 6.0071. A privacy loss distribution (PLD) accountant gives an interval, $[6.1377, 6.2377]$. These numbers describe the same training run. Which one do you report, and what else must you say so that someone else can check it?

37.1.1. The one idea: bounds and approximations

The numbers differ because the accountants make two different kinds of statement, and you can only report one kind.

An **upper bound** comes with a proof that holds for every pair of neighbouring datasets. It may be loose, so the true ε may be smaller, but the run really is (ε, δ)-DP with the ε it reports. Per-step composition, RDP with any of its conversions, and the pessimistic PLD are upper bounds. An **approximation** has no such proof. It may land close to the truth, but nothing stops it from landing below, and then it reports a number for which the run is *not* (ε, δ)-DP. The GDP central-limit approximation is of this kind, and on the running example it does land below: it falls under the PLD *lower* bound at every T.

The optimistic PLD makes a third kind of statement, a certified **lower bound**: the true ε is at least this large. It is not a privacy guarantee, since it says the run is no better than this, but it tells you how far any valid upper bound can fall. The true ε sits between the pessimistic and the optimistic PLD.

So the rule is short. **Report the tightest upper bound whose assumptions hold for the code you ran, and report enough that someone else can recompute it.** Each section of this chapter unpacks one clause of that rule. Table 37.1 lists the sections.

Table 37.1.: The sections of this chapter and where each one is used.

Section	Question	Where you use it
Section 37.2	How do the accountants compare on one DP-SGD run, and which are bounds?	Picking an accountant
Section 37.3	How much noise does each accountant ask for at a target ε?	Calibrating σ before training
Section 37.4	Which accountant is tight for which mechanism?	Accounting for anything other than DP-SGD
Section 37.5	Do the accountant's assumptions match the training code?	Code review of a private training pipeline
Section 37.6	What must a privacy statement contain?	Papers, model cards, audits
Section 37.7	How do you check an accountant?	Testing your own, or someone else's, accountant

This chapter adds little new theory: the ordering of the bounds and the monotonicity behind the inverse problem are the only new derivations. Every accountant is the one derived earlier in the part, and the script imports it from that chapter's code rather than re-implementing it. Each section below restates what an accountant does where it uses it, so you can read this chapter on its own. The running example and the order grid are those of the whole part.

37.2. Every accountant on one run

37.2.1. Context

This is the question the part has built up to: for DP-SGD with $q = 0.01$, $\sigma = 1$ and up to $T = 10{,}000$ steps, compute ε at $\delta = 10^{-5}$ with every accountant, and see what choosing a loose one costs. Amplification by subsampling and Numerical accounting each computed some of these numbers. This section puts them in one table, adds the optimal conversion of an RDP curve, and says for each accountant what it assumes and whether it is a bound.

37.2.2. Statement

All accountants start from the same object: what one step of DP-SGD reveals about one record. Look at the noisy gradient sum along the direction of that record's clipped gradient, and measure

it in units of the clipping norm C. Without the record, the output is pure noise, $\mathcal{N}(0, \sigma^2)$. With the record, the record is in the batch with probability q, and then its gradient shifts the output by 1; otherwise it is absent and the output is the same noise. So the output is the mixture $(1-q)\mathcal{N}(0, \sigma^2) + q\mathcal{N}(1, \sigma^2)$. The accountants differ in what they keep of this pair and how they combine T copies of it. Here they are, each with where it was derived:

1. **Per step, then composition** (Amplification by subsampling, Section 33.7). First find an $(\varepsilon_0, \delta_0)$ guarantee for one Gaussian step on its own. Then use subsampling: because the record is missing from the batch with probability $1-q$, the factor e^{ε_0} by which it can change a probability is diluted to $1 + q(e^{\varepsilon_0} - 1)$, which is Equation 33.5, $\varepsilon_1 = \ln(1 + q(e^{\varepsilon_0} - 1))$. Finally compose T steps, either by basic composition, where the ε's simply add to $T\varepsilon_1$, or by advanced composition, which grows like $\sqrt{T}$ at the price of an extra δ'.
2. **RDP, Mironov's conversion** (Rényi DP). RDP describes one step by a curve $\varepsilon(\alpha)$, the Rényi divergence of order $\alpha > 1$ between the two output distributions; for the subsampled Gaussian it is Equation 33.9. Its appeal is that curves of composed steps simply add, so T steps have curve $T\,\varepsilon(\alpha)$. To get back to (ε, δ), Mironov's conversion uses the fact that δ is at most the chance that the privacy loss L (defined in item 6) exceeds ε. The curve fixes the moment $\mathbb{E}[e^{(\alpha-1)L}] = e^{(\alpha-1)T\varepsilon(\alpha)}$, so Markov's inequality gives $\Pr[L > \varepsilon] \le e^{(\alpha-1)(T\varepsilon(\alpha)-\varepsilon)}$. Setting the right side equal to δ and solving gives, at each order, $\varepsilon = T\,\varepsilon(\alpha) + \frac{\ln(1/\delta)}{\alpha-1}$, and the conversion takes the best order: $\varepsilon = \min_\alpha \left[T\,\varepsilon(\alpha) + \frac{\ln(1/\delta)}{\alpha-1}\right]$.
3. **RDP, improved conversion** (From Rényi DP to (ε, δ) and to tests, Equation 30.7). The same curve, converted with a sharper analysis of the same tail (Balle et al. 2020) that saves a fixed amount at each order: $\varepsilon = \min_\alpha \left[T\,\varepsilon(\alpha) + \ln\frac{\alpha-1}{\alpha} - \frac{\ln\delta + \ln\alpha}{\alpha-1}\right]$.
4. **RDP, optimal conversion** (Section 30.5). The best any conversion of the curve can do: the smallest ε that every pair of distributions with the curve $T\,\varepsilon(\alpha)$ satisfies at δ.
5. **GDP central-limit approximation** (f-DP and Gaussian DP, Equation 32.17). A mechanism is **μ-GDP** if telling its two output distributions apart is no easier than telling $\mathcal{N}(0,1)$ from $\mathcal{N}(\mu,1)$. The privacy loss of T steps is a sum of T small losses, so by the central limit theorem it is close to Gaussian, and the approximation treats the run as μ-GDP with $\mu = q\sqrt{T(e^{1/\sigma^2} - 1)}$. It then reads ε off the exact (ε, δ) curve of a μ-GDP mechanism, Equation 32.10.
6. **PLD, pessimistic and optimistic** (Numerical accounting, Equation 34.6). The **privacy loss** at an output y is the log of how much more likely y is on one of the two neighbouring datasets than on the other, and its distribution over outputs is the PLD. Each order of the pair gives its own PLD: the **remove** direction puts the dataset with the record first, so the loss measures how much more likely y is with the record than without it, and the **add** direction puts it second. Under composition the losses add, so the PLD of T steps is the T-fold convolution of one step's PLD, which a computer does quickly with the fast Fourier transform (FFT). The convolution needs the loss on a grid, here of width $h = 10^{-5}$. Rounding every loss up gives the pessimistic PLD, rounding it down the optimistic one. Solve each for ε, and take the larger of the add and remove directions, since the guarantee must hold whichever of the two datasets has the record (each direction's pair dominates its case, as Section L.2 in the appendices proves).

Table 37.2 gives every accountant's ε on the running example.

Table 37.2.: DP-SGD with $q = 0.01$, $\sigma = 1$: ε at $\delta = 10^{-5}$ after T steps under every accountant of this part. Basic and advanced are per-step amplification followed by composition; the PLD columns use the grid $h = 10^{-5}$.

T	Basic	Advanced	RDP, Mironov	RDP, improved	RDP, optimal	GDP CLT	PLD upper	PLD lower
1	0.20	1.13	1.3175	0.9555	0.4899	0.0368	0.1995	0.1994
10	3.64	7.88	1.4145	1.0353	0.7951	0.1304	0.3800	0.3799
100	58.01	78.10	1.6118	1.2141	1.1538	0.4575	0.7185	0.7175
1,000	839.39	1258.64	2.5380	2.1014	2.1009	1.6177	1.8332	1.8232
10,000	11296.93	24379.55	7.4287	6.7127	6.7127	6.0071	6.2377	6.1377

37.2.3. Derivation: what each accountant assumes, and why it is a bound

Every row of Table 37.2 assumes the same model of the training run: Poisson sampling at rate q, add/remove neighbours (the two datasets differ by one record being present or absent), per-example clipping to norm C and Gaussian noise of standard deviation σC on the summed gradients, and every intermediate noisy gradient released. Under that model, one step is the Poisson-subsampled Gaussian pair of the statement, $(1-q)\mathcal{N}(0,\sigma^2)+q\mathcal{N}(1,\sigma^2)$ against $\mathcal{N}(0,\sigma^2)$, in units of C (Amplification by subsampling). The accountants differ only in what they keep of this pair, and each step below says whether what is kept still gives a proof.

1. **Per step, then composition: an upper bound.** One step is $(\varepsilon_1, q\delta_0)$-DP by the amplification theorem (Section 33.3), and basic and advanced composition hold even when each step is chosen after seeing the earlier outputs, which is how SGD works (Composition). So the result is a proof. It is very loose because each step's whole privacy loss distribution is replaced by just two numbers, ε_1 and $q\delta_0$, and composition has to assume the worst distribution consistent with them at every step.
2. **RDP with Mironov's or the improved conversion: an upper bound.** Three facts make this a proof. The subsampled curve Equation 33.9 is the exact Rényi divergence of the pair, not an estimate. RDP curves add under adaptive composition (Equation 29.10), because the Rényi divergence is the log of a moment of the likelihood ratio, and the moment of a product of independent factors is the product of their moments. And both conversions are proved for every pair with the curve (Section 30.3, Section 30.4). The accountant evaluates the curve only on a grid of orders, and minimizing over fewer orders can only give a larger ε, so the grid costs tightness, never validity.
3. **RDP with the optimal conversion: an upper bound.** It computes the largest $\delta(\varepsilon)$ over all pairs of distributions with the given RDP curve. The real pair has that curve, so it is in the set, and its $\delta(\varepsilon)$ is no larger than the maximum (Section 30.5). The same argument shows it is the tightest bound any accountant that sees only the curve can give: some pair in the set attains the maximum, and such an accountant cannot tell that pair from the real one.
4. **The GDP central-limit approximation: not a bound.** Equation 32.17 comes from two approximations (Section 32.8). It is a limit as $T \to \infty$ with $q\sqrt{T}$ held fixed, and it uses a second-order expansion of the per-step loss, keeping its mean and variance and dropping

the rest. Neither step comes with an error bound in the tail of the loss distribution, and $\delta = 10^{-5}$ is read exactly there: it asks about the chance of a rare, large loss, which is where a Gaussian approximation is least reliable.

5. **The pessimistic PLD: an upper bound; the optimistic PLD: a lower bound.** Rounding every loss up describes a pair that leaks at least as much as the real one (a dominating pair), and composing two dominating pairs gives a dominating pair, so the rounding error keeps its sign through all T convolutions. Rounding down does the same in the other direction. So $\delta^{\downarrow}(\varepsilon) \le \delta(\varepsilon) \le \delta^{\uparrow}(\varepsilon)$ for every ε (Equation 34.6). The upper bound holds under adaptive composition of the fixed per-step pair (Section K.3 in the appendices proves it). How far apart are the two? Each step's loss moves by less than one grid width h between rounding down and rounding up, so after T steps the two composed losses differ by at most Th, and so do the ε's they give, as long as no tail is truncated (Section 34.5). Here $Th = 10{,}000 \times 10^{-5} = 0.1$.

Steps 2, 3 and 5 put the bounds in two orders, which together read

$$\varepsilon_{\text{RDP, Mironov}} \;\ge\; \varepsilon_{\text{RDP, improved}} \;\ge\; \varepsilon_{\text{RDP, optimal}} \;\ge\; \varepsilon_{\text{true}}, \qquad \varepsilon^{\uparrow}_{\text{PLD}} \;\ge\; \varepsilon_{\text{true}} \;\ge\; \varepsilon^{\downarrow}_{\text{PLD}}. \tag{37.1}$$

The second chain is the sandwich of step 5. In the first chain, the last inequality is step 3. Mironov's conversion is above the improved one because at every order the improved one is smaller by $\Delta(\alpha) = \frac{\ln \alpha}{\alpha - 1} + \ln \frac{\alpha}{\alpha - 1} > 0$ (Equation 30.10); both terms are positive for $\alpha > 1$, and if one expression is above another at every order, its minimum over the grid is above too. The improved conversion is above the optimal one because the optimal one is, by definition, the smallest ε valid for every pair with the curve, and the improved one is one such valid ε.

The theory does not order the two chains against each other. You might expect the RDP bounds to always sit above the PLD upper bound, because RDP throws away information. But the pessimistic PLD describes a rounded-up pair, not the real one, and its ε may exceed the truth by up to Th. A bound from the curve alone that came very close to the truth could therefore fall below it. Without truncation, all that follows is $\varepsilon_{\text{RDP, optimal}} \ge \varepsilon_{\text{true}} \ge \varepsilon^{\uparrow}_{\text{PLD}} - Th$. On the running example the script checks both chains at all nine values of T from 1 to 10,000. It also finds RDP optimal $\ge$ PLD upper at every one of them, because the curve slack (at least 0.2677, from Table 37.4 below) is far larger than Th (at most 0.1000). That is an observation about this example, not a theorem. The script also checks that the CLT value is below the PLD lower bound at every T.

37.2.4. Interpretation

Figure 37.1 plots the table on a log scale, with each accountant's ratio to the PLD upper bound beside it. Table 37.3 lists the ratios. Since the PLD upper bound is within Th of the truth, a ratio well above 1 measures how much an accountant overstates ε, and a ratio below the PLD lower column means the number is not a valid guarantee.

Table 37.3.: Each accountant's ε divided by the PLD upper bound, from Table 37.2.

T	Basic	Advanced	RDP, Mironov	RDP, improved	RDP, optimal	GDP CLT	PLD lower
1	1.00	5.66	6.61	4.79	2.46	0.18	1.00

T	Basic	Advanced	RDP, Mironov	RDP, improved	RDP, optimal	GDP CLT	PLD lower
10	9.58	20.74	3.72	2.72	2.09	0.34	1.00
100	80.73	108.69	2.24	1.69	1.61	0.64	1.00
1,000	457.88	686.57	1.38	1.15	1.15	0.88	0.99
10,000	1811.07	3908.41	1.19	1.08	1.08	0.96	0.98

Per-step composition is useless beyond a handful of steps. It is the right answer only at $T = 1$, where there is nothing to compose and basic composition is just the amplified one-step guarantee. At $T = 10{,}000$ it is off by a factor of over a thousand, because adding ε's assumes every step leaks its worst case, while in reality the losses of different steps mostly cancel. Advanced composition is worse than basic here, for the reason given in Section 33.7. Its bound is $\varepsilon_1\sqrt{2T\ln(1/\delta')}+T\varepsilon_1(e^{\varepsilon_1}-1)$: a $\sqrt{T}$ term with a large constant (at $\delta' = 10^{-5}$, $\sqrt{2\ln(10^5)} \approx 4.80$), plus a term that still grows like T. The $\sqrt{T}$ only wins when ε_1 is so small that the second term is negligible, and the amplified per-step ε_1 is too large for that.

RDP is a safe bound, and its slack has two sources. RDP with the improved conversion exceeds the PLD upper bound for two separate reasons, and Table 37.4 splits the excess accordingly. The first is the conversion: turning the curve into one (ε, δ) pair with the improved formula loses against the best possible conversion of the same curve, and that loss is improved minus optimal. The second is the curve itself: even the best conversion of the curve is above the PLD, because the curve keeps only a family of moments of the privacy loss, not its whole distribution, and that loss is optimal minus PLD upper.

Conversion slack dominates short runs. At $T = 1$ the conversion loses 0.4656 of the 0.7561 excess. The reason is the term $\ln(1/\delta)/(\alpha-1)$ in the conversion (about $11.5/(\alpha-1)$ at $\delta = 10^{-5}$), which you pay however small the curve is. When the curve is tiny, as after one step, this fixed toll is most of the answer.

Curve slack dominates long runs. After many steps the curve $T\,\varepsilon(\alpha)$ is large, the best order moves up, and the fixed toll shrinks in comparison. From $T = 1000$ on, the conversion slack is negligible (0.0005 at $T = 1000$, zero to four decimals at $T = 10{,}000$), and almost all the slack is in the curve. That last 7.6% at $T = 10{,}000$ is what only a numerical accountant removes, because only it keeps the whole distribution.

The CLT under-reports here. It is below the certified lower bound at every T: at $T = 10{,}000$, 6.0071 against 6.1377. Its ratio climbs toward 1 as T grows, as a central limit theorem should, since a sum of more terms is closer to Gaussian. But at no T in the table is it a valid guarantee.

The PLD bracket is the truth, to within Th. At $T = 10{,}000$ the width is $6.2377 - 6.1377 = 0.1000$ on this grid, exactly Th. If that is too wide, refine h. Its only other error, truncating the far tails of the loss, is pushed in the safe direction on each side (mass is moved so that the upper bound only rises and the lower bound only falls), so h is the one knob to turn.

Table 37.4.: Where the RDP accountant (improved conversion) loses against the PLD upper bound. Conversion slack is improved minus optimal conversion; curve slack is optimal conversion minus PLD upper bound.

T	Conversion slack	Curve slack	Total	Excess over PLD upper
1	0.4656	0.2905	0.7561	379.1%
10	0.2402	0.4151	0.6554	172.5%
100	0.0603	0.4353	0.4956	69.0%
1,000	0.0005	0.2677	0.2681	14.6%
10,000	0.0000	0.4750	0.4750	7.6%

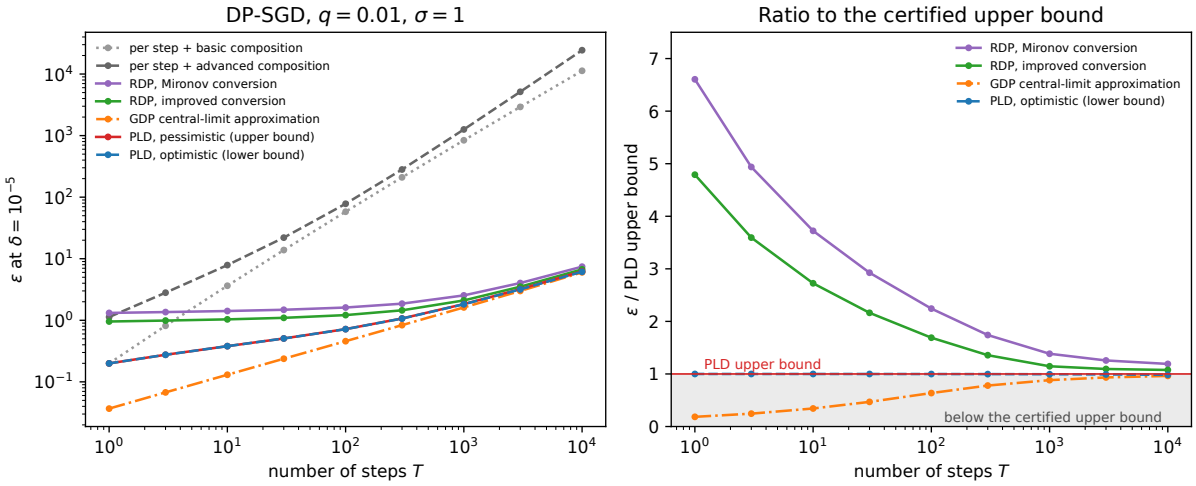

Figure 37.1.: Left: ε at $\delta = 10^{-5}$ against the number of steps T for DP-SGD with $q = 0.01$, $\sigma = 1$, under per-step basic and advanced composition, RDP with Mironov's and the improved conversion, the GDP central-limit approximation, and the pessimistic and optimistic PLD on the grid $h = 10^{-5}$ (the two PLD curves overlap). Right: RDP (both conversions), the CLT and the PLD lower bound divided by the PLD upper bound; per-step composition (ratios 1 to 3908) is off the scale. Ratios above 1 are valid but loose; the shaded region below 1 is where only the PLD lower bound may lie, and the CLT lies there at every T.

37.2.5. Example: the number you would have reported

Suppose you ran 1,000 steps. Depending on the accountant, your paper says $\varepsilon = 2.54$ (RDP with Mironov's conversion, as in older code), 2.10 (RDP with the improved conversion, as in Opacus's RDP accountant), 1.83 (a PLD accountant), or 1.62 (the CLT). The first three are true statements about the run, because each is an upper bound; the third is the most informative, because it is the smallest. The fourth is false: the optimistic PLD proves $\varepsilon \geq 1.8232$, so the true ε is larger than 1.62 and the run is not $(1.62, 10^{-5})$-DP.

37.2.6. Check yourself

- At $T = 1$, per-step basic composition gives 0.20 and RDP gives 0.9555. Does that make the RDP accountant wrong? *(No. Both are upper bounds, and the basic one happens to be tighter for a single step, because RDP's conversion pays* $\ln(1/\delta)/(\alpha - 1)$ *even when the curve is tiny. RDP wins as soon as there is something to compose.)*
- Why can the optimal conversion of an RDP curve never beat the pessimistic PLD by more than Th? *(It must cover every pair with the same RDP curve, and the real pair is one of them, so it is at least the true* ε*. The pessimistic PLD is at most* Th *above the true* ε*. So the optimal conversion can fall below the PLD upper bound, but by at most* Th *(without truncation). Here the curve slack is much larger than* Th*, and the script finds optimal* $\geq$ *PLD upper at every* T*.)*

37.3. The inverse problem: noise for a target ε

37.3.1. Context

Practitioners rarely compute ε after the fact. They fix a budget, say $\varepsilon = 3$ at $\delta = 10^{-5}$, fix the number of steps and the batch size, and ask how much noise they must add. The noise multiplier is then the knob that sets utility. The noise added to the gradient sum has standard deviation σC, and the sum is divided by the expected batch size qn for n records, so the noise in the averaged gradient has standard deviation $\sigma C/(qn)$. A loose accountant overstates ε at every σ, so it asks for a larger σ to meet the same budget: its slack turns directly into extra noise.

37.3.2. Statement

For each accountant A, write $\varepsilon_A(\sigma)$ for the ε it reports at δ for the run with noise multiplier σ. The noise it requires for a target ε^* is the smallest σ at which its reported ε meets the target:

$$\sigma_A(\varepsilon^*) = \min\{\sigma > 0 : \varepsilon_A(\sigma) \leq \varepsilon^*\}. \tag{37.2}$$

Table 37.5 gives it for $T = 10{,}000$, $q = 0.01$, $\delta = 10^{-5}$ and three targets.

Table 37.5.: The noise multiplier σ each accountant requires for a target ε at $\delta = 10^{-5}$, with $T = 10{,}000$ steps at $q = 0.01$. PLD on the grid $h = 10^{-5}$; the PLD lower column is the σ at which the optimistic bound reaches the target.

Target ε	Advanced	RDP, Mironov	RDP, improved	GDP CLT	PLD upper	PLD lower
1	24.682	4.974	4.126	3.796	3.988	3.654
3	10.505	1.854	1.662	1.549	1.584	1.547
8	5.711	0.962	0.917	0.868	0.885	0.880

37.3.3. Derivation

The plan is to show that more noise never raises any accountant's ε, so that Equation 37.2 asks for the point where a decreasing function crosses a level, and then to find that point numerically.

1. **Every bound decreases in σ.** The idea is that a noisier run can be produced from a less noisy one without touching the data, and that cannot reveal more. Fix $\sigma < \sigma'$. (a) *Post-processing:* the variances of independent Gaussians add, so adding independent $\mathcal{N}(0, \sigma'^2 - \sigma^2)$ noise to the output of the step with noise σ gives exactly the step with noise σ', in both runs and in every step. That map does not look at the data. (b) *Data processing:* the data-processing inequality (Divergences) says that passing two distributions through the same data-independent map can only make them harder to tell apart, so every divergence between them can only fall. That applies to the per-step and the composed pair, and to both the Rényi divergences and the hockey-stick divergence that defines $\delta(\varepsilon)$. Every accountant is built from those divergences, so its ε falls too. For the discretized PLD this holds only up to grid effects of order Th, since rounding can move a value by up to that much. The CLT's $\mu = q\sqrt{T(e^{1/\sigma^2} - 1)}$ falls in σ directly, because e^{1/σ^2} does.
2. **So Equation 37.2 is a root of a decreasing function,** $\varepsilon_A(\sigma) - \varepsilon^*$, and any bracketing method finds it: start from a low σ where the function is positive and a high one where it is negative, and shrink the interval while keeping the sign change inside. The script uses false position with the Illinois modification. False position places each new guess where the straight line through the two ends crosses zero, rather than at the midpoint as bisection does. The Illinois modification halves the function value kept at an end that has not moved for two rounds, which stops one end from getting stuck. It needs only a handful of evaluations. That matters for the PLD, where each evaluation is two FFT compositions of 10,000 steps. The script stops when the bracket is narrower than 10^{-4} and returns the upper end, where $\varepsilon_A \leq \varepsilon^*$. The method does not need exact monotonicity for this. Up to discretization, the returned σ may not be the minimum in Equation 37.2, but it was checked to satisfy $\varepsilon_A(\sigma) \leq \varepsilon^*$, which is all safety needs. For an upper-bound accountant the returned σ is therefore safe.
3. **The bracket for the PLD comes from the other accountants.** The RDP value serves as the upper end: RDP was above the PLD upper bound at every T in Table 37.2, so it should need more noise, though the theory does not guarantee it (Equation 37.1). Ninety percent of the smaller of the RDP and CLT values serves as the lower end. Because neither end is guaranteed, the solver checks that the two ends really bracket the root, with the function positive at one end and negative at the other, and stops with an error if they do not.
4. **The CLT has a closed form.** First find the μ^* whose GDP curve Equation 32.10 gives ε^* at δ. Then solve $\mu = q\sqrt{T(e^{1/\sigma^2} - 1)}$ for σ: squaring gives $q^2T(e^{1/\sigma^2} - 1) = \mu^{*2}$, so $e^{1/\sigma^2} = 1 + \mu^{*2}/(q^2T)$, and taking logs and square roots, $\sigma = 1/\sqrt{\ln(1 + \mu^{*2}/(q^2T))}$.

As a check, the RDP column reproduces $\sigma = 4.126$ for $\varepsilon = 1$ from Exercise 4 in the exercise book of Amplification by subsampling, and the PLD upper bound at $\sigma = 3.9884$ is 1.0000, as the solution of $\varepsilon_A(\sigma) = 1$ should give.

37.3.4. Interpretation

Figure 37.2 shows each accountant's σ relative to the PLD upper bound's, the tightest certified one.

Advanced composition needs six times the noise. It asks for 6.19 to 6.63 times the σ of the PLD ($24.682/3.988 \approx 6.19$ at $\varepsilon = 1$, $10.505/1.584 \approx 6.63$ at $\varepsilon = 3$), a noise level at which DP-SGD rarely trains a useful model.

The RDP conversions cost a few percent of noise. Mironov's conversion costs 8.6 to 24.7% more noise, most at the strictest target, where its fixed $\ln(1/\delta)/(\alpha - 1)$ toll is the largest share of a small ε. RDP with the improved conversion costs 3.4 to 4.9% more noise. This is the σ-side image of the 7.6% ε-excess in Table 37.4, and it is smaller because ε falls faster than σ rises: in this range a small relative increase in σ buys a larger relative decrease in ε, so closing a gap in ε costs a smaller gap in σ. Seen from the other side, at $\sigma = 0.8851$, where the PLD certifies $\varepsilon = 8$, the RDP accountant reports 8.6330.

The CLT asks for less noise than the certified bound needs, 2.0 to 4.8% less. At $\varepsilon = 8$ this is provably too little: at the CLT's $\sigma = 0.8676$ the *optimistic* PLD, a lower bound on the true ε, already gives 8.2594, so the run is not $(8, 10^{-5})$-DP. At $\varepsilon = 1$ and 3 the grid is too coarse to tell. At the CLT's σ the PLD bracket is $[0.9550, 1.0550]$ and $[2.9938, 3.0938]$, and both contain the target, so the truth could be on either side.

The sandwich width matters most at small targets. The width $Th = 0.1$ is a fixed amount of ε, and it is 10% of $\varepsilon = 1$, so the PLD brackets σ only to $[3.654, 3.988]$. For a tight σ at a small target, refine h.

37.3.5. Example: what 4% of noise is worth

With $n = 50{,}000$ records and $q = 0.01$, the expected batch holds $0.01 \times 50{,}000 = 500$ records. At $\varepsilon = 8$, the RDP accountant sets $\sigma = 0.917$, so the averaged gradient carries noise of standard deviation $0.917C/500$. The PLD accountant sets $\sigma = 0.885$: the RDP accountant asks for 3.6% more noise for the same certified budget (the ratio 1.036 in Figure 37.2). The same budget, with a tighter accountant, buys a less noisy model. In the other direction, the PLD lets you keep σ and train longer; the exercises quantify that.

37.3.6. Check yourself

- Why does the script return the upper end of the final bracket rather than its midpoint? *(The upper end is a σ at which the accountant's ε was checked to be at most the target. For an upper-bound accountant that σ certifiably meets the budget; the midpoint might not.)*
- A colleague calibrates σ with the CLT and then reports the ε of the PLD upper bound at that σ. Is their report valid? *(Yes. The reported number comes from a bound, so it is valid. It is just above the target they meant to meet: 8.3594 instead of 8 at the $\varepsilon = 8$ target.)*

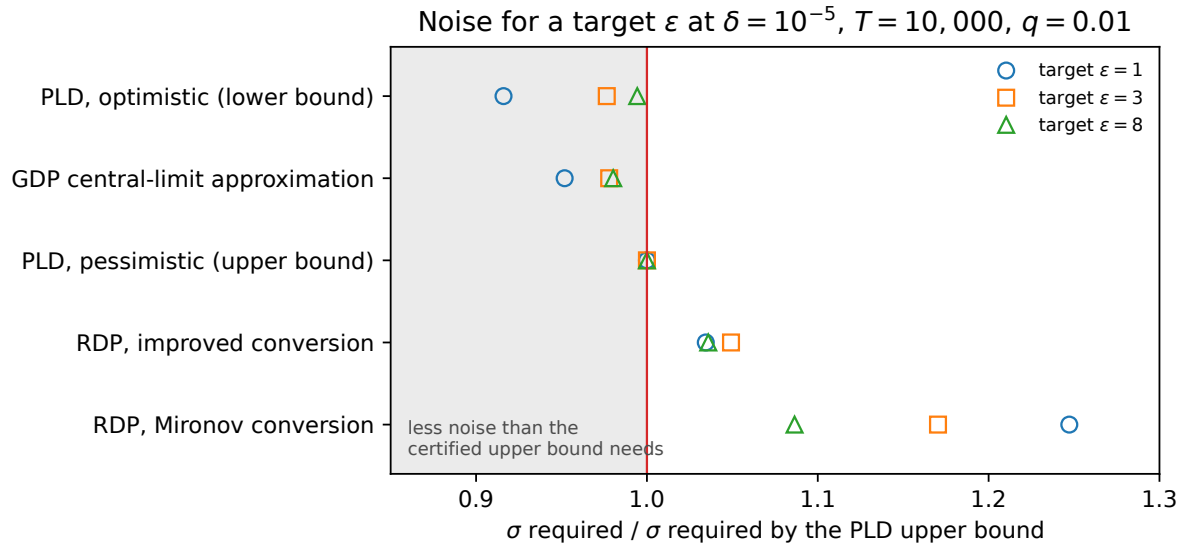

Figure 37.2.: For each target ε at $\delta = 10^{-5}$ ($T = 10{,}000$, $q = 0.01$), the noise multiplier each accountant requires, divided by the one the PLD upper bound requires. RDP with Mironov's conversion asks for up to 25% more noise and RDP with the improved conversion about 4% more. The CLT and the PLD lower bound fall in the shaded region: they ask for less noise than any certified accountant can justify. Advanced composition (6.19 to 6.63) is off the chart.

37.4. Where each accountant is tight

37.4.1. Context

DP-SGD is one mechanism. You will also release statistics with the Gaussian mechanism, answer queries with pure-DP mechanisms (those with $\delta = 0$), shuffle locally randomized reports, or stop training adaptively. The ranking of accountants changes with the mechanism, because what makes an accountant tight is whether the summary it keeps describes that mechanism's privacy loss exactly. This section collects, from the earlier chapters of this part, which accountant is tight for which mechanism, and puts numbers on three of the rows.

37.4.2. Statement

Table 37.6 is the decision table.

Table 37.6.: Which accountant to use for which mechanism, with the chapter or section that establishes it.

Mechanism	Use	Why, and how tight	Avoid
Gaussian, no subsampling (any number of steps, any sensitivity mix)	GDP or zero-concentrated differential privacy (zCDP), converted exactly with Equation 32.10	μ^2 adds and the Gaussian profile is exact (f-DP and Gaussian DP). RDP and zCDP keep the curve exactly but the conversion loses 5 to 10% (Section 30.7)	Per-step (ε, δ) composition
Poisson-subsampled Gaussian (DP-SGD)	PLD, pessimistic, with the optimistic value as error bar	Certified bracket of width Th (Numerical accounting). RDP with the improved conversion is 7.6 to 69% above it on the running example for $T \geq 100$	zCDP, which cannot express amplification (Section 31.8); the CLT as a guarantee
Pure-DP steps (randomized response, Laplace, exponential mechanism)	PLD (exact for finite outputs), or RDP with the mechanism's own curve	The privacy loss takes few values, so the PLD is exact or nearly so. zCDP with $\rho = \varepsilon^2/2$ is convenient but loose for large ε (Section 31.4)	Advanced composition when a tighter accountant is available
Adaptive choice of noise, stopping or per-record budgets	RDP filter at a fixed order (Adaptive composition)	Free at a fixed order (Section 36.5); an odometer costs a union bound over orders	Plugging realized ε_t into a fixed-parameter theorem
Local randomizers behind a shuffler	Exact computation for binary randomized response; numeric clone bound otherwise (Amplification by shuffling and by iteration)	The closed-form clone bound is 4.47 to 7.55 times the exact value there	The Poisson-subsampling accountant

Mechanism	Use	Why, and how tight	Avoid
Only the last iterate released	Amplification by iteration (Amplification by shuffling and by iteration)	Needs a convex, smooth loss, contractive steps and no released checkpoints; rarely applies to deep learning	Any hidden-state claim for non-convex training

37.4.3. Derivation: three rows with numbers

The script computes three rows at $\delta = 10^{-5}$, one where the composed loss is exactly Gaussian, one where it takes only a few values, and the DP-SGD case where it is neither.

1. **Gaussian without subsampling.** A Gaussian step with sensitivity 1 and noise multiplier σ is exactly μ-GDP with $\mu = 1/\sigma$, and under composition the squares of μ add, just as variances of independent Gaussians do (f-DP and Gaussian DP). So one hundred steps with $\sigma = 10$ compose to $\mu = \sqrt{100 \times (1/10)^2} = \sqrt{100}/10 = 1$. The exact ε from Equation 32.10 is 4.3772. RDP's curve for this run, $\alpha\mu^2/2$, is also exact, but converting it costs: it gives 4.7285 with the improved conversion, 8.0% above, and 5.2985 with Mironov's. Here zCDP, which describes the curve by a line $\rho\alpha$, is the same as RDP, because the curve already is a line.
2. **Pure DP: one hundred steps of randomized response with $\varepsilon_0 = 0.1$.** In randomized response each output is e^{ε_0} times more likely under one dataset than the other, in one direction or the other, so its privacy loss is $\pm\varepsilon_0$. The composed loss is ε_0 times (number of + steps minus number of − steps), so the composed PLD is a binomial and the exact $\delta(\varepsilon)$ is a finite sum (Numerical accounting). The exact ε is 4.3068. RDP with the exact randomized-response curve gives 4.6154. zCDP needs a ρ with $\varepsilon(\alpha) \le \rho\alpha$; the smallest that works for randomized response is $\varepsilon_0 \tanh(\varepsilon_0/2)$ per step, which is also the sharp charge every ε_0-DP mechanism satisfies (Equation 31.7 in Concentrated DP), and it gives 4.7263. Advanced composition with $\delta' = \delta$ gives 5.8502, and basic composition $100 \times 0.1 = 10.0000$.
3. **The subsampled Gaussian at $T = 10{,}000$.** From Table 37.2, the PLD brackets ε in $[6.1377, 6.2377]$, RDP (improved) gives 6.7127, 7.6% above the upper bound, and the CLT gives 6.0071, below the bracket.

37.4.4. Interpretation

The more structure the accountant keeps, the tighter it is. The ranking in each row follows the ladder of the part's introduction. An (ε, δ) pair keeps two numbers, zCDP one line, RDP a whole curve, GDP the whole trade-off function (the best type II error of any test at each type I error) when that function is Gaussian, and the PLD the entire distribution of the privacy loss. Each rung loses information the next one keeps, and lost information has to be filled in with a worst case.

The right tool depends on what is Gaussian. When the composed pair is exactly Gaussian, as in the first row, GDP is exact and costs nothing. When subsampling makes it a mixture, as in DP-SGD, no closed form is exact, and only the PLD is both certified and tight.

Adaptivity is the one place where RDP is the natural tool. If the noise or the stopping time is chosen while training runs, based on what has been released, the per-step pair is not fixed in advance. The Rényi filter of Section 36.5 handles that and loses nothing at a fixed order, whereas the PLD accountant above assumes the per-step pair is fixed in advance. The references of Adaptive composition include filters built on GDP and PLDs (Koskela, Tobaben & Honkela 2023) for when the RDP slack matters.

37.4.5. Example: an analytics pipeline

A team releases 100 noisy counts with the Gaussian mechanism at $\sigma = 10$ and reports $\varepsilon = 5.2985$, from an old RDP accountant with Mironov's conversion. The same release is exactly $(4.3772, 10^{-5})$-DP, as GDP shows. The reported number is 21.0% above the truth ($5.2985/4.3772 \approx 1.210$): the team could have answered more queries, or added less noise, at no cost in privacy.

37.4.6. Check yourself

- For the randomized-response row, why is the PLD exact rather than a bracket? *(The privacy loss takes only the values $\pm\varepsilon_0$, so the composed loss lies on the lattice $\{(2j-k)\varepsilon_0\}$, where j is the number of $+$ steps, and no rounding is needed; $\delta(\varepsilon)$ is a finite binomial sum.)*
- Why is zCDP the wrong accountant for DP-SGD even though it is exact for the Gaussian? *(The ratio $\varepsilon(\alpha)/\alpha$ of the subsampled curve tends to $1/(2\sigma^2)$ as α grows, so the smallest ρ with $\varepsilon(\alpha) \le \rho\alpha$ for all α is the unsubsampled $1/(2\sigma^2)$, even though the curve is far below that line at small orders. zCDP cannot express the amplification. See Section 31.8.)*

37.5. Matching the accountant to the code

37.5.1. Context

Every number in Table 37.2 assumes a model of the training run. The accountant cannot check that model against your code: it takes q, σ and T and trusts that the code does what the theorem assumes. Ponomareva et al. (2023, Section 5.3.1) put the point in one heading: "privacy accounting assumptions should match training reality". They note that many papers have reported the Poisson-sampling number while training with shuffled fixed-size batches, going back to Abadi et al. (2016). A mismatch does not make the number a little loose. It makes it a statement about a different algorithm.

37.5.2. Statement

Before reporting ε, check each item of Table 37.7 against the code.

Table 37.7.: A checklist for matching the accountant to the training code.

Item	What the accountant assumes	What to check in the code	If it does not match
Sampling scheme	Poisson sampling at rate q	Is each record included independently with probability q, giving variable batch sizes?	Fixed-size random batches: account the Poisson pair with $\sigma/2$ (Table 33.4). Shuffle and partition: no amplification theorem applies; report the guarantee without amplification, for zero-out neighbours
Neighbouring relation	Add/remove one record	Is the guarantee stated for add/remove, replace-one or zero-out?	Replace-one under Poisson sampling costs more per step: the group-privacy bound is about $e^{\varepsilon} + 1$ times the add/remove value, and the exact pure-DP cost is about twice it for small ε (Section 33.4, Equation 33.8)
Privacy unit	One example	Can one person contribute several examples?	Account for users: clip and sample per user, or pay group privacy
Released outputs	Every noisy gradient	Are checkpoints, logs or gradients exposed?	Nothing to fix: the guarantee covers them all. Claiming less leakage needs Section 35.6 and its conditions
Hyperparameter tuning	Not counted	Were learning rate, clipping norm or σ chosen by looking at results on the private data?	Account for the tuning runs too, or tune on public data
Adaptive parameters	σ, q and T fixed in advance	Early stopping, noise schedules, per-record budgets?	Use a filter (Section 36.5)

Item	What the accountant assumes	What to check in the code	If it does not match
Implementation	Exact real-valued Gaussian noise, exact clipping	Floating-point noise sampling, gradient accumulation across devices, clipping applied before or after accumulation	Out of scope of the accountant: a question for the implementation and its verification, not for this part

37.5.3. Derivation: the price of three mismatches

1. **Fixed-size batches accounted as Poisson.** Suppose each step draws a fresh random batch of exactly qn records. With a fixed batch size, adding a record has to push another one out, so in effect one record is swapped for another, and the batch sum can move by up to $2C$ instead of C. Lebeda et al. (2024, Proposition 9; Table 33.4) show that such a run is covered by the Poisson pair with noise multiplier $\sigma/2$: the same noise, measured against a shift twice as large. At $T = 10{,}000$ the RDP accountant then gives 47.42 instead of 6.71, as in Amplification by subsampling, and the PLD upper bound gives 43.42 instead of 6.24.
2. **Shuffle and partition.** Here each epoch shuffles the data once and cuts it into consecutive batches, so the record is used exactly once per epoch, and there is no amplification theorem that holds for every dataset (Section 33.4). What remains certain is the composition of the record's own steps, one per epoch, for zero-out neighbours, the relation of Table 33.4 for this sampler: the two datasets differ in that the record's gradient is replaced by zero, so the batch that holds it moves by at most C in each epoch. With noise σC, that is a Gaussian mechanism with $\mu = 1/\sigma$. Then 100 epochs at $\sigma = 1$ are 100 Gaussian mechanisms with $\mu = 1$, whose squares add to $\mu = \sqrt{100} = 10$ (Section 32.6), so Equation 32.10 gives $\varepsilon = 91.8173$. This needs the zero-out relation. Under add/remove there is no clean bound at all, because inserting a record shifts the fixed partition into batches and changes every batch after it. Under replace-one, the batch sum moves by up to $2C$, so $\mu = 2$ per epoch, $\mu = \sqrt{100} \times 2 = 20$ in total, and $\varepsilon = 284.39$. Ponomareva et al. recommend reporting such a guarantee without amplification whenever the sampling assumption does not hold.
3. **Tuning on the private data.** If you train 10 configurations on the private data and release the best, which one is best depends on all 10 runs, so the release is a post-processing of all 10 of them, and its privacy cost is that of the 10 runs composed, ten times the run. With RDP, ten times the curve converts to $\varepsilon = 27.23$; for 100 configurations, 145.17. Papernot & Steinke (2022) give much better bounds for tuning procedures that try a random number of configurations. NIST SP 800-226 (Section 4.3) recommends tuning on non-sensitive data, or with a differentially private algorithm.

37.5.4. Interpretation

The sampling scheme is the largest single risk. A factor of 6.96 in ε ($43.42/6.24 \approx 6.96$) from a one-line change in the data loader is more than the choice between the RDP and PLD accountants (at most 1.19 here, from Table 37.3). Opacus, for one, uses Poisson sampling by default when you make a model private.

The privacy unit decides what is protected. The guarantee is about datasets that differ in one unit, so it protects one unit. NIST SP 800-226 (Section 2.4) calls a guarantee whose unit is one event, when a person contributes many, a privacy hazard. Example-level DP-SGD on a dataset with many examples per user protects each example, not each user.

The accountant does not see the implementation. The theorems assume exact real-valued Gaussian noise. Floating-point sampling of noise can break the guarantee of a mechanism that is correct on paper (NIST SP 800-226, Section 4.3). That is a question for formal methods and careful implementation, not for an accountant.

37.5.5. Example: a code review

A training script uses a `DataLoader` with `shuffle=True` and `batch_size=500` on 50,000 records for 100 epochs, and calls an RDP accountant with `sample_rate=0.01`. The checklist flags the first row. The sampler is shuffle and partition, so the Poisson accountant's 6.71 does not apply. The certified guarantee is the unamplified 91.8173, for zero-out neighbours. Switching the loader to Poisson sampling, a change of a few lines, makes the accountant's assumptions true and the guarantee 6.24 with a PLD accountant.

37.5.6. Check yourself

- Your code draws fixed-size random batches, and you want the Poisson accountant's 6.24 to be honest. What noise multiplier must you train with? *(Twice the one in the accountant: $\sigma = 2$, since fixed-size batches are dominated by the Poisson pair with $\sigma/2$, and $2/2 = 1$ is the σ the accountant used.)*
- Does releasing every checkpoint of a DP-SGD run cost extra privacy? *(No. The accountant already assumes every noisy gradient is released, and checkpoints are a post-processing of them.)*

37.6. What to report

37.6.1. Context

An ε without its assumptions cannot be checked, compared or even read: the same number means different things for one example or one user, with or without tuning, at $\delta = 10^{-5}$ or 10^{-10}. Two guidance documents say what a statement should contain. NIST SP 800-226, "Guidelines for Evaluating Differential Privacy Guarantees" (Near, Darais, Lefkovitz & Howarth, March 2025), is written for anyone evaluating a DP claim. Ponomareva et al., "How to DP-fy ML" (JAIR 2023), Section 5.3.3, is written for machine learning.

37.6.2. Statement

From Ponomareva et al. (2023, Section 5.3.3), a report should give:

1. **The DP setting:** central or local, and who is trusted.
2. **The instantiated definition:** which data accesses are covered (one training run, or tuning too), what the mechanism's output is, the unit of privacy, and the neighbouring relation.
3. **Accounting details:** the type of accounting (RDP, PLD, …), its assumptions and whether they hold, and the formal statement, such as the (ε, δ) or ρ values, for the final model and for the tuning.
4. **Transparency:** code, when possible, using standard libraries for the mechanism and the accountant.

On δ, both documents want it small compared with $1/n$ for n units of privacy. The reason is that δ is the probability with which the promise may fail. A mechanism that publishes one randomly chosen record in full changes its output distribution by only about $1/n$ when one record changes, so it meets a δ of about $1/n$ with $\varepsilon = 0$, and yet it exposes someone completely. A δ near $1/n$ therefore allows guarantees that protect nobody. Ponomareva et al. (Section 5.3.2) give the convention $\delta \ll 1/n$, for example $\delta = n^{-1.1}$, with n counted in units of privacy. NIST SP 800-226 (Section 2.3) gives $\delta \leq 1/n^2$ as a common recommendation, calls values above 10^{-5} suspicious, and asks you to report the original parameters of an RDP, zCDP or GDP guarantee alongside any (ε, δ) conversion, so that others can interpret it more precisely.

For DP-SGD, add what the accountant needs to recompute ε: the sampling scheme, q (or batch size and n), T (or epochs), σ, and the accountant's version and discretization. Report the clipping norm C too, although ε does not depend on it.

37.6.3. Derivation: the numbers in the statement

Take the running example with $n = 50{,}000$ records. Then the expected batch is $qn = 500$, $T = 10{,}000$ steps are $Tq = 100$ epochs (each step touches a fraction q of the data), and the conventions give $1/n = 2.0 \times 10^{-5}$, $n^{-1.1} = 6.8 \times 10^{-6}$ and $1/n^2 = 4.0 \times 10^{-10}$. The pessimistic PLD composed for $T = 10{,}000$ is computed once. Solving it at several δ is cheap, because it only means evaluating $\delta(\varepsilon)$ on the same composed distribution, and Table 37.8 gives the result.

Table 37.8.: The running example's privacy profile: ε at several δ for $T = 10{,}000$, $q = 0.01$, $\sigma = 1$.

δ	PLD upper	PLD lower	RDP, improved
2.0×10^{-5} $(1/n)$	6.0068	5.9068	6.4884
1.0×10^{-5}	6.2377	6.1377	6.7127
6.8×10^{-6} $(n^{-1.1})$	6.3641	6.2641	6.8353
1.0×10^{-6}	6.9574	6.8574	7.4140
4.0×10^{-10} $(1/n^2)$	9.0502	8.9378	9.4540

$\delta = 10^{-5}$ is half of $1/n = 2.0 \times 10^{-5}$ for this dataset, so it does not meet Ponomareva et al.'s "much smaller than $1/n$". At $1/n^2$, as NIST suggests, the certified ε rises to 9.0502.

The PLD bracket has width 0.1000, the $Th = 10{,}000 \times 10^{-5}$ of Numerical accounting, at every δ down to 10^{-6}, and $9.0502 - 8.9378 = 0.1124$ at $1/n^2$, slightly more. Without truncation the width is at most Th (Section 34.5), so the excess comes from the tails the accountant truncates. Each step's PLD moves up to 10^{-15} of tail mass on each side, in the safe direction. Over 10^4 steps that is of order $10^4 \times 10^{-15} = 10^{-11}$, a few percent of $\delta = 4 \times 10^{-10}$, so it starts to matter only at such a small δ.

The RDP accountant's original parameter, the thing NIST asks you to report, is its curve. At the best order $\alpha = 4.1$ the composed curve is $\varepsilon(4.1) = 3.7336$, which the improved conversion turns into 6.7127.

37.6.4. Interpretation

Report the profile, not a point. A single (ε, δ) pair cannot be converted to a smaller δ (Exercise 3 in the exercise book), because many different mechanisms share that one pair and they behave differently at smaller δ. So a reader who wants $\delta = 1/n^2$ needs either the PLD or the RDP curve, or your table. Table 37.8 costs one line.

Report the accountant's error bar. For a PLD accountant, the optimistic value says how much the number could still fall. For RDP, nothing does: it has no matching lower bound. That is one more reason to prefer the PLD.

State the fallback. If any item of Table 37.7 is in doubt, give the guarantee that does not rely on it, as Ponomareva et al. recommend for amplification. A reader can then see what holds even in the worst case.

37.6.5. Example: a filled-in privacy statement

> **Privacy guarantee.** The model was trained with DP-SGD in the central model: the training server is trusted to run the code below, and the guarantee covers every intermediate noisy gradient, hence every checkpoint and the final model. **Unit of privacy:** one training example; each person contributes at most one example. **Neighbouring relation:** add or remove one example. **Training:** Poisson sampling with rate $q = 0.01$ ($n = 50{,}000$ examples, expected batch size 500), $T = 10{,}000$ steps (100 epochs), per-example clipping norm $C = 1$, Gaussian noise multiplier $\sigma = 1$. **Accountant:** privacy loss distributions, pessimistic discretization on the grid $h = 10^{-5}$, both add and remove directions (this book's `numerical_accounting.py`). **Guarantee:** $(6.24, 10^{-5})$-DP and $(9.06, 4.0 \times 10^{-10})$-DP. The optimistic discretization gives 6.1377 and 8.9378, so the accountant's own error is at most 0.1000 and 0.1124. For comparison, the RDP accountant with the improved conversion gives 6.7127 at $\delta = 10^{-5}$. **Not covered:** hyperparameters were tuned on a public proxy dataset; no tuning on the private data was performed. **If the sampling assumption failed** (for example, shuffled fixed-size batches), the guarantee without amplification is $(91.82, 10^{-5})$-DP for zero-out neighbours (one example's gradient replaced by zero).

Each number in the statement is in Table 37.8 or Section 37.5. Upper bounds are rounded up, never to the nearest value: 9.0502 becomes 9.06, because 9.05 would be a claim the accountant has not certified.

37.6.6. Check yourself

- Why does the statement give the clipping norm even though ε does not depend on it? *(The noise added is σC, so C with σ tells a reader the actual noise level and lets them check the implementation. Ponomareva et al. (Section 4.2) note that the common convention is to report σ and C separately, so that the noise reads as a fraction of the clipping norm and transfers between models.)*
- A paper reports "$\varepsilon = 3$" and nothing else. Name two items without which you cannot interpret it. *(Any two of: δ, the unit of privacy, the neighbouring relation, the sampling scheme, the accountant.)*

37.7. Checking your accountant

37.7.1. Context

An accountant is code, and code has bugs. Before you trust a number, whether from your own accountant or a library's, run checks whose answers you know. A good check is a case where the truth is known exactly, or a property every correct accountant must have.

37.7.2. Statement

Four checks, each run by the script:

1. **Set $q = 1$ and compare with the closed form.** A bound must lie above the exact ε of T full-batch Gaussian steps.
2. **Run the PLD machinery on a pair with a closed form.** The PLD bracket for the plain Gaussian must contain the exact ε.
3. **Check both chains of Equation 37.1 at every T,** and that no upper bound falls below the optimistic PLD.
4. **Round-trip δ.** The composed pessimistic PLD, evaluated at its own ε, must give back the δ it was solved at, and its ε must increase with T.

37.7.3. Derivation: why each answer is known

1. **$q = 1$.** Without subsampling every record is in every batch, so each step is the plain Gaussian mechanism. That mechanism is exactly μ-GDP with $\mu = 1/\sigma$, and since squares of μ add under composition, T of them are exactly $\sqrt{T \times (1/\sigma)^2} = \sqrt{T}/\sigma$-GDP (Section 32.6). Equation 32.10 then gives the exact ε, and every upper bound must be at least this.
2. **The plain Gaussian PLD.** The same closed form is the truth for the composed Gaussian pair. The pessimistic and optimistic discretizations bracket the truth, and without truncation they are within Th of each other (Equation 34.6), so the bracket must contain the closed form.
3. **The chains.** They were proved above for every correct implementation, so a violation is a bug, not slack.

4. **The round trip.** Solving $\delta(\varepsilon) = \delta$ for ε and evaluating δ at the solution are inverse operations on the same decreasing profile, so they must give back δ. For the growth in T: whatever the first T steps release is part of what the first $T + 1$ steps release, so the T-step transcript is obtained from the $(T + 1)$-step one by dropping the last output. Dropping an output is a data-independent map, so by the data-processing inequality the T-step pair is no easier to tell apart, and no correct accountant can decrease in T.

37.7.4. Example: the checks on this book's accountants

1. For $\sigma = 1$, $T = 10$, $q = 1$: the exact μ is $\sqrt{10}/1 = 3.1623$, and the exact ε is 17.8566. The RDP accountant gives 19.0536, above it as a bound must be. The CLT formula, with $q = 1$, gives $\mu = \sqrt{10(e-1)} = 4.1452$ instead of 3.1623 and $\varepsilon = 25.5853$: it fails the check, because its derivation assumes small q (Section 32.8).
2. On the plain Gaussian with $\mu = 1$ and $T = 10$ at $h = 10^{-3}$, the PLD bracket $[17.8516, 17.8616]$ contains the closed form 17.8566. Its width is $10 \times 10^{-3} = 0.01$, which is Th.
3. Both chains hold on the running example at all nine values of T, and the CLT lies below the PLD lower bound at every one.
4. Evaluating the composed pessimistic PLD at its own ε gives back $\delta = 1.000 \times 10^{-5}$, and the PLD upper bound increases with T.

37.7.5. Interpretation: comparing with independent libraries

This book's accountants use no library, so that every line can be read. Production code should use a maintained one and compare against a second. Three are widely used: Google's `dp_accounting` (RDP and PLD accountants), Opacus (RDP, privacy loss random variable (PRV) and GDP accountants; its default is the PRV accountant), and Microsoft's `prv_accountant` (Gopi, Lee & Wutschitz 2021), which returns a lower bound, an estimate and an upper bound for ε. What agreement should you expect?

RDP accountants agree when the grid and the conversion agree. Two RDP accountants differ only in the orders they try and the formula they convert with. Opacus's default orders are this part's grid without 128, 256 and 512, and its conversion is the improved one (Balle et al. 2020, Theorem 21). On the running example the best orders lie between 4.1 and 9.9, inside both grids, so the results should agree to the precision of the fractional-order computation. If they differ by about $\Delta(\alpha)$ of Equation 30.10, the fixed amount by which the improved conversion beats Mironov's at order α, one of them uses Mironov's conversion. At order 10 that gap is $\frac{\ln 10}{9} + \ln \frac{10}{9} = 0.3612$ (Table 30.3).

Fractional orders are a known weak spot. At an integer order the subsampled Gaussian's RDP is a finite sum, but at a fractional order it needs an infinite series with terms of both signs. `dp_accounting` 0.6.0 computes it with a series whose negative terms it counts as positive, so it returns a loose upper bound there, not the exact value. Opacus keeps the signs and is exact. Checking the fixed-size-batch value 47.42 of Section 37.5 with `dp_accounting` 0.6.0 gives 49.43 (computed with that library, not by this book's scripts). Compare at integer orders, or against Opacus.

PLD and PRV accountants agree within their error bars. Different discretizations give different numbers, but every certified upper bound must lie above the truth and every certified lower bound below it, so every upper bound must lie above every lower bound. If two libraries' brackets do not overlap, one of them has a bug.

No accountant may fall below a certified lower bound. The optimistic PLD is the referee: any reported upper bound below it, like the CLT's, is wrong.

A cross-check against the libraries, run outside this book's scripts, gives a clean result. The RDP and PLD numbers of this chapter agree with Opacus 1.6.0, `dp_accounting` 0.6.0 and `prv_accountant` 0.2.0 to the printed precision, and the libraries' tight PLD estimate at $T = 10{,}000$ is about 6.19, inside the bracket $[6.1377, 6.2377]$. These library values (and the 49.43 above) are quoted from the libraries; the book's scripts do not import them and cannot print them.

37.7.6. Check yourself

- Your RDP accountant reports 7.43 for the running example at $T = 10{,}000$ and a colleague's reports 6.71. Which conversion does each use? *(7.43 is Mironov's, 6.71 the improved one; see Table 37.2.)*
- Why is $q = 1$ a good test case for a DP-SGD accountant? *(The composed pair is exactly Gaussian, so the true ε has a closed form. A bound must lie above it, and an approximation that misses it is caught at once.)*

37.8. Code

The script code/choosing_an_accountant.py imports every accountant from the chapter that derived it and implements nothing new except the comparison, the inverse problem and the checks. Its public functions are `accountant_table(q, sigma, delta, ks)`, which returns one `AccountantRow` per T with every accountant's ε, and `sigma_for_target(eps_target, q, steps, delta, accountant)`, which solves Equation 37.2 for any accountant named in `ACCOUNTANTS`. From the repository root:

```
uv run python code/part04-privacy-accounting/choosing_an_accountant.py
```

It runs in about two and a half minutes, almost all of it in PLD compositions. **Output** (seed 0; nothing is random), summarized in Table 37.9:

Table 37.9.: The script's output with the default seed.

Experiment	Result
Every accountant, $T = 1$ to 10,000	Table 37.2, Table 37.3, Table 37.4; both chains of Equation 37.1 hold at every T, and RDP optimal $\geq$ PLD upper is observed at every T; CLT below the PLD lower bound at every T

Experiment	Result
Noise for a target ε	Table 37.5; PLD upper bound at $\sigma = 3.9884$ is 1.0000
Other mechanisms	Gaussian $\mu = 1$: 4.3772 exact, 4.7285 RDP; randomized response: 4.3068 exact, 4.6154 RDP, 4.7263 zCDP, 5.8502 advanced
Mismatches	Fixed-size batches: 47.42 (RDP), 43.42 (PLD); no amplification: 91.8173 (zero-out), 284.39 (replace-one); 10 tuning runs: 27.23
Privacy profile	Table 37.8
Sanity checks	$q = 1$: 17.8566 exact, 19.0536 RDP, 25.5853 CLT; Gaussian PLD $[17.8516, 17.8616]$

tests/test_choosing_an_accountant.py checks that the output still matches, and calls the two public functions directly.

What to take from it. First, the accountants of the part agree where they must. Every number shared with Amplification by subsampling and Numerical accounting is reproduced to the printed digits, and the bounds satisfy both proved chains of Equation 37.1. Second, the gaps between them are the cost of the choice: per-step composition is off by orders of magnitude, RDP by 7.6% at 10,000 steps and much more for short runs, and the CLT is invalid on this example. Third, mismatched assumptions cost more than the choice between RDP and PLD: a factor of 6.96 over the Poisson PLD bound for fixed-size batches, and 14.72 without amplification (91.8173/6.2377).

37.10. Cheat sheet

Table 37.10 collects the chapter's results for DP-SGD with $q = 0.01$, $\sigma = 1$, $\delta = 10^{-5}$.

Table 37.10.: The accountants on the running example, what kind of statement each makes, and when to use it.

Accountant	Kind	ε at $T = 10{,}000$	σ for $\varepsilon = 3$	When to use it
Per step + advanced composition	Upper bound	24379.55	10.505	Never for DP-SGD
RDP, Mironov conversion	Upper bound	7.4287	1.854	Never: the improved conversion is free
RDP, improved conversion	Upper bound	6.7127	1.662	Quick bounds, adaptive filters, many heterogeneous mechanisms

Accountant	Kind	ε at $T = 10{,}000$	σ for $\varepsilon = 3$	When to use it
PLD, pessimistic	Upper bound, within Th of the truth	6.2377	1.584	The number to report
PLD, optimistic	Lower bound	6.1377	1.547	The error bar, and the referee for other accountants
GDP CLT	Approximation	6.0071	1.549	Intuition only; under-reports here

Rules of thumb

- Report the pessimistic PLD, with the optimistic value beside it. Use RDP with the improved conversion when you need adaptivity or a quick bound, and expect it to overstate ε by 5 to 10% for long runs and by far more for short ones.
- Never report a CLT number as a guarantee. Check any reported number against the PLD lower bound.
- Calibrate σ with the accountant you will report: a looser accountant costs noise, an approximation can cost the guarantee.
- Check the sampling scheme first. Fixed-size or shuffled batches accounted as Poisson is the most expensive error in practice.
- Report the privacy unit, the neighbouring relation, q, T, σ, C, the accountant and its discretization, ε at several δ including one well below $1/n$, and what was not accounted for.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

Part V.

Differential privacy in machine learning

The previous parts built the guarantee and the tools to account for it. This part trains models with it. It asks the questions that decide whether a private model is worth deploying: **how do you train with differential privacy (DP), how much accuracy does it cost, which knobs move that cost, and how do you check that the trained model is as private as the accountant claims?** The answers are mostly about one algorithm, stochastic gradient descent (SGD) with per-example clipping and Gaussian noise, called DP-SGD, and about everything around it: how its hyperparameters are chosen, what replaces it when its assumptions fail, how public data and the choice of privacy unit change it, who pays for its noise, which ε to target, and how to audit the result. The last chapter turns the guarantee to a different use: the same noise that protects people also keeps a reused validation or test set honest.

Who this part is for

You are expected to have read the earlier parts. From Optimization you need SGD, strong convexity and the sensitivity of regularized empirical risk minimization (ERM). From Membership inference you need the likelihood-ratio attack (LiRA) and the true and false positive rates of an attack. From the DP foundations you need the Gaussian mechanism (The Laplace and Gaussian mechanisms), clipping (Beyond global sensitivity), the exponential mechanism and report-noisy-max (Selection) and the lower bounds of Lower bounds. From the accounting part you need Gaussian differential privacy (GDP) and trade-off functions (f-DP and Gaussian DP), amplification by subsampling and the Rényi differential privacy (RDP) accountant for DP-SGD (Amplification by subsampling), and what to report (Choosing an accountant). The last chapter also uses the replace-one argument of Algorithmic stability and generalization and the sparse vector technique of Selection. Each chapter restates the facts it uses and links to them.

The common thread

A private training algorithm has two halves. The **privacy half** says which quantity has bounded sensitivity and how much noise covers it; it is a theorem, and the accountants of the previous part turn it into a number. The **utility half** says how much the noise and the bounding cost; it is mostly measured, rarely proved. Every chapter of this part moves one of the two.

The first two chapters build the algorithm: Private ERM compares three places to inject noise into training and shows why, in practice, only noise on the gradients survives non-convex models, and DP-SGD adds clipping, minibatches and accounting. The next three ask what else spends the budget or could spend it better: hyperparameter search; mechanisms that do not rely on random batches, such as the follow the regularized leader (FTRL) algorithm run on noisy gradient sums, DP-FTRL; and private prediction instead of private training, such as private aggregation of teacher ensembles (PATE). The next three change the setting: public data, a different privacy unit, and the effect on under-represented groups. The next two close the loop between theory and practice: which ε to choose, and how to test a claim empirically. The last chapter uses the privacy half for a different purpose. A mechanism that reveals little about any one record cannot be overfitted, so DP also lets one holdout set answer many adaptively chosen questions, the situation of every hyperparameter search and leaderboard. Table 37.11 lists them.

Table 37.11.: The chapters of this part, the question each answers, and the earlier chapters it uses.

Chapter	The question it answers	Builds on
Private empirical risk minimization	Where can noise enter training, what does each choice cost, and what rate can a convex model reach?	6, 7, 20, 24, 27, 32
DP-SGD	How do clipping, noise and sampling make deep-learning training private, and what does each knob do?	6, 20, 24, 33, 37, 38
Hyperparameter tuning and private selection	How much privacy does tuning leak, and how do you pay for it honestly?	22, 29, 39
DP-FTRL and matrix factorization	How do you train privately without trusting random batches?	20, 32, 39
Private prediction: PATE and in-context learning	When is it better to privatize answers than weights?	22, 24, 29, 39
Public data and private fine-tuning	How much does a public pretrained model buy, and why does fine-tuning fewer parameters help?	39, 40
User-level differential privacy	What changes when one person contributes many records?	19, 39
Disparate impact	Who pays for the noise and the clipping?	39
Choosing ε	Which ε should you target, and how do you justify it?	18, 32, 37, 39
Auditing private training	Is the model as private as the accountant says?	10, 32, 39, 46
Adaptive data analysis	How many adaptively chosen questions can one holdout set answer, and how do you reuse it safely?	7, 19, 20, 22, 23, 31, 40

The running examples

Two models recur. The first is **regularized logistic regression** in $d = 10$ dimensions on synthetic data, where the exact minimizer can be computed and every method can be compared with the non-private optimum; Private ERM introduces it. The second is a **small neural network** trained with DP-SGD on synthetic data, small enough that every experiment of the part runs on a laptop in seconds, yet non-convex, so that clipping and noise behave as they do in deep learning;

DP-SGD introduces it. The full-scale experiment, DP-SGD on CIFAR-10 audited with LiRA, needs a GPU and PyTorch, which are not dependencies of the repository; the chapters scale it down and say how.

How to read this part

Order. Read chapters 38 and 39 first, in order: every later chapter uses DP-SGD. Chapters 40 and 41 change how the algorithm is run, and can be read in either order. Chapters 42 to 45 are independent of each other. Chapter 46 uses the vocabulary of all the earlier ones, and chapter 47 should come after the others, because it checks what the others claim. Chapter 48 can be read at any point after chapter 40, whose hyperparameter search is its motivating example. It needs DP-SGD only for that example.

Structure. The chapters follow the shape of the earlier parts: why the topic matters, a toolkit, one section per result with a derivation, interpretation, worked example and two check-yourself questions, then code, references and a cheat sheet. Exercises with worked solutions are in the exercise book, a companion website, with a link at the end of each chapter.

Run the code. Each chapter has a script in `code/` that prints every number its text quotes, except values attributed to a paper, and regenerates its figures, for example

```
uv run python code/part05-dp-ml/dp_erm.py
```

Every model is written in NumPy, gradients included, so you can see exactly what each algorithm computes.

Notation

The part uses the notation of the earlier parts, extended in Table 37.12.

Table 37.12.: Notation used throughout this part, in addition to that of the earlier parts.

Symbol	Meaning
$D = (z_1, \dots, z_n)$, $z_i = (x_i, y_i)$	A training set of n records with features x_i and labels y_i; a neighbouring dataset D' adds or removes one record, $D \sim D'$
$\theta \in \mathbb{R}^d$, $\ell(\theta; z)$, $\mathcal{L}(\theta; D)$	The model parameters; the loss on one record; the empirical risk, the training objective (with its regularizer, when there is one)
θ_t, θ^*, $\tilde{\theta}$	The iterate at step t; the non-private minimizer; a private release
$g_i = \nabla_\theta \ell(\theta; z_i)$, $\bar{g}_i$	The gradient of record i's loss, a per-example gradient; the clipped one

Symbol	Meaning
C	The clipping norm: per-example gradients are rescaled to length at most C
σ	The noise multiplier: the noise standard deviation in units of C
q, $B = qn$, T	The sampling rate; the expected batch size; the number of steps
η	The learning rate
$\mu(\varepsilon, \delta)$	The largest ratio of sensitivity to noise standard deviation for which a Gaussian mechanism is (ε, δ)-DP

What you will be able to do

By the end of this part you should be able to:

- train a convex model privately by output, objective or gradient perturbation, and predict its excess risk;
- implement DP-SGD from scratch, with per-example clipping, Poisson sampling and an RDP accountant, and explain what each hyperparameter trades;
- account for hyperparameter search, and run a private selection procedure;
- explain when DP-FTRL or a matrix-factorization mechanism beats DP-SGD, and why;
- train a teacher ensemble and answer queries with PATE or a private in-context learner;
- decide whether to fine-tune all parameters or a few, with a public pretrained model;
- account for user-level privacy, and bound each user's contribution;
- measure and explain the disparate impact of private training on small groups;
- choose an ε and justify it to someone who will hold you to it;
- audit a private training run with canaries and turn the attack's success into an empirical lower bound on ε;
- explain why a reused holdout set overfits, size a holdout set for adaptively chosen questions, and reuse one safely with Gaussian noise or Thresholdout.

38. Private empirical risk minimization

38.1. Why this matters

Most of machine learning is **empirical risk minimization (ERM)**: choose the parameters θ that minimize the average loss on the training data, usually plus a penalty on the size of θ. The trained weights are a function of every training record, and Membership inference showed that they give some of those records away. Differential privacy (DP) promises the opposite: the distribution of whatever you release changes by at most a factor e^{ε}, plus a slack δ, when one record is replaced. To keep that promise for a trained model, randomness has to enter somewhere between the data and the released weights. This chapter asks where.

Two familiar examples show how directly an exact minimizer can expose a record. The median of an odd number of values minimizes the average absolute loss, and it *is* one of the values, the middle one, released exactly. A hard-margin support vector machine (SVM) maximizes the margin between the classes, and its weight vector is a weighted sum of a few training records, the support vectors that sit closest to the boundary. Add one record just inside the margin and it becomes a support vector, so the hyperplane swings toward it, by an amount that does not shrink as the dataset grows. Neither model leaks by accident: an exact minimizer is a function of the records, and nothing stops a single record from moving it.

There are three natural places, and each gives a classic algorithm. **Output perturbation** trains as usual and adds noise to the final weights. **Objective perturbation** adds a random linear term to the objective, then minimizes it exactly. **Gradient perturbation** adds noise to every gradient during training. All three were analysed for convex losses between 2008 and 2014, by Chaudhuri, Monteleoni and Sarwate, by Kifer, Smith and Thakurta, and by Bassily, Smith and Thakurta, and the third is the ancestor of the algorithm almost every private deep-learning system runs today: stochastic gradient descent (SGD) with per-example clipping and Gaussian noise, DP-SGD, the subject of the next chapter. A fourth place, the data themselves, is not on the list. Adding noise to each record before training is the local model of Trust models, in which every record must hide itself from everyone. That model needs far more data for the same accuracy than adding the noise once, inside the computation.

38.1.1. The one idea: privacy needs a bound on how far one record can move what you release

Every DP mechanism in this book works the same way. Find a quantity whose change, when one record is replaced, is bounded by a known number, its **sensitivity**. Then add noise large enough to hide a change of that size. The three methods differ only in *which* quantity they bound.

Output perturbation bounds the minimizer itself. Strong convexity, the curvature a ridge penalty $\frac{\lambda}{2}\|\theta\|^2$ adds, guarantees that replacing one of n records moves the minimizer by at most $2L/(\lambda n)$, where L bounds the length of each record's loss gradient (Optimization). Objective perturbation

bounds the *gradient* of the objective at every point, which also moves by at most $2L/n$, and turns that into a bound on the output's density through a change of variables. Gradient perturbation bounds the gradient at the points the algorithm actually visits, one step at a time, and composes the steps.

The order matters because each step back toward the data needs fewer assumptions. Output perturbation needs an exact, unique minimizer of a strongly convex objective. Objective perturbation needs that and a loss with bounded curvature. Gradient perturbation, for its privacy, needs only that each record's gradient is bounded: no convexity, no exact solution. That is why it is the one that survives in deep learning.

Table 38.1 lists the results and where each is used.

Table 38.1.: The results of this chapter and where each is used.

Result	Where it is used
Output perturbation: noise of scale $2L/(\lambda n)$ on the minimizer	Convex models trained to convergence; the baseline the others are measured against
Sensitivity of an approximate minimizer	Why output perturbation needs the exact solution, and how much an inexact one costs
Objective perturbation: a random linear term, minimized exactly	Private logistic regression and linear support vector machines; why curvature in the data helps
Noisy gradient descent: Gaussian noise on every gradient	The privacy argument of DP-SGD; every iterative private trainer
Noisy projected gradient descent without a ridge	The $\sqrt{d}/(n\varepsilon)$ rate for convex Lipschitz losses; why noise is just more gradient variance; Public data
Excess risk of all three, and the optimal rates	Choosing between them; what no method can beat (Lower bounds)
What survives without convexity	Why deep learning uses gradient perturbation, with clipping

Notation. A training set $D = (z_1, \dots, z_n)$ holds n records $z_i = (x_i, y_i)$ with features $x_i \in \mathbb{R}^d$ and labels $y_i \in \{-1, +1\}$. The loss of parameters θ on a record is $\ell(\theta; z)$, and the objective is the empirical risk, which in this chapter includes the ridge penalty,

$$\mathcal{L}(\theta; D) = \frac{1}{n} \sum_{i=1}^{n} \ell(\theta; z_i) + \frac{\lambda}{2} \|\theta\|^2, \tag{38.1}$$

with minimizer $\theta^*(D)$. Neighbouring datasets $D \sim D'$ differ by **replacing** one record, z in D by z' in D', so both have size n; the next chapter switches to adding or removing one, and says why. L bounds the length of every gradient $\nabla_\theta \ell(\theta; z)$, $\|\cdot\|$ is the Euclidean norm, and a released, private version of the parameters is written $\tilde{\theta}$. The **excess risk** of a release is $\mathcal{L}(\tilde{\theta}; D) - \mathcal{L}(\theta^*; D)$, how much worse it fits the training objective than the exact minimizer.

The running example. Regularized logistic regression, with loss $\ell(\theta;(x,y)) = \ln(1+e^{-y\langle\theta,x\rangle})$, in $d = 10$ dimensions with ridge $\lambda = 0.01$. The features are uniform on the unit sphere, $\|x\| = 1$, and the labels come from a logistic model whose true weights have length 5. The derivative of $\ln(1+e^{-m})$ in the margin $m = y\langle\theta,x\rangle$ lies in $(-1,0)$, so each gradient has length at most $\|x\| = 1$ and $L = 1$. Every method targets $\varepsilon = 1$, with $\delta = 10^{-5}$ for those that need a δ, on n from 1,000 to 100,000 records.

How to read this chapter. Read the toolkit, then Section 38.3, which sets the pattern. Section 38.4 has the chapter's one long derivation; its one-dimensional example shows each step on numbers. Section 38.5 is the one to know well, because the next chapter builds on it. Section 38.6 drops the ridge and derives the rate for convex Lipschitz losses. Section 38.7 and Section 38.8 say which method to use when.

38.2. Toolkit: six facts every derivation uses

38.2.1. Fact 1 — The Gaussian mechanism, calibrated exactly

To release a vector-valued function $f(D)$ whose value moves by at most $\Delta_2 f$ in Euclidean length between neighbours (its ℓ_2 **sensitivity**), add independent normal noise $\mathcal{N}(0,\sigma^2)$ to each coordinate. What matters for privacy is only the ratio $\mu = \Delta_2 f/\sigma$, the shift measured in noise standard deviations: rotate so the shift lies along one axis, and the other coordinates have the same distribution under both datasets. The mechanism is then (ε,δ)-DP exactly when

$$\delta \geq \Phi\Big(\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) - e^{\varepsilon}\,\Phi\Big(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big), \tag{38.2}$$

where Φ is the standard normal distribution function (The Laplace and Gaussian mechanisms, Balle & Wang 2018). The right side increases with μ, so for each (ε,δ) there is a largest admissible ratio $\mu(\varepsilon,\delta)$, and the smallest noise is $\sigma = \Delta_2 f/\mu(\varepsilon,\delta)$. For $\varepsilon = 1$ and $\delta = 10^{-5}$, $\mu = 0.2681$, so $\sigma = 3.7306\,\Delta_2 f$. The classic formula $\sigma = \Delta_2 f\sqrt{2\ln(1.25/\delta)}/\varepsilon$ gives $4.8448\,\Delta_2 f$, 30% more noise for the same guarantee; this chapter always uses the exact calibration.

38.2.2. Fact 2 — The regularized minimizer moves by at most $2L/(\lambda n)$

The ridge is the same device that stops a model from overfitting, and for the same reason. Fit a polynomial of high degree to a handful of points without a penalty and it passes through every point, so it swings wildly between them, and it swings again if you delete one point. A penalty on the size of the weights makes the fit prefer smooth curves, which change little when one point goes. Generalization and privacy both ask for that stability, and the ridge supplies a guaranteed amount of it.

Optimization proves the bound, and the argument is short enough to restate. Replacing z by z' changes $\mathcal{L}$ by $h(v) = \frac{1}{n}(\ell(v;z') - \ell(v;z))$, whose gradient has length at most $2L/n$: one gradient leaves, another arrives. At the new minimizer $\theta' = \theta^*(D')$, the old objective's gradient is therefore $\nabla\mathcal{L}(\theta';D) = -\nabla h(\theta')$, of length at most $2L/n$. The ridge makes $\mathcal{L}(\cdot;D)$ λ-**strongly convex**: its

gradient grows by at least λ per unit of distance in every direction, so a point where the gradient has length g is within g/λ of the minimizer. Hence

$$\|\theta^*(D) - \theta^*(D')\| \le \frac{2L}{\lambda n}. \tag{38.3}$$

The same argument gives a bound for any point, not only the exact minimizer: if $\|\nabla \mathcal{L}(\theta; D)\| \le g$, then $\|\theta - \theta^*(D)\| \le g/\lambda$.

38.2.3. Fact 3 — Noise with density proportional to $e^{-\|b\|/s}$

Pure ε-DP, with $\delta = 0$, needs noise whose density falls off no faster than exponentially in every direction. The standard choice in d dimensions has density $\nu(b) \propto e^{-\|b\|/s}$: it depends on b only through its length. If f has ℓ_2 sensitivity $\Delta_2 f$ and $s = \Delta_2 f/\varepsilon$, then $f(D) + b$ is ε-DP. At any output y, the ratio of the two output densities is $e^{(\|y - f(D')\| - \|y - f(D)\|)/s}$. By the triangle inequality the exponent is at most $\|f(D) - f(D')\|/s \le \Delta_2 f/s = \varepsilon$.

To sample it, split b into a direction and a length. The density depends only on the length r, and the sphere of radius r has surface area proportional to r^{d-1}, so the length has density proportional to $r^{d-1}e^{-r/s}$. That is a **gamma distribution** with shape d and scale s, and the direction is uniform on the sphere. Its moments are $\mathbb{E}\|b\| = ds$ and $\mathbb{E}\|b\|^2 = d(d+1)s^2$. Compare the Gaussian, whose squared length has mean $d\sigma^2$: the pure-DP noise is longer by a factor that grows with d.

38.2.4. Fact 4 — Change of variables for densities

If a random vector b has density ν and θ is obtained from b by a smooth invertible map, write the inverse as $b = \phi(\theta)$. Then θ has density

$$p(\theta) = \nu(\phi(\theta)) \left| \det \nabla \phi(\theta) \right|. \tag{38.4}$$

The determinant corrects for stretching: if ϕ squeezes a small box around θ into a box of half the volume around b, the probability of that box is the same, so the density at θ is half the density at b. In one dimension this is the familiar $p(\theta) = \nu(\phi(\theta))|\phi'(\theta)|$.

38.2.5. Fact 5 — Adaptive Gaussian steps compose into one Gaussian

Run T Gaussian mechanisms in sequence, each allowed to depend on the outputs of the earlier ones, with sensitivity-to-noise ratios $\mu_1, \dots, \mu_T$. The whole sequence is exactly as private as a single Gaussian mechanism with ratio

$$\mu = \sqrt{\mu_1^2 + \cdots + \mu_T^2}. \tag{38.5}$$

This is composition of Gaussian differential privacy (GDP) from f-DP and Gaussian differential privacy. The reason is that the privacy loss of each step is a normal random variable with variance μ_t^2 and mean $\mu_t^2/2$, given the past. Their sum is normal with variance $\sum_t \mu_t^2$ and half that as its mean, which is the privacy loss of one Gaussian with ratio μ. So T equal steps with ratio μ_{step} give $\mu = \sqrt{T}\,\mu_{\text{step}}$, and Equation 38.2 converts the total to (ε, δ) with no slack.

38.2.6. Fact 6 — Projected SGD needs only unbiased gradients of bounded second moment

Sometimes the weights must stay inside a closed convex set fixed in advance, written $\mathcal{W}$, such as the ball of all weights with length at most a radius R. After each step, the optimizer replaces its point by the closest point of the set, which is called **projecting** onto it. For the ball, that shrinks a point that left the ball back to the sphere of radius R.

Projected stochastic gradient descent steps along a random vector g_t instead of the true gradient of the objective $\mathcal{L}$. Optimization proves that only two properties of g_t matter. Given the points visited so far, it must be right on average,

$$\mathbb{E}[g_t \mid \theta_1, \dots, \theta_t] = \nabla \mathcal{L}(\theta_t), \tag{38.6}$$

and its squared length must be bounded on average by a number written G^2,

$$\mathbb{E}\|g_t\|^2 \le G^2. \tag{38.7}$$

Suppose $\mathcal{L}$ is convex, and its minimizer θ^* over $\mathcal{W}$ is within distance R of the starting point. Run T steps with the learning rate $\eta = R/(G\sqrt{T})$ (also called the step size), and average the points visited into $\bar{\theta}_T = \frac{1}{T}\sum_{t=1}^{T} \theta_t$. Then

$$\mathbb{E}[\mathcal{L}(\bar{\theta}_T)] - \mathcal{L}(\theta^*) \le \frac{RG}{\sqrt{T}}. \tag{38.8}$$

The proof follows the squared distance to θ^*. Each step shrinks it by an amount that convexity ties to the current error, and grows it by at most $\eta^2\|g_t\|^2$. So the randomness of g_t enters only through that second term, that is through G^2, and neither smoothness nor strong convexity is needed.

38.3. Output perturbation

38.3.1. Context

The simplest private trainer treats training as a black box: compute the exact minimizer $\theta^*(D)$, then add noise. Fact 2 says the minimizer is a function with ℓ_2 sensitivity $2L/(\lambda n)$, so this is just the Gaussian mechanism (or Fact 3's mechanism) applied to it. Chaudhuri & Monteleoni (2008) introduced it for logistic regression. Two questions remain: how much accuracy does it cost, and what happens when, as always in practice, the minimizer is only computed approximately?

38.3.2. Statement

Release

$$\tilde{\theta} = \theta^*(D) + Z, \qquad Z \sim \mathcal{N}(0, \sigma^2 I), \qquad \sigma = \frac{2L}{\lambda n\, \mu(\varepsilon, \delta)}. \tag{38.9}$$

This is (ε, δ)-DP for replace-one neighbours. Replacing Z by noise with density $\propto e^{-\|b\|/s}$ and $s = 2L/(\lambda n \varepsilon)$ gives pure ε-DP. If the objective has Hessian H at θ^*, the excess risk is, to second order,

$$\mathbb{E}[\mathcal{L}(\tilde{\theta}) - \mathcal{L}(\theta^*)] \approx \frac{1}{2}\,\mathbb{E}[Z^\top H Z] = \frac{\mathbb{E}\|Z\|^2}{2d}\,\operatorname{tr} H, \tag{38.10}$$

for any noise whose direction is uniform, so $\frac{\sigma^2}{2}\operatorname{tr} H$ for the Gaussian. Without the second-order approximation, Section M.1 in the appendices brackets the excess risk exactly between $\frac{\lambda}{2}\mathbb{E}\|Z\|^2$ and $\frac{\beta}{2}\mathbb{E}\|Z\|^2$, where λ and β are the smallest and largest curvature of $\mathcal{L}$. An approximate minimizer θ with $\|\nabla\mathcal{L}(\theta; D)\| \le g$ has sensitivity at most

$$\frac{2L}{\lambda n} + \frac{2g}{\lambda}. \tag{38.11}$$

38.3.3. Derivation

1. **Privacy.** By Fact 2, θ^* moves by at most $\Delta_2\theta^* = 2L/(\lambda n)$ between neighbours. Adding Gaussian noise with $\sigma = \Delta_2\theta^*/\mu(\varepsilon, \delta)$ is (ε, δ)-DP by Fact 1, and adding noise $\propto e^{-\|b\|/s}$ with $s = \Delta_2\theta^*/\varepsilon$ is ε-DP by Fact 3. Nothing else about the data reaches the output.
2. **Expand the objective around its minimizer.** The gradient vanishes at θ^*, so a second-order Taylor expansion gives $\mathcal{L}(\theta^* + Z) - \mathcal{L}(\theta^*) \approx \frac{1}{2}Z^\top H Z$, with $H = \nabla^2\mathcal{L}(\theta^*)$. The noise is small next to the scale on which the curvature changes in the cases of interest; Section 38.7 checks the approximation against simulation.
3. **Average over the direction.** Write $Z = \|Z\|u$ with u a unit vector. For a uniformly random direction, $\mathbb{E}[u_i u_j]$ is $1/d$ when $i = j$, because the d squared coordinates of a unit vector add up to 1 and are exchangeable, and 0 otherwise, by symmetry under flipping one coordinate's sign. So $\mathbb{E}[u^\top H u] = \sum_i H_{ii}/d = \operatorname{tr} H/d$, and if the length is independent of the direction, as for both noises here, $\mathbb{E}[Z^\top H Z] = \mathbb{E}\|Z\|^2 \operatorname{tr} H/d$. For the Gaussian, $\mathbb{E}\|Z\|^2 = d\sigma^2$. This is Equation 38.10.
4. **Approximate minimizers.** Let θ and θ' be the outputs of the optimizer on D and D', with gradients of length at most g. By the last line of Fact 2, each is within g/λ of its exact minimizer. The triangle inequality along the path $\theta \to \theta^*(D) \to \theta^*(D') \to \theta'$ gives $\|\theta - \theta'\| \le g/\lambda + 2L/(\lambda n) + g/\lambda$, which is Equation 38.11. The stopping rule must be a gradient check, not a step count: only the gradient bound is guaranteed on every dataset.

38.3.4. Interpretation

The noise is calibrated to the worst case, the damage to the actual case. The sensitivity $2L/(\lambda n)$ uses only the curvature λ that the ridge guarantees. The damage, Equation 38.10, is measured by the actual curvature H, which includes the data's own. Put the two together for the Gaussian: the excess risk is about $\frac{\operatorname{tr} H}{2} \cdot \frac{4L^2}{\lambda^2 n^2 \mu^2}$. If every eigenvalue of H is close to some h, this is $\frac{2dL^2}{\mu^2 n^2} \cdot \frac{h}{\lambda^2}$. The factor h/λ^2 grows as the ridge shrinks, whatever the data look like. A small ridge buys a better non-private fit and costs a lot of noise.

It falls like $1/n^2$. The noise standard deviation falls like $1/n$, so its square, and the excess risk with it, falls like $1/n^2$. The statistical error of the non-private minimizer falls only like $1/n$, so for large n privacy eventually costs less than sampling does, in this convex, low-dimensional setting.

It needs the exact solution. Equation 38.11 adds $2g/\lambda$ to the sensitivity. To keep that below the exact term, the optimizer must reach a gradient of length $g \le L/n$, which shrinks with the dataset. An optimizer stopped after a fixed number of steps has no such guarantee on every dataset, and then the sensitivity bound, and the privacy proof, do not apply. Wu et al. (2017) analyse output perturbation of SGD run for a fixed number of passes directly, with a different sensitivity bound.

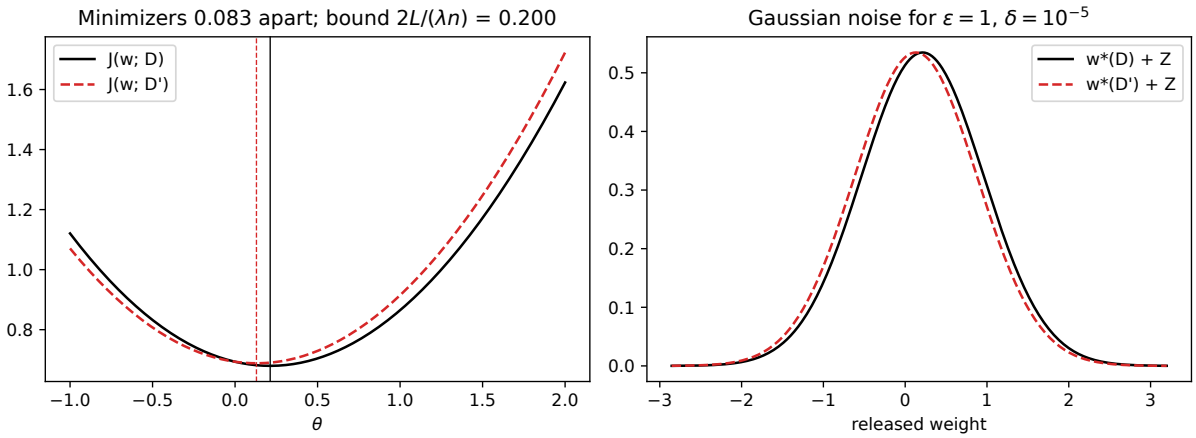

Figure 38.1.: Left: two neighbouring regularized logistic objectives in one dimension ($n = 20$, $\lambda = 0.5$), their minimizers (vertical lines) 0.083 apart, below the bound $2L/(\lambda n) = 0.2$. Right: the released weight's density under each dataset with Gaussian noise for $\varepsilon = 1$, $\delta = 10^{-5}$; the noise must hide a shift as large as the bound, not the actual shift.

38.3.5. Example: one dimension, then the running example

Take one feature, $n = 20$ records and $\lambda = 0.5$ (Figure 38.1). Replacing the last record, which has $x = 1$, by the same feature with the opposite label moves the minimizer from 0.2128 to 0.1296, by 0.0832. The bound is $2/(0.5 \times 20) = 0.2$, and that is what the noise is calibrated to: $\sigma = 3.7306 \times 0.2 = 0.7461$. The two output densities overlap almost completely, as they must.

In the running example ($d = 10$, $\lambda = 0.01$), $n = 10{,}000$ gives sensitivity $2/(0.01 \times 10{,}000) = 0.02$ and $\sigma = 0.07461$ per coordinate, next to a minimizer of length 2.886. The Hessian at θ^* has eigenvalues between 0.0263 and 0.0330, and trace 0.3129. Equation 38.10 predicts $\frac{1}{2} \times 0.07461^2 \times 0.3129 = 8.711 \times 10^{-4}$, and 20 simulated releases average 9.274×10^{-4}. The pure-DP version, with noise $\propto e^{-\|b\|/s}$ and $s = 0.02$, has $\mathbb{E}\|b\|^2 = 110 \times 0.02^2$; the prediction 6.885×10^{-4} and the simulated 8.321×10^{-4} differ by more, because the squared length of gamma noise varies a lot from draw to draw and 20 draws average it only roughly.

Stopping early is costly. With a gradient tolerance of $g = 10^{-6}$ the sensitivity is 0.0202, essentially exact. With $g = 10^{-4}$ it doubles to 0.04, and with $g = 10^{-3}$ it is 0.22, eleven times the exact value. A tolerance that looks tight, 10^{-3}, multiplies the noise by eleven and the excess risk by about 121.

38.3.6. Check yourself

- You halve the ridge λ. By what factor does the Gaussian noise grow, and roughly by what factor does the excess risk grow if the data's curvature dominates H? *(The noise doubles, since $\sigma \propto 1/\lambda$. With H unchanged the excess risk, proportional to $\sigma^2 \operatorname{tr} H$, grows fourfold.)*
- Why must the stopping rule be "stop when $\|\nabla \mathcal{L}\| \le g$" rather than "stop after 50 Newton steps"? *(The privacy proof needs the sensitivity bound on every pair of neighbouring datasets.*

A gradient check guarantees it everywhere; a step count only guarantees it on datasets where 50 steps happen to be enough.)

38.4. Objective perturbation

38.4.1. Context

Output perturbation wastes the data's curvature: it pays for the worst case λ and is judged on the actual H. Chaudhuri, Monteleoni & Sarwate (2011) put the noise inside the optimization instead. Add a random linear term $\frac{1}{n}\langle b, \theta\rangle$ to the objective and minimize exactly. A linear term is a constant force; the objective's curvature, all of it, resists that force. Where the data add curvature, the minimizer moves less. The price is a subtler privacy proof, because the output is no longer "something fixed plus noise".

38.4.2. Statement

Let the loss have the form $\ell(\theta; (x, y)) = g(y\langle\theta, x\rangle)$ with g convex and twice differentiable, $|g'| \le 1$ and $0 \le g'' \le c$, and let $\|x\| \le 1$; so the gradients have length at most $L = 1$. Logistic regression qualifies with $c = \frac{1}{4}$. Set

$$\varepsilon' = \varepsilon - 2\ln\Big(1 + \frac{c}{n\lambda}\Big), \tag{38.12}$$

draw b with density $\nu(b) \propto e^{-\varepsilon'\|b\|/2}$ (Fact 3 with $s = 2/\varepsilon'$), and release

$$\tilde\theta = \arg\min_\theta \Big[\mathcal{L}(\theta; D) + \frac{1}{n}\langle b, \theta\rangle\Big]. \tag{38.13}$$

If $\varepsilon' > 0$, this is ε-DP for replace-one neighbours (Chaudhuri, Monteleoni & Sarwate 2011, Algorithm 2). If not, increase the ridge to $\lambda + \lambda_+$ with $\lambda_+ = \frac{c}{n(e^{\varepsilon/4}-1)} - \lambda$, which makes the logarithm $\varepsilon/4$ and lets $\varepsilon' = \varepsilon/2$.

The minimizer moves, to first order, by $-H^{-1}b/n$, so the excess risk is about

$$\mathbb{E}\big[\mathcal{L}(\tilde\theta) - \mathcal{L}(\theta^*)\big] \approx \frac{1}{2n^2}\mathbb{E}\big[b^\top H^{-1} b\big] = \frac{\mathbb{E}\|b\|^2}{2dn^2}\,\operatorname{tr} H^{-1}. \tag{38.14}$$

Without the approximation, Section M.1 in the appendices brackets it between $\lambda\mathbb{E}\|b\|^2/(2\beta^2 n^2)$ and $\mathbb{E}\|b\|^2/(2\lambda n^2)$.

38.4.3. Derivation

The plan is to write the density of $\tilde\theta$ explicitly with Fact 4, then bound the ratio of the two densities, for D and D', at every point. The ratio splits into a noise factor and a stretching factor, and each consumes part of ε.

1. **From the output back to the noise.** The perturbed objective is λ-strongly convex, so it has exactly one minimizer, where its gradient is zero: $\nabla\mathcal{L}(\tilde{\theta}; D) + b/n = 0$. Solving for b,

$$b = \phi_D(\tilde{\theta}) = -n\nabla\mathcal{L}(\tilde{\theta}; D) = -\sum_{i=1}^{n} \nabla\ell(\tilde{\theta}; z_i) - n\lambda\tilde{\theta}. \tag{38.15}$$

   Every θ is the output for exactly one b, namely $\phi_D(\theta)$, so the map from noise to output is invertible and ϕ_D is its inverse.
2. **The density of the output.** By Fact 4, $p_D(\theta) = \nu(\phi_D(\theta))\,|\det\nabla\phi_D(\theta)|$, and the same for D' with $\phi_{D'}$. The ratio at any θ is

$$\frac{p_D(\theta)}{p_{D'}(\theta)} = \underbrace{\frac{\nu(\phi_D(\theta))}{\nu(\phi_{D'}(\theta))}}_{\text{noise}} \cdot \underbrace{\frac{|\det\nabla\phi_D(\theta)|}{|\det\nabla\phi_{D'}(\theta)|}}_{\text{Jacobian}}. \tag{38.16}$$

3. **The noise factor is at most $e^{\varepsilon'}$.** The sums in ϕ_D and $\phi_{D'}$ share every term except the replaced record's, so $\phi_{D'}(\theta) - \phi_D(\theta) = \nabla\ell(\theta; z) - \nabla\ell(\theta; z')$, of length at most 2. The noise factor is $e^{\varepsilon'(\|\phi_{D'}(\theta)\| - \|\phi_D(\theta)\|)/2}$, and by the triangle inequality the exponent is at most $\varepsilon' \cdot 2/2 = \varepsilon'$.
4. **The Jacobian is the Hessian.** $\nabla\phi_D(\theta) = -n\nabla^2\mathcal{L}(\theta; D) = -A$, with $A = \sum_i g''(m_i)x_i x_i^\top + n\lambda I$, where $m_i = y_i\langle\theta, x_i\rangle$ is the margin; the chain rule gives each loss's Hessian as $g''(m_i)$ times $y_i^2 x_i x_i^\top = x_i x_i^\top$. Every term is positive semi-definite and $n\lambda I$ is added, so all eigenvalues of A are at least $n\lambda$. For D' the matrix is $A' = A + E$ with $E = g''(m')x'x'^\top - g''(m)xx^\top$: one rank-one term in, one out.
5. **The Jacobian factor is at most $(1 + c/(n\lambda))^2$.** The ratio of determinants is $\det(A')/\det(A) = \det(I + A^{-1}E) = \det(I + K)$ with $K = A^{-1/2}EA^{-1/2}$, since $A^{-1}E$ and K are similar matrices. K is symmetric and is the difference of two rank-one positive semi-definite matrices, $g''(m')\tilde{x}'\tilde{x}'^\top - g''(m)\tilde{x}\tilde{x}^\top$ with $\tilde{x} = A^{-1/2}x$. A rank-one matrix $vv^\top$ has one nonzero eigenvalue, $\|v\|^2$, and here $\|\tilde{x}\|^2 = x^\top A^{-1}x \le \|x\|^2/(n\lambda) \le 1/(n\lambda)$. So K has at most two nonzero eigenvalues, which we call κ_1 and κ_2, each between $-a$ and a with $a = c/(n\lambda)$, and $\det(I + K) = (1 + \kappa_1)(1 + \kappa_2) \le (1 + a)^2$. Exchanging the roles of D and D' gives the same bound for the inverse ratio, because A' also has all eigenvalues at least $n\lambda$.
6. **Add the two budgets.** The log of the density ratio is at most $\varepsilon' + 2\ln(1 + c/(n\lambda)) = \varepsilon$ by Equation 38.12, at every θ and in both directions. A bound on the density ratio everywhere is pure ε-DP.
7. **When $\varepsilon' \le 0$.** The Jacobian factor alone would exceed ε. A larger ridge shrinks a: with $\lambda + \lambda_+$ in place of λ, $c/(n(\lambda + \lambda_+)) = e^{\varepsilon/4} - 1$, so $2\ln(1 + a) = \varepsilon/2$, and the noise gets the other half.
8. **Excess risk.** To first order in b, the perturbed minimizer solves $H(\tilde{\theta} - \theta^*) + b/n = 0$, so $\tilde{\theta} - \theta^* = -H^{-1}b/n$. Substituting this into the second-order expansion $\mathcal{L}(\tilde{\theta}) - \mathcal{L}(\theta^*) \approx \frac{1}{2}(\tilde{\theta} - \theta^*)^\top H(\tilde{\theta} - \theta^*)$ of step 2 of Section 38.3 gives $\frac{1}{2n^2}b^\top H^{-1}HH^{-1}b = \frac{1}{2n^2}b^\top H^{-1}b$. Averaging over the uniform direction, as in step 3 there, replaces $b^\top H^{-1}b$ by $\mathbb{E}\|b\|^2 \operatorname{tr} H^{-1}/d$, which is Equation 38.14.

Walk-through in one dimension. With $d = 1$ everything in steps 1–5 is a number, and the script computes both densities exactly on a grid of outputs. Take $n = 5$ records with features in $[-1, 1]$, $\lambda = 0.1$ and $\varepsilon = 1$. Then $c/(n\lambda) = 0.25/0.5 = 0.5$, the Jacobian budget is $2\ln 1.5 = 0.8109$, and the noise gets $\varepsilon' = 0.1891$. Figure 38.2 shows one dataset: the two densities, and their log

ratio, which stays inside $\pm\varepsilon$. Over 500 random datasets and replacements, the largest log ratio anywhere on the grid is 0.3779. Its noise part never exceeds 0.0992, about half its budget of 0.1891, and its Jacobian part never exceeds 0.3395, well under its budget of 0.8109, and under even $\ln 1.5 = 0.4055$, half of it.

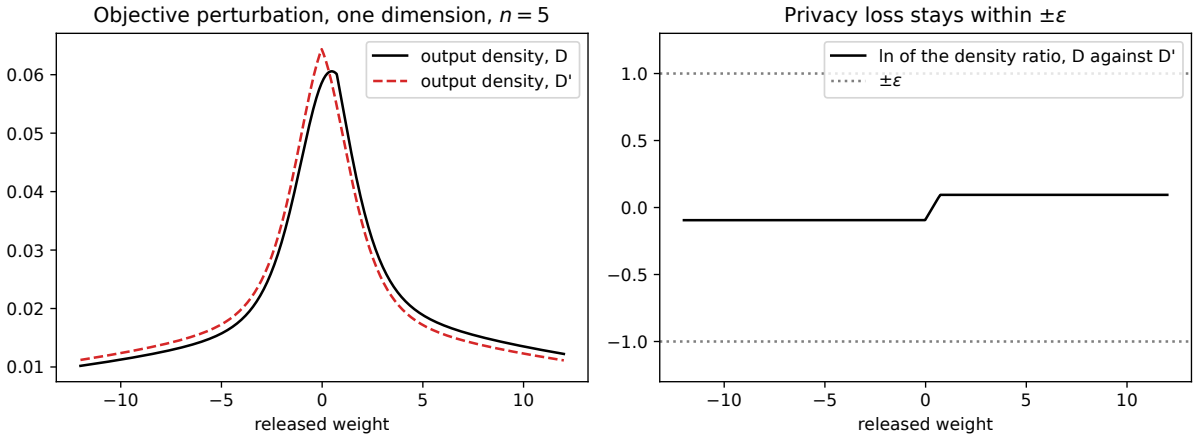

Figure 38.2.: Objective perturbation in one dimension, $n = 5$, $\lambda = 0.1$, $\varepsilon = 1$. Left: the exact densities of the released weight under a dataset and its neighbour, computed by change of variables. Right: their log ratio, the privacy loss, which stays well inside $\pm\varepsilon$.

38.4.4. Interpretation

Where the slack is. Both factors in step 2 are bounded by worst cases that cannot happen together, and mostly cannot happen at all for logistic regression. The noise factor reaches $e^{\varepsilon'}$ only if the old and new record have full-length gradients pointing in opposite directions. A logistic gradient has full length only when its margin is very negative, and two records whose gradients point in opposite directions have opposite margins, so at most one of them can be saturated: the difference has length at most about 1, not 2, which is why the noise part stops at half its budget. The Jacobian bound charges both the record that leaves and the one that arrives the full curvature c, while their eigenvalues $\kappa_1 \geq 0 \geq \kappa_2$ have opposite signs, so the product $(1+\kappa_1)(1+\kappa_2)$ is at most $1 + a$: the Jacobian needs only half its budget (Exercise 6 in the exercise book). The analysis is safe, not tight.

Curvature helps. Compare Equation 38.14 with Equation 38.10. In output perturbation the noise has length about $1/(\lambda n)$ and the damage is weighted by H; in objective perturbation the noise has length about 1, is divided by n, and the damage is weighted by H^{-1}. If every eigenvalue of H is close to h, the ratio of the two excess risks is about $(h/\lambda)^2$ (with $\varepsilon' \approx \varepsilon$). When the ridge supplies all the curvature, $h = \lambda$ and the two are equivalent. When the data supply more, objective perturbation wins quadratically.

What it needs. It needs exact minimization, which no computer delivers. An iterative solver stops early, and floating-point arithmetic rounds every number. Rounding can itself leak, as Mironov (2012) showed for a textbook implementation of Laplace noise (Discrete mechanisms). Beyond that, it needs twice-differentiable losses (the hinge loss of a support vector machine must

be smoothed first), a bound c on the curvature, and a loss that depends on θ through one inner product, which makes each record's Hessian rank one. Kifer, Smith & Thakurta (2012) extend it to Gaussian noise with (ε, δ)-DP and to constrained problems, and Iyengar et al. (2019) give a version that tolerates approximate minimization by adding a little output noise on top.

38.4.5. Example: the running example at $n = 10{,}000$

At $n = 10{,}000$ the Jacobian budget is $2\ln(1 + 0.25/100) = 0.0050$, so $\varepsilon' = 0.9950$: almost all of ε goes to the noise. (At $n = 100$ the split would be $\varepsilon' = 0.5537$, and the Jacobian would take almost half.) The noise has $\mathbb{E}\|b\|^2 = d(d+1)(2/\varepsilon')^2$, and $\operatorname{tr} H^{-1} = 320.7$, so Equation 38.14 predicts an excess risk of 7.127×10^{-5}; 20 simulated releases average 8.156×10^{-5}. The pure-DP output perturbation of Section 38.3, with the same ε, had 8.321×10^{-4}: objective perturbation is ten times better. The rule of thumb $(h/\lambda)^2$ predicts this: the objective's curvature, ridge included, lies between 0.0263 and 0.0330, about three times the ridge's 0.01, and $3^2 = 9$.

38.4.6. Check yourself

- Why does the proof need the minimizer to be unique? *(Step 1 inverts the map from noise to output. If two weights both minimized the perturbed objective, the output would not be a function of b, and Fact 4 would not apply.)*
- If you double n, what happens to the share of ε that the Jacobian consumes? *(It roughly halves: $2\ln(1 + c/(n\lambda)) \approx 2c/(n\lambda)$ for large n.)*

38.5. Gradient perturbation: noisy gradient descent

38.5.1. Context

The first two methods release one point and need the exact minimizer. Real training is iterative and stops early. Gradient perturbation, proposed by Williams & McSherry (2010) and analysed by Song, Chaudhuri & Sarwate (2013) and Bassily, Smith & Thakurta (2014), makes each step of the optimizer private and composes the steps. Here is its simplest form, full-batch gradient descent with Gaussian noise. Its privacy argument uses nothing about convexity; convexity enters only when you ask how accurate it is.

38.5.2. Statement

Start from $\theta_0 = 0$ and run T steps of

$$\theta_{t+1} = \theta_t - \eta(\nabla \mathcal{L}(\theta_t; D) + \xi_t), \qquad \xi_t \sim \mathcal{N}(0, \sigma^2 I) \text{ independent}, \qquad \sigma = \frac{2L}{n} \cdot \frac{\sqrt{T}}{\mu(\varepsilon, \delta)}. \quad (38.17)$$

Releasing all the iterates $\theta_1, \dots, \theta_T$ is (ε, δ)-DP for replace-one neighbours, for any loss whose per-record gradients have length at most L, convex or not.

For a λ-strongly convex, β-smooth objective (curvature between λ and β everywhere) and learning rate $\eta = 1/\beta$, the excess risk of the last iterate is approximately

$$\mathbb{E}[\mathcal{L}(\theta_T) - \mathcal{L}(\theta^*)] \approx \left(1 - \frac{\lambda}{\beta}\right)^T (\mathcal{L}(\theta_0) - \mathcal{L}(\theta^*)) + \frac{d\sigma^2}{4\beta}, \tag{38.18}$$

an optimization error that shrinks with T plus a noise floor that grows with T, because $\sigma^2 \propto T$.

38.5.3. Derivation

1. **One step is a Gaussian mechanism.** Given θ_t, the step releases $\nabla\mathcal{L}(\theta_t; D)+\xi_t$. The ridge term $\lambda\theta_t$ is the same on both datasets, and the averages differ only in the replaced record, so the gradient moves by $\frac{1}{n}\|\nabla\ell(\theta_t; z) - \nabla\ell(\theta_t; z')\| \le 2L/n$. Its ratio is $\mu_{\text{step}} = 2L/(n\sigma)$. The point θ_t was itself computed from earlier noisy gradients, but it is public at that moment, which is what adaptive composition allows.
2. **Compose.** By Fact 5, T such steps are exactly as private as one Gaussian with $\mu = \sqrt{T} \cdot 2L/(n\sigma)$. Setting this to $\mu(\varepsilon, \delta)$ gives the σ of Equation 38.17. The iterates are computed from the noisy gradients and θ_0 alone, so releasing them is post-processing.
3. **Where convexity was not used.** Steps 1 and 2 bounded the gradient's change by $2L/n$ at the point θ_t, whatever θ_t is. Nothing required a minimizer, convexity or smoothness.
4. **Optimization error.** Without noise, gradient descent with learning rate $\eta = 1/\beta$ on a λ-strongly convex, β-smooth function shrinks $\mathcal{L}(\theta_t) - \mathcal{L}(\theta^*)$ by at least a factor $1 - \lambda/\beta$ per step (Optimization), which gives the first term.
5. **The noise floor.** Near the minimizer, the gradient is about $H(\theta_t - \theta^*)$, so the error $e_t = \theta_t - \theta^*$ evolves as $e_{t+1} \approx (I - \eta H)e_t - \eta\xi_t$. Along an eigenvector of H with curvature h, the error's variance v settles where one step leaves it unchanged: $v = (1 - \eta h)^2 v + \eta^2\sigma^2$, so $v = \eta^2\sigma^2/(1 - (1 - \eta h)^2) = \eta\sigma^2/(h(2 - \eta h))$. Its cost is $\frac{1}{2}hv = \eta\sigma^2/(2(2 - \eta h))$, about $\eta\sigma^2/4$ when ηh is small. Summing over the d directions with $\eta = 1/\beta$ gives $d\sigma^2/(4\beta)$, and the curvature h has cancelled: directions with little curvature wander farther but cost less per unit of wandering.

38.5.4. Interpretation

The step count is a privacy parameter. Every step spends budget, so the noise per step grows like $\sqrt{T}$ and the noise floor like T. Too few steps leave optimization error, too many drown the solution in noise. Figure 38.3 shows the trade-off on the running example. And you cannot pick the best T by trying several and keeping the one with the best validation score without paying for it: that selection is itself a computation on the data, the subject of Hyperparameter tuning.

A public rule for T. Equation 38.18 can be evaluated without looking at the data, using only public quantities: λ, the curvature bound $\beta = \frac{1}{4} + \lambda$ for logistic loss with unit features, $\mathcal{L}(\theta_0) = \ln 2$ for $\theta_0 = 0$ (each loss is $\ln 2$ at $\theta = 0$, and $\mathcal{L}(\theta^*) \ge 0$), d, n and the budget. The rule picks the T that minimizes it. It is pessimistic, because it only knows that the curvature is at least λ.

Why it is the one that generalizes. Gradient perturbation needs a gradient bound, not a minimizer. For a neural network no such bound holds, because gradients can be arbitrarily

long, but you can force one by **clipping**: rescale each record's gradient to length at most C before averaging, exactly as Beyond global sensitivity clips a value before averaging it. That, with minibatches instead of full batches, is DP-SGD.

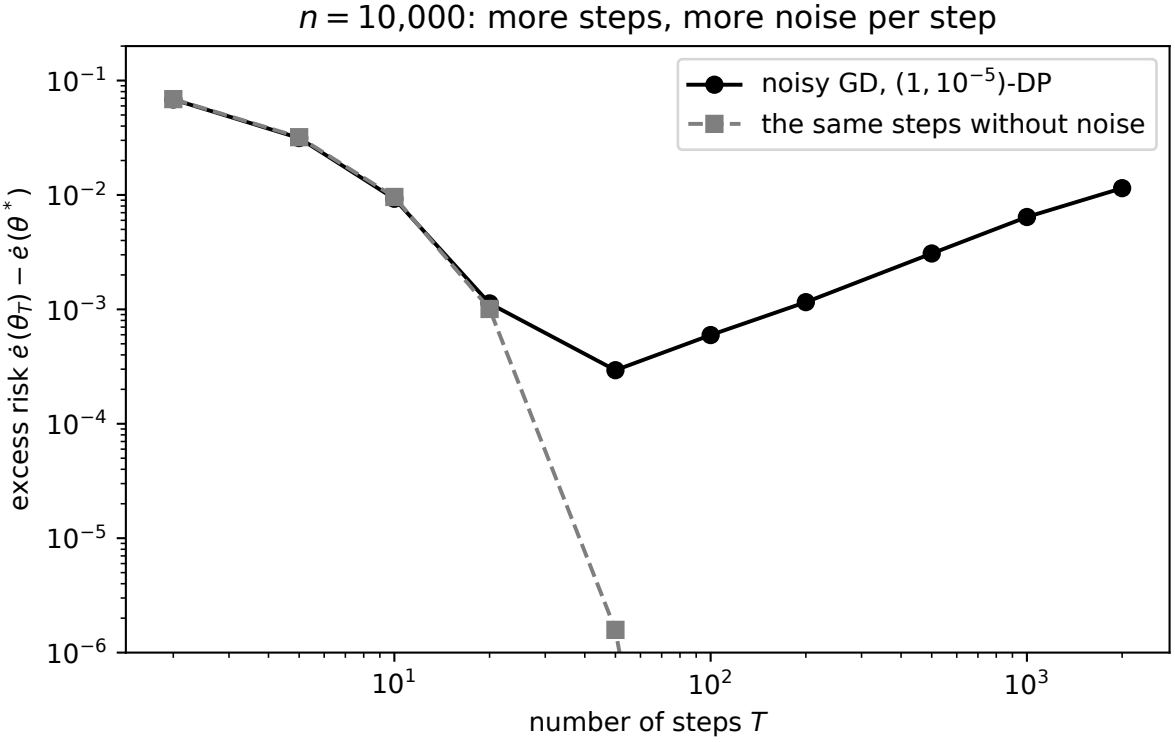

Figure 38.3.: Excess risk of noisy gradient descent at $n = 10{,}000$, $(\varepsilon, \delta) = (1, 10^{-5})$, against the number of steps T, averaged over datasets, with the same steps without noise (dashed). The noiseless error falls geometrically and reaches machine precision; the noisy run is limited by noise that grows with T, so its error is smallest near $T = 50$.

38.5.5. Example: choosing T for the running example

For $n = 10{,}000$, the public rule picks $T = 218$, which gives per-step noise $\sigma = 0.01102$ on the mean gradient and an estimated excess risk of 1.301×10^{-3}. Simulated runs average 1.384×10^{-3}, close to the estimate.

Figure 38.3 shows that the rule overshoots. With the actual curvature of the data, between 0.0263 and 0.0330 rather than the 0.01 the rule assumes, noiseless gradient descent is already within 2.679×10^{-11} of the minimum after 100 steps. Measured over 10 datasets, the excess risk is 1.027×10^{-3} at $T = 20$, 2.875×10^{-4} at $T = 50$, 7.137×10^{-4} at $T = 100$ and 6.018×10^{-3} at $T = 1{,}000$. The best T is near 50, four times smaller than the rule's, and gives five times less excess risk. You may only use that knowledge if you obtained it privately, or from public data that resembles yours.

Table 38.2.: Noisy gradient descent on the running example: the step count chosen by minimizing Equation 38.18 with public quantities only, the resulting noise, and the estimated excess risk.

n	Steps T (public rule)	Per-step σ on the mean gradient	Estimated excess risk
1,000	100	0.07461	6.725×10^{-2}
3,000	156	0.03106	1.080×10^{-2}
10,000	218	0.01102	1.301×10^{-3}
30,000	274	0.004117	1.779×10^{-4}
100,000	335	0.001366	1.930×10^{-5}

The step count grows slowly with n, like $\ln n$, because the optimization error shrinks geometrically while the target, the noise floor, shrinks like $1/n^2$ (Table 38.2).

38.5.6. Check yourself

- Noisy gradient descent with $T = 100$ steps is $(1, 10^{-5})$-DP. You run it for $T = 400$ steps with the same per-step noise. What is μ now? *(Twice as large: $\mu = \sqrt{T}\,\mu_{step}$, and $\sqrt{400/100} = 2$. So $\mu = 2 \times 0.2681 = 0.5362$, a weaker guarantee.)*
- In step 1 of the derivation, why is it allowed that the point θ_t at which the gradient is evaluated depends on the data? *(Because θ_t is computed from earlier released outputs only. Adaptive composition covers mechanisms chosen based on earlier outputs, so the bound holds conditionally on the past, at whatever θ_t it produced.)*

38.6. Noisy projected gradient descent without a ridge

38.6.1. Context

Every method so far leaned on the ridge. Output and objective perturbation need it for their privacy, and the noise floor of Equation 38.18 needs it for its accuracy. Many models have no ridge, though, or one so small that a bound in $1/\lambda$ says nothing. A linear classifier trained with the hinge or logistic loss inside a fixed ball of weights is convex and has bounded gradients, but it is not strongly convex. How accurate can a private trainer be on such a model, and where does the dimension enter? Bassily, Smith & Thakurta (2014) answer with noisy gradient descent and the convergence guarantee of projected SGD, and get a rate of order $RL\sqrt{d}/(n\varepsilon)$ for gradients of length at most L in a ball of radius R. The derivation also shows that privacy noise acts on the optimizer exactly like any other gradient noise.

38.6.2. Statement

Keep the weights in the ball $\mathcal{W} = \{\|\theta\| \le R\}$, fixed in advance. Let the loss be convex in θ with per-record gradients of length at most L, and minimize the plain average $\mathcal{L}(\theta; D) = \frac{1}{n}\sum_i \ell(\theta; z_i)$,

with no ridge. Start from $\theta_1 = 0$ and run T steps of

$$\theta_{t+1} = \Pi_{\mathcal{W}}\Big(\theta_t - \eta(\nabla\mathcal{L}(\theta_t; D) + \xi_t)\Big), \qquad \xi_t \sim \mathcal{N}(0, \sigma^2 I), \qquad \sigma = \frac{2L}{n} \cdot \frac{\sqrt{T}}{\mu(\varepsilon, \delta)}, \tag{38.19}$$

where $\Pi_{\mathcal{W}}$ is the projection onto the ball and $\mu(\varepsilon, \delta)$ is, as in Fact 1, the largest ratio of sensitivity to noise at which one Gaussian release is (ε, δ)-DP. Use the learning rate $\eta = R/(G\sqrt{T})$ with $G^2 = L^2 + d\sigma^2$, and release the average of the iterates, $\bar{\theta} = \frac{1}{T}\sum_{t=1}^{T} \theta_t$. The release is (ε, δ)-DP for replace-one neighbours, and its excess risk over the best weights in the ball is at most

$$\mathbb{E}[\mathcal{L}(\bar{\theta}; D)] - \min_{\theta \in \mathcal{W}} \mathcal{L}(\theta; D) \le RL\sqrt{\frac{1}{T} + \frac{4d}{n^2\mu(\varepsilon, \delta)^2}}. \tag{38.20}$$

Once $T \ge n^2\mu^2/(4d)$, this is at most $2\sqrt{2}\, RL\sqrt{d}/(n\mu)$. For $\varepsilon < 1$ the exact ratio is at least the classic one, $\mu \ge \varepsilon/\sqrt{2\ln(1.25/\delta)}$, so

$$\mathbb{E}[\mathcal{L}(\bar{\theta}; D)] - \min_{\theta \in \mathcal{W}} \mathcal{L}(\theta; D) \le \frac{4RL\sqrt{d\ln(1.25/\delta)}}{n\varepsilon}. \tag{38.21}$$

38.6.3. Derivation

1. **Privacy.** Each step releases the noisy gradient $\nabla\mathcal{L}(\theta_t; D) + \xi_t$, whose noiseless part moves by at most $2L/n$ when one record is replaced, as in step 1 of Section 38.5. Fact 5 composes the T steps into one Gaussian with ratio $\sqrt{T} \cdot 2L/(n\sigma) = \mu(\varepsilon, \delta)$. The projection uses only the public ball, and the average uses only the iterates, so both are post-processing.
2. **The noisy gradient is unbiased.** Write $g_t = \nabla\mathcal{L}(\theta_t; D) + \xi_t$. Given the past, ξ_t is fresh noise with mean zero, so $\mathbb{E}[g_t] = \nabla\mathcal{L}(\theta_t; D)$, the first condition of Fact 6.
3. **Its second moment is $L^2 + d\sigma^2$.** Expand the square: $\mathbb{E}\|g_t\|^2 = \|\nabla\mathcal{L}\|^2 + 2\,\mathbb{E}\langle\nabla\mathcal{L}, \xi_t\rangle + \mathbb{E}\|\xi_t\|^2$. The gradient of $\mathcal{L}$ is an average of vectors of length at most L, so its length is at most L. The cross term is zero, because ξ_t has mean zero and is independent of θ_t. The last term is $d\sigma^2$, one σ^2 per coordinate. So $G^2 = L^2 + d\sigma^2$ satisfies the second condition of Fact 6.
4. **Apply Fact 6.** The minimizer over the ball and the start $\theta_1 = 0$ both lie in the ball, so they are at most R apart. With the learning rate $\eta = R/(G\sqrt{T})$, Equation 38.8 bounds the excess risk of $\bar{\theta}$ by $RG/\sqrt{T} = R\sqrt{(L^2 + d\sigma^2)/T}$.
5. **The step count cancels from the noise term.** By Equation 38.19, $\sigma^2 = 4L^2T/(n^2\mu^2)$, so $d\sigma^2/T = 4L^2d/(n^2\mu^2)$, whatever T is. Factoring out L^2 gives Equation 38.20.
6. **Choose T.** The first term under the root falls with T and the second does not. When $T \ge n^2\mu^2/(4d)$, the first is at most the second, and the root is at most $\sqrt{8d/(n^2\mu^2)} = 2\sqrt{2}\,\sqrt{d}/(n\mu)$.
7. **In terms of ε.** The classic calibration of Fact 1 adds noise $\Delta_2 f\sqrt{2\ln(1.25/\delta)}/\varepsilon$, and it is (ε, δ)-DP for $\varepsilon < 1$. The exact calibration uses the least noise that is (ε, δ)-DP, so it adds no more noise than the classic one, and its ratio μ is at least the classic ratio,

$$\frac{1}{\mu} \le \frac{\sqrt{2\ln(1.25/\delta)}}{\varepsilon}. \tag{38.22}$$

   Substituting this into step 6 gives $2\sqrt{2} \cdot \sqrt{2} = 4$ in front, which is Equation 38.21.

38.6.4. Interpretation

Privacy noise is just more gradient variance. The convergence guarantee of Fact 6 does not care where the randomness of g_t comes from, only how large its second moment is. Sampling one record instead of averaging all of them raises G^2, and so does Gaussian noise for privacy, by $d\sigma^2$. That is where the dimension enters the cost of privacy: one σ^2 for every coordinate the optimizer moves. Public data and private fine-tuning builds on this, by training fewer coordinates.

More steps never hurt here. In Section 38.5 the noise floor grew with T, because the learning rate $\eta = 1/\beta$ was fixed while the noise per step grew like $\sqrt{T}$. Here the learning rate shrinks like $1/\sqrt{T}$ and the iterates are averaged, and step 5 shows the two effects cancel exactly. The noise term is fixed by n, d and the budget, and extra steps only remove optimization error. So the step count needs no tuning. It only has to reach the public threshold $n^2\mu^2/(4d)$.

The rate cannot be beaten. For convex losses with L-bounded gradients over a ball of radius R, Bassily, Smith & Thakurta (2014) prove that, as long as $\sqrt{d} \le n\varepsilon$, every (ε, δ)-DP algorithm has excess risk of order $RL\sqrt{d}/(n\varepsilon)$ on some dataset, by the fingerprinting argument of Lower bounds. Section M.1 in the appendices derives this lower bound step by step, with explicit but loose constants. Equation 38.21 matches it up to the factor $\sqrt{\ln(1/\delta)}$ and constants. Compare the strongly convex rate Equation 38.23 of Section 38.7, which is of order $d/(\lambda n^2\varepsilon^2)$: a guaranteed curvature λ turns $\sqrt{d}/(n\varepsilon)$ into its square, divided by λ.

The cost is computation. Full-batch steps touch all n records, so $T \approx n^2\mu^2/(4d)$ steps cost about $n^3\mu^2/(4d)$ gradient evaluations. Bassily, Smith & Thakurta use one random record per step instead, about n^2 steps. Sampling makes each step cheaper, and by Amplification by subsampling also more private, so the noise per step can be smaller. The rate is the same up to logarithms. Random batches, clipping and an accountant for many such steps are the ingredients of DP-SGD in the next chapter.

It is a worst case. The bound uses only convexity and the gradient bound, and the worst case is a loss that is nearly linear around its minimizer. The logistic loss is curved there, so the measured excess risk falls faster than $1/n$, as the example shows.

38.6.5. Example: logistic regression in a ball

Take the running example's data, with $d = 10$ features and gradients of length at most $L = 1$, drop the ridge, and keep the weights in the ball of radius $R = 5$. The budget is $\varepsilon = 1$ and $\delta = 10^{-5}$, for which the exact ratio is $\mu = 0.2681$. The classic ratio $\varepsilon/\sqrt{2\ln(1.25/\delta)}$ is smaller, 0.2064, as step 7 requires. With a thousand records the rule $T = \lceil n^2\mu^2/(4d) \rceil$ gives 1,797 steps, and the noise on the mean gradient is $\sigma = 0.3163$. The noise adds $d\sigma^2 = 10 \times 0.3163^2$ to the second moment, so $G^2 = 2.0004$, about twice the noiseless $L^2 = 1$. The learning rate is then 0.0834, and Equation 38.20 evaluates to 0.1668.

The bound falls with the number of steps but levels off at its limit, $2RL\sqrt{d}/(n\mu) = 0.1180$. It is 0.5137 after 100 steps and 0.1973 after 1,000. After 10,000 steps it is 0.1281, and after 100,000 it is 0.1190, within 1% of the limit.

Table 38.3 runs the algorithm for three dataset sizes, five datasets each.

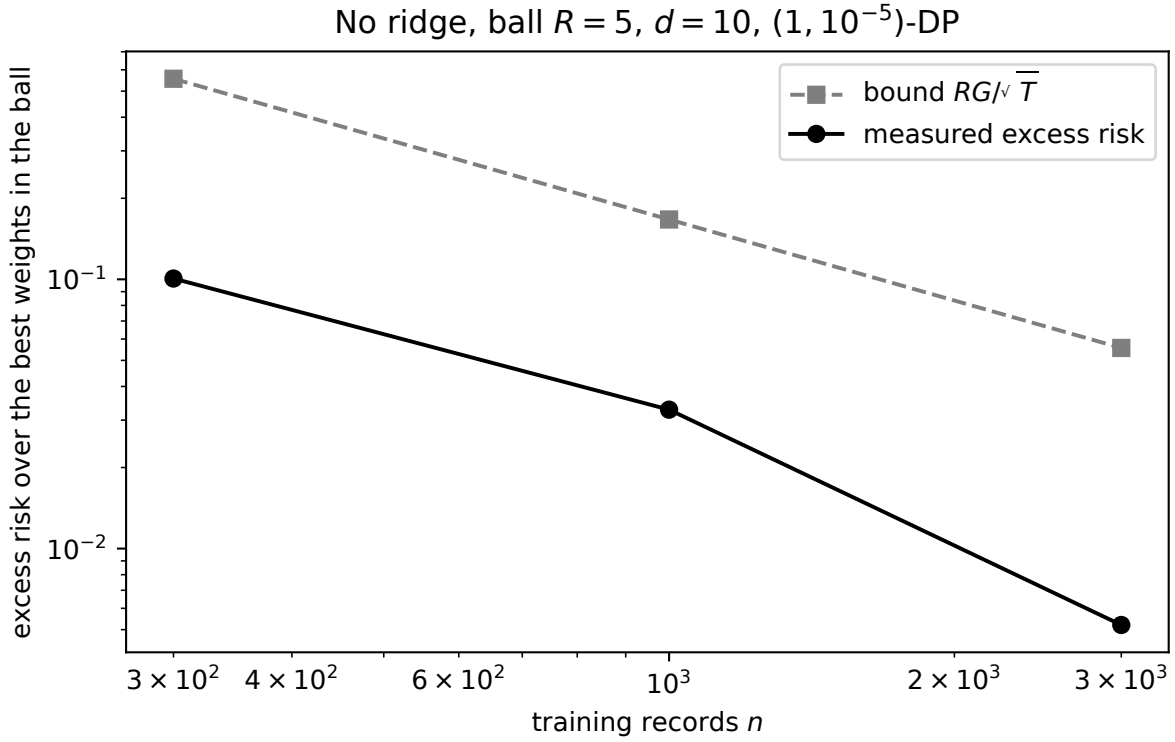

Figure 38.4.: Noisy projected gradient descent on unregularized logistic regression in the ball of radius 5, $d = 10$, $(1, 10^{-5})$-DP, with $T = \lceil n^2\mu^2/(4d) \rceil$ steps: the measured excess risk over the best weights in the ball (circles) against the bound Equation 38.20 (squares), averaged over 3 datasets drawn separately from those of the table. The bound falls like $1/n$; the measured excess risk falls faster.

Table 38.3.: Noisy projected gradient descent without a ridge on the running example's data, ball of radius 5, $(1, 10^{-5})$-DP: mean excess risk over 5 datasets against the bound.

n	Steps T	σ	Measured excess risk	Bound Equation 38.20	Bound / measured
300	162	0.3166	1.119×10^{-1}	5.558×10^{-1}	5.0
1,000	1,797	0.3163	3.028×10^{-2}	1.668×10^{-1}	5.5
3,000	16,167	0.3162	7.297×10^{-3}	5.561×10^{-2}	7.6

The bound holds at every n and is loose by a factor of 5 to 8. Its log-log slope in n is -1.00, while the measured slope is -1.18, steeper because the logistic loss has curvature near its minimizer that the bound does not use (Figure 38.4). The rule's σ is the same at every n, because $T \propto n^2$ and $\sigma \propto \sqrt{T}/n$.

The dimension enters as $\sqrt{d}$. At $n = 10{,}000$ the limit $2RL\sqrt{d}/(n\mu)$ is 0.0118 for $d = 10$, 0.0236 for $d = 40$ and 0.0472 for $d = 160$: each fourfold increase in d doubles it. The step rule needs 179,629, 44,908 and 11,227 steps for these three dimensions, which is why the batch-size-one version matters in practice.

38.6.6. Check yourself

- Noisy gradient descent with a ridge has a noise floor that grows with the number of steps, but here extra steps never raise the bound. What is different? *(Here the learning rate shrinks like $1/\sqrt{T}$ and the iterates are averaged, so the noise contributes $d\sigma^2/T$, which does not depend on T. With a fixed learning rate $\eta = 1/\beta$ and the last iterate, the floor is $d\sigma^2/(4\beta)$, which grows with $\sigma^2 \propto T$.)*
- You double the dimension and keep everything else. By what factor does the limit of the bound grow, and what happens to the number of steps the rule asks for? *(The limit grows by $\sqrt{2}$, since it is proportional to $\sqrt{d}$. The rule's $T = n^2\mu^2/(4d)$ halves.)*

38.7. How the three compare

38.7.1. Context

Each method is private by its own argument. Which should you use? Theory answers by rates, how the excess risk falls with n, d and ε, and by lower bounds that no method can beat. Simulation answers for the running example. They agree on the rate and disagree on the constant, and the constant is what you choose by.

38.7.2. Statement

For λ-strongly convex objectives with L-Lipschitz losses, Bassily, Smith & Thakurta (2014) show that the best achievable expected excess risk under (ε, δ)-DP is of order

$$\frac{L^2\, d}{\lambda\, n^2 \varepsilon^2}, \tag{38.23}$$

up to logarithmic factors in n and $1/\delta$. Their upper bound, attained by noisy stochastic gradient descent, carries such factors. Their lower bound, which holds for every (ε, δ)-DP algorithm, does not, so the two match only up to those logarithms. Section M.1 in the appendices proves both sides with explicit constants; with full gradients and a weighted average of the iterates, the upper bound needs no logarithm of n. For convex objectives over a ball of radius R, without strong convexity, the rate is of order $LR\sqrt{d}/(n\varepsilon)$ up to logarithms, and Section 38.6 derives the upper bound. The lower bounds come from the fingerprinting codes of Lower bounds: a private algorithm whose output is too accurate would let an adversary trace which records were used.

On the running example, Table 38.4 gives the measured excess risk of the four private releases.

Table 38.4.: Mean excess risk $\mathcal{L}(\tilde{\theta}) - \mathcal{L}(\theta^*)$ over 20 datasets of the running example ($d = 10$, $\lambda = 0.01$, $\varepsilon = 1$, $\delta = 10^{-5}$ for the Gaussian methods), and the slope of a straight-line fit of ln excess risk against $\ln n$.

n	Output, Gaussian	Output, pure	Objective, pure	Noisy gradient descent (public T)
1,000	8.170×10^{-2}	7.060×10^{-2}	1.009×10^{-2}	6.558×10^{-2}
3,000	1.211×10^{-2}	7.206×10^{-3}	6.303×10^{-4}	8.888×10^{-3}
10,000	9.274×10^{-4}	8.321×10^{-4}	8.156×10^{-5}	1.384×10^{-3}
30,000	9.973×10^{-5}	8.943×10^{-5}	7.135×10^{-6}	1.538×10^{-4}
100,000	8.543×10^{-6}	6.379×10^{-6}	8.798×10^{-7}	1.621×10^{-5}
Slope in $\ln n$	-2.01	-2.00	-2.01	-1.79

38.7.3. Derivation

The upper bounds for output and objective perturbation are Equation 38.10 and Equation 38.14 with the noise of each method substituted. Both have $\mathbb{E}\|\text{noise}\|^2 \propto 1/n^2$ (the output noise has scale $1/(\lambda n)$; the objective noise has scale 1 and is divided by n), which gives the $1/n^2$. For noisy gradient descent, the noise floor $d\sigma^2/(4\beta)$ has $\sigma^2 \propto T/n^2$, and the optimization error must be pushed below it, which takes $T \propto \frac{\beta}{\lambda} \ln n$ steps; this gives $1/n^2$ times a logarithm. Bassily, Smith & Thakurta (2014) give both proofs. Section M.1 in the appendices derives an upper bound of this order, with explicit constants, for noisy projected gradient descent, and the lower bound by a reduction to the fingerprinting bound.

38.7.4. Interpretation

The rate is the same; the constants are not. All three methods fall like $1/n^2$, and noisy gradient descent a little slower, -1.79, because its step count grows with $\ln n$. On this problem objective perturbation is about ten times better than output perturbation at every n, the $(h/\lambda)^2$ of Section 38.4, and noisy gradient descent with the public step rule is the worst of the three for $n \geq 10{,}000$. Tuned privately to $T \approx 50$, it would sit between the two perturbation methods.

Pure against approximate DP. At $d = 10$ the pure-DP noise of Fact 3 and the Gaussian are close: their mean squared lengths are $d(d+1)s^2 = 110\,(\Delta_2 f)^2$ at $\varepsilon = 1$ and $d\sigma^2 = 10 \times 3.7306^2\,(\Delta_2 f)^2 = 139.2\,(\Delta_2 f)^2$, which is why the pure-DP column is slightly better here. At

$d = 100$ they are 10,100 $(\Delta_2 f)^2$ against 1,392 $(\Delta_2 f)^2$: pure DP costs a factor that grows like d, the price of $\delta = 0$ that Lower bounds proves unavoidable.

Accuracy is forgiving. Excess risk is a fine measure, but you care about predictions. On held-out data the non-private model has accuracy 0.747 at $n = 1{,}000$; output perturbation drops it to 0.681, noisy gradient descent to 0.695 and objective perturbation only to 0.736. By $n = 10{,}000$ all four are within 0.002 of the non-private 0.753. A low-dimensional convex model on ten thousand records can be made private almost for free.

Training error is not test error. The excess risk in this chapter is measured on the training objective. A deployed model is judged instead by its **population risk**, the expected loss on a new record drawn from the same distribution as the training data. For convex losses with L-bounded gradients over a ball of radius R, Bassily, Feldman, Talwar & Thakurta (2019) show that the best population excess risk under (ε, δ)-DP is of order

$$LR\Big(\frac{1}{\sqrt{n}} + \frac{\sqrt{d\ln(1/\delta)}}{n\varepsilon}\Big). \tag{38.24}$$

The first term is what any learner pays for seeing only n samples, private or not. The second is the price of privacy, and it is the smaller of the two once n exceeds about $d\ln(1/\delta)/\varepsilon^2$. So, with enough data, privacy adds nothing to the error that sampling already causes, the same conclusion that Section 38.3 reached for strongly convex objectives.

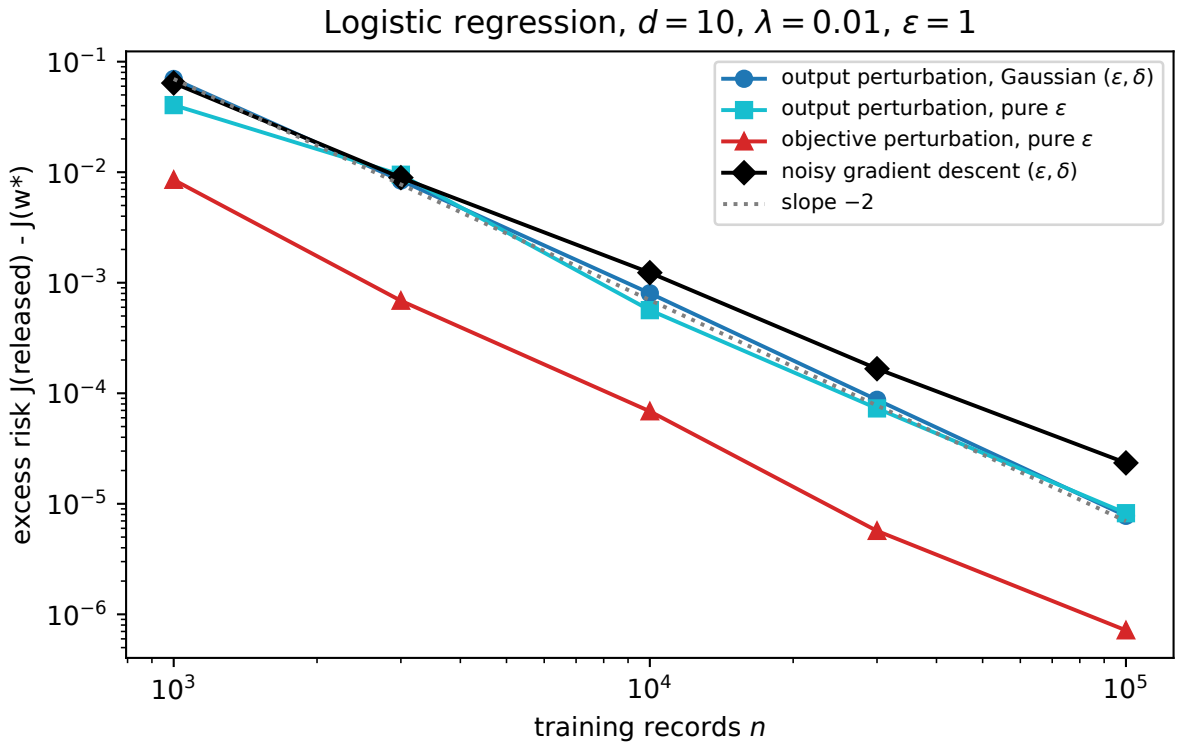

Figure 38.5.: Excess risk of the four private releases against the dataset size on the running example, log-log, with a line of slope -2. All fall like $1/n^2$; objective perturbation is about ten times better than output perturbation throughout.

38.7.5. Example: reading the rate

Equation 38.23 predicts how much data you need. Suppose an excess risk of 10^{-4} is acceptable, and output perturbation gives 9.274×10^{-4} at $n = 10{,}000$. The rate $1/n^2$ says that multiplying n by $\sqrt{9.274} = 3.05$ brings it to about 10^{-4}; Table 38.4 confirms it, with 9.973×10^{-5} at $n = 30{,}000$. Equivalently, halving ε costs the same as halving n, because n and ε appear only as the product $n\varepsilon$: to keep the same accuracy at half the budget, you need twice the data.

38.7.6. Check yourself

- In Equation 38.23, why do n and ε appear only as the product $n\varepsilon$? *(Every sensitivity in this chapter is proportional to $1/n$ and every noise to sensitivity over ε, so the noise scale is proportional to $1/(n\varepsilon)$.)*
- Objective perturbation beat output perturbation by a factor of ten. Name a problem on which it would not help at all. *(Any problem whose data add no curvature beyond the ridge, such as a linear loss: then $H = \lambda I$, $h = \lambda$, and the ratio $(h/\lambda)^2$ is 1.)*

38.8. When the model is not convex

38.8.1. Context

A neural network's loss is not convex in its parameters. What survives of the three methods?

38.8.2. Statement

The privacy proofs of Section 38.3 and Section 38.4 do not carry over to non-convex objectives, because both need a unique minimizer that moves only a little when one record changes. Neither method becomes impossible. Output perturbation over a bounded set of weights is always private with noise scaled to the set's diameter, but then the noise swamps the answer. Objective perturbation can be proved private without convexity (Neel, Roth, Vietri & Wu 2020), but only if the optimizer returns a global minimizer of the perturbed objective, which no practical optimizer for a neural network guarantees. Noisy gradient descent keeps its guarantee, Equation 38.17, for any loss whose per-record gradients have length at most L, and loses only its accuracy guarantee. When no such L exists, clipping each per-record gradient to length C makes $L = C$.

38.8.3. Derivation

1. **The minimizer can jump.** Optimization gives a one-dimensional loss with two wells, $\frac{1}{4}(\theta^2-1)^2-y\theta$ with labels $y = \pm 1$, whose empirical minimizer sits in the well favoured by the majority label. With 501 labels $+1$ and 500 labels -1, changing one label flips the majority and moves the minimizer by 2.0010. No $1/n$ appears: the sensitivity of the minimizer is a constant, so output perturbation would need noise with $\sigma = 3.7306 \times 2.0010 = 7.465$ at $\varepsilon = 1$, more than three times the distance between the wells, whatever the dataset size.

2. **The objective-perturbation proof breaks at step 1.** Without strong convexity the perturbed objective can have several minimizers, the map from noise to output is no longer invertible, and Fact 4 cannot be applied. Neel et al. (2020) replace the change of variables with a different argument. It shows that a variant of objective perturbation is private for bounded, Lipschitz losses, convex or not, when the perturbed objective is handed to an oracle that returns its global minimizer, or a point provably close to it. The guarantee is therefore about that minimizer, and it holds only for an optimizer that is certain to find it. Gradient descent on a neural network finds a local minimum that depends on the starting point, and the guarantee says nothing about that.
3. **Gradient perturbation survives.** Its derivation in Section 38.5 used only the gradient bound at the visited points (step 3 there).
4. **Clipping supplies the bound.** Replace each per-record gradient $\nabla\ell(\theta; z_i)$ by $\nabla\ell(\theta; z_i)\min(1, C/\|\nabla\ell(\theta; z_i)\|)$, which has length at most C and is unchanged when it is already shorter. The average of clipped gradients changes by at most $2C/n$ when one record is replaced, and the derivation goes through with $L = C$.

38.8.4. Interpretation

What the non-convex case loses is the guarantee of accuracy, not of privacy. Noisy gradient descent on a neural network is private whatever the network does; whether it learns anything is an empirical question, and the answer depends on the clipping norm, the noise and the number of steps, which the next chapter studies. Clipping also changes what is being optimized: the average of clipped gradients is not the gradient of $\mathcal{L}$, so the algorithm no longer minimizes $\mathcal{L}$, a bias that the next chapter measures.

Full-batch gradient descent is also too slow for large datasets: each step touches every record. Using a random minibatch at each step makes each step cheaper and, by Amplification by subsampling, more private per step, because each record is used only with probability q. Clipping, noise, minibatches and a subsampled-Gaussian accountant together are DP-SGD.

38.8.5. Example: two wells and output perturbation

Take the double-well loss with $n = 1{,}001$, whose minimizer sits in one of the two wells near ± 1. Output perturbation with $\sigma = 7.465$ releases a weight whose standard deviation is more than seven times the distance from either well to the origin; the released value carries almost no information about which well the data chose, which is exactly what privacy demands, since one record decides it. Noisy gradient descent with clipping still moves toward whichever well the noisy average gradient points to; on datasets where many records agree, the average gradient is large compared with the noise and the method finds the majority well with high probability.

38.8.6. Check yourself

- Why does clipping not break the privacy proof, even though it changes the gradients? *(The proof needs only that each step releases a function of the data with bounded sensitivity plus Gaussian noise. The clipped average is such a function, with sensitivity $2C/n$, whatever it is the gradient of.)*

- Does noisy gradient descent on a non-convex loss need to find the global minimum to be private? *(No. Privacy holds for every run, whatever point it reaches; finding a good point is a question of accuracy only.)*

38.9. Code: check every number by computation

The script code/dp_erm.py implements the three methods for regularized logistic regression with exact Newton solves, computes the exact output densities of objective perturbation in one dimension, runs noisy projected gradient descent without a ridge against its bound, and runs the comparison. From the repository root:

```
uv run python code/part05-dp-ml/dp_erm.py
```

Its public functions are used by later chapters of this part: `make_logistic_data`, `fit_logistic`, `logistic_objective`, `logistic_grad`, `excess_risk`, `gaussian_delta(eps, mu)`, `gaussian_mu(eps, delta)`, `gaussian_sigma(sensitivity, eps, delta)` and `project_ball`.

Output (seed 0), summarized in Table 38.5:

Table 38.5.: The script's output with the default seed.

Experiment	Result
Gaussian calibration, $\varepsilon = 1$, $\delta = 10^{-5}$	$\mu = 0.2681$; exact $\sigma = 3.7306\,\Delta_2 f$ against classic $4.8448\,\Delta_2 f$
Output perturbation, one dimension	Minimizers 0.0832 apart, bound 0.2
Output perturbation, $n = 10{,}000$	Predicted excess risk 8.711×10^{-4}, measured 9.274×10^{-4}
Approximate minimizer, $g = 10^{-3}$	Sensitivity 0.22 against 0.02 exact
Objective perturbation, one dimension, 500 datasets	Largest log ratio 0.3779 against $\varepsilon = 1$; noise part 0.0992 of 0.1891, Jacobian part 0.3395 of 0.8109
Objective perturbation, $n = 10{,}000$	Predicted 7.127×10^{-5}, measured 8.156×10^{-5}
Noisy gradient descent, $n = 10{,}000$	Public rule $T = 218$, measured 1.384×10^{-3}; best $T \approx 50$ gives 2.875×10^{-4}
Noisy projected gradient descent, no ridge, $n = 1{,}000$	$T = 1{,}797$, bound 0.1668, measured 3.028×10^{-2}
Slopes in $\ln n$	-2.01, -2.00, -2.01, -1.79 with a ridge; -1.18 measured and -1.00 for the bound without

tests/test_dp_erm.py checks that the output still matches.

What to take from it. Three things. First, the privacy proofs can be checked numerically where the output distribution is computable: in one dimension the change-of-variables density

is exact, and the log ratio stays inside its bound with room to spare. Second, the second-order predictions of excess risk match simulation to within the sampling error, so you can predict the cost of privacy before training. Third, all methods have the same $1/n^2$ rate on this problem, and the constant, a factor of ten here, comes from how each method uses the data's curvature. Without the ridge the guaranteed rate slows to $1/n$, and the measured excess risk stays five to eight times below its bound.

38.11. Cheat sheet

n records, ridge λ, per-record gradients of length at most L, replace-one neighbours, $\mu(\varepsilon, \delta)$ the largest admissible Gaussian ratio (0.2681 at $\varepsilon = 1$, $\delta = 10^{-5}$), H the Hessian at the minimizer. Table 38.6 collects the results.

Table 38.6.: Every result of the chapter.

Result	Formula	Needs	Guarantee
Sensitivity of the minimizer	$2L/(\lambda n)$	λ-strong convexity, exact minimizer	—
Approximate minimizer	$2L/(\lambda n) + 2g/\lambda$	$\lVert\nabla\mathcal{L}\rVert \le g$ checked at stopping	—
Output perturbation	$\theta^* + \mathcal{N}(0, \sigma^2 I)$, $\sigma = 2L/(\lambda n \mu)$	As above	(ε, δ)-DP
Output, pure	$\theta^* + b$, $\nu(b) \propto e^{-\lVert b\rVert \lambda n \varepsilon/(2L)}$	As above	ε-DP
Excess risk, output	$\approx \mathbb{E}\lVert Z\rVert^2 \operatorname{tr} H/(2d)$	Second order	—
Objective perturbation	$\arg\min \mathcal{L} + \langle b, \theta\rangle/n$, $\nu(b) \propto e^{-\varepsilon'\lVert b\rVert/2}$, $\varepsilon' = \varepsilon - 2\ln(1 + c/(n\lambda))$	Loss $g(y\langle\theta, x\rangle)$, $\lvert g'\rvert \le 1$, $0 \le g'' \le c$, $\lVert x\rVert \le 1$, exact minimizer	ε-DP
Excess risk, objective	$\approx \mathbb{E}\lVert b\rVert^2 \operatorname{tr} H^{-1}/(2dn^2)$	Second order	—
Noisy gradient descent	$\sigma = (2L/n)\sqrt{T}/\mu$ on the mean gradient	Per-record gradients $\le L$ (or clipped)	(ε, δ)-DP, all iterates
Excess risk, noisy gradient descent	$\approx (1 - \lambda/\beta)^T(\mathcal{L}(\theta_0) - \mathcal{L}(\theta^*)) + d\sigma^2/(4\beta)$	Strong convexity, smoothness, $\eta = 1/\beta$	—
Optimal rate, strongly convex	$L^2 d/(\lambda n^2 \varepsilon^2)$, up to logarithms in n and $1/\delta$	λ-strong convexity	Bassily, Smith & Thakurta (2014)
Noisy projected gradient descent, no ridge	$\sigma = (2L/n)\sqrt{T}/\mu$, learning rate $\eta = R/(G\sqrt{T})$, $G^2 = L^2 + d\sigma^2$, averaged iterate	Convex, gradients $\le L$, ball of radius R	(ε, δ)-DP
Excess risk, no ridge	$\le RL\sqrt{1/T + 4d/(n^2\mu^2)} \le 4RL\sqrt{d\ln(1.25/\delta)}/(n\varepsilon)$	$T \ge n^2\mu^2/(4d)$, $\varepsilon < 1$	Optimal up to logarithms

Rules of thumb

- All three methods give excess risk falling like $1/(n\varepsilon)^2$ on strongly convex problems. Halving ε costs as much as halving the data.

- Output perturbation pays for the ridge's curvature, objective perturbation benefits from the data's. If the data add curvature h beyond λ, expect objective perturbation to win by about $(h/\lambda)^2$.
- Output and objective perturbation need the exact minimizer; stop on a gradient tolerance well below L/n, never on a step count.
- The number of steps of noisy gradient descent is part of the privacy budget. Choose it from public quantities, or pay for choosing it.
- Only gradient perturbation is private without convexity. Clip per-record gradients to get the bound it needs.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

39. DP-SGD

39.1. Why this matters

Private empirical risk minimization ended with one method left standing for non-convex models: gradient descent with Gaussian noise on every step. Its privacy proof needs only that one record moves each step's gradient by a bounded amount, and clipping each record's gradient supplies that bound for any model. Two more changes make it practical for differential privacy (DP). Each step uses a random minibatch instead of the full dataset, which makes steps cheap and, by amplification, more private. And an accountant composes thousands of such steps into one (ε, δ). The result is stochastic gradient descent (SGD) with per-example clipping and Gaussian noise, DP-SGD, introduced by Abadi et al. (2016). Nearly every private deep-learning system runs it, through libraries such as Opacus, TensorFlow Privacy and JAX Privacy.

Part 4 computed the privacy of DP-SGD without running it. Amplification by subsampling and Choosing an accountant report $\varepsilon = 6.71$ at $\delta = 10^{-5}$ for a sampling rate q of 0.01, a noise multiplier σ of 1 and 10,000 steps. This chapter runs that configuration on a neural network, and asks what the noise and the clipping cost and how to choose the knobs that control them.

39.1.1. The one idea: the analysis never looks inside the model

Each step of DP-SGD releases a noisy **sum of clipped per-example gradients**. Clipping rescales each record's gradient to length at most C, so adding or removing one record changes the sum by at most C, whatever the network, the loss or the current parameters. The privacy proof stops there. Everything else, the architecture, the data, whether training converges, affects only accuracy.

That split organizes the chapter. The knobs divide into two groups. The noise multiplier σ, the sampling rate q and the number of steps T determine ε through the accountant, and nothing else does. The clipping norm C and the learning rate η do not change ε at all; they change how much of the gradient survives clipping and how much the noise moves the weights. The cost of privacy comes in two forms: a **bias** from clipping, which changes the direction of the average gradient, and a **variance** from the noise, which makes each step partly random.

Table 39.1 lists the results and where each is used.

Table 39.1.: The results of this chapter and where each is used.

Result	Where it is used
The algorithm and its (ε, δ) guarantee	Every chapter of this part; what to check in an implementation

Result	Where it is used
Clipping: the expected update, scale invariance and the choice of C	Tuning DP-SGD; disparate impact
Batch size at a fixed budget	Choosing q and T; large-batch private training
Per-example gradient norms without per-example gradients	Implementing DP-SGD at scale; public data and fine-tuning
Microbatches cost a factor $2m$ in noise; vectorization costs nothing	Choosing how to speed up per-example clipping
Privacy against accuracy on the running example	The baseline every later chapter improves on

Notation. A training set D has n records $z_i = (x_i, y_i)$. The model has d parameters, written $\theta \in \mathbb{R}^d$, and $g_i = \nabla_\theta \ell(\theta; z_i)$ is the gradient of record i's loss, its **per-example gradient**. C is the clipping norm, σ the noise multiplier (the noise standard deviation in units of C), q the sampling rate, $B = qn$ the expected batch size, T the number of steps and η the learning rate. The learning rate is also called the step size. Neighbouring datasets now differ by **adding or removing** one record, $D' = D \cup \{z\}$, because Poisson sampling pairs with that relation (Amplification by subsampling); the previous chapter used replacement.

The running example. Inputs are 50-dimensional standard normal vectors, and labels are the sign of the output of a fixed random **teacher** network with 8 hidden tanh units, so a perfect classifier exists. The **student** is a network with one hidden layer of 64 tanh units and a logistic loss, $d = 3{,}329$ parameters including biases, trained on $n = 10{,}000$ records and tested on 20,000 more. DP-SGD runs with $q = 0.01$ (expected batch $B = 100$), $C = 0.5$, $\eta = 0.5$, $\sigma = 1$ and $T = 10{,}000$ steps, 100 epochs: exactly Part 4's running example. The dataset is fixed; only the training randomness changes between runs.

How to read this chapter. Read the toolkit and Section 39.3, which states what the guarantee covers and what it assumes. Section 39.4 and Section 39.5 say how to set the knobs. Section 39.6 and Section 39.7 are about implementation and can be skipped on a first reading, except for the warning about microbatches. Section 39.8 puts the pieces together.

39.2. Toolkit: four facts every derivation uses

39.2.1. Fact 1 — A Gaussian mechanism is described by one ratio

Add noise $\mathcal{N}(0, s^2 I)$ to a vector-valued function whose value moves by at most Δ in Euclidean length between neighbours. Its privacy depends only on $\mu = \Delta/s$, the shift measured in noise standard deviations, because rotating the space puts the shift on one axis and leaves identical noise on the others (The Laplace and Gaussian mechanisms). For a clipped sum with noise σC, $\Delta = C$ and $\mu = 1/\sigma$: the clipping norm cancels.

39.2.2. Fact 2 — The Poisson-subsampled Gaussian and its accountant

If each record enters the batch independently with probability q, one step's output with the record is a mixture: with probability $1-q$ the record was not drawn and the output is the same as without it, with probability q it was drawn and the output is shifted. In the worst case the two distributions to compare are the mixture $(1-q)\mathcal{N}(0,\sigma^2)+q\mathcal{N}(1,\sigma^2)$ and $\mathcal{N}(0,\sigma^2)$, in one dimension. An (ε,δ) pair says only that the privacy loss exceeds ε with probability at most δ, not how far beyond ε that rare loss goes, and so it does not compose well. The accountant therefore tracks the whole distribution of the loss through its moments. That is the Rényi differential privacy (RDP) curve, the Rényi divergence of order α between the two distributions, which Abadi et al. (2016) introduced as the moments accountant. For integer α it has the exact form

$$\varepsilon_{q,\sigma}(\alpha)=\frac{1}{\alpha-1}\ln\sum_{j=0}^{\alpha}\binom{\alpha}{j}(1-q)^{\alpha-j}q^{j}e^{(j^2-j)/(2\sigma^2)}, \tag{39.1}$$

and a numerical integral for other orders (Amplification by subsampling). RDP curves add under composition, even when each step depends on the previous outputs (Rényi DP), and the composed curve converts to (ε,δ) at the best order,

$$\varepsilon=\min_{\alpha}\left[T\varepsilon_{q,\sigma}(\alpha)+\ln\frac{\alpha-1}{\alpha}-\frac{\ln\delta+\ln\alpha}{\alpha-1}\right] \tag{39.2}$$

(Balle et al. 2020; From Rényi DP to (ε, δ)). For small q and orders that are not too large, only the $j=2$ term of Equation 39.1 matters beyond the first two, and the curve is close to $\frac{\alpha}{2}q^2(e^{1/\sigma^2}-1)$.

39.2.3. Fact 3 — Post-processing

Any computation on a private output, which does not touch the data again, is as private as the output itself (Post-processing, group privacy and composition). Dividing a noisy sum by a public constant, taking a gradient step with it, and releasing the resulting weights are all post-processing.

39.2.4. Fact 4 — A dense layer's gradient is an outer product

For a dense layer that maps an input $a\in\mathbb{R}^{d_{\text{in}}}$ to Wa, the gradient of a loss with respect to W is $va^{\top}$, where v is the gradient with respect to the layer's output, the **back-propagated error**. Each entry is $\partial\ell/\partial W_{jk}=v_j a_k$, because W_{jk} multiplies a_k and contributes to output j only. Gradient inversion uses the same fact to reconstruct inputs from gradients; here it makes per-example gradient norms cheap.

39.3. The algorithm and its guarantee

39.3.1. Context

What exactly does DP-SGD compute, and which (ε,δ) does it satisfy? The answer has to be precise, because each detail of the algorithm is an assumption of the proof, and implementations

that change a detail can lose the guarantee without any visible symptom.

39.3.2. Statement

Start from parameters θ_0 chosen independently of the data. For $t = 0, \dots, T-1$:

1. **Sample.** Put each record in the batch S_t independently with probability q.
2. **Per-example gradients.** For each $i \in S_t$, compute $g_i = \nabla_\theta \ell(\theta_t; z_i)$.
3. **Clip.** Rescale each to length at most C: $\bar{g}_i = g_i \min(1, C/\|g_i\|)$.
4. **Noisy sum.** $G_t = \sum_{i \in S_t} \bar{g}_i + \xi_t$ with $\xi_t \sim \mathcal{N}(0, \sigma^2 C^2 I)$.
5. **Step.** $\theta_{t+1} = \theta_t - \eta\, G_t / B$, with $B = qn$ the expected batch size.

Releasing all of $\theta_1, \dots, \theta_T$ is (ε, δ)-DP for add/remove neighbours, with ε given by Equation 39.2. Section C.5 in the appendices derives this from scratch, from clipping to the final ε, with worked numbers. The guarantee does not depend on the loss, the model, C or η.

39.3.3. Derivation

1. **One record moves the clipped sum by at most C.** Fix the parameters θ_t and the batch of the other records. If the record z is in the batch, the sum contains one extra term $\bar{g}_z$, of length at most C; every other term is the same for D and D', because each is computed from its own record alone.
2. **One step is a subsampled Gaussian mechanism.** With noise σC, Fact 1 gives the ratio $1/\sigma$ for a step on which z is drawn. Under Poisson sampling, z is drawn with probability q independently of the other records, so the step's output on D' is the mixture of Fact 2. Rescaling by C and rotating, the worst case over the direction and length of $\bar{g}_z$ is the one-dimensional pair of Fact 2, a shift of exactly C along one axis; a shorter shift is the same pair with extra noise, which cannot be less private.
3. **Dividing by B is post-processing.** $B = qn$ is a fixed public number, so θ_{t+1} is computed from θ_t and G_t alone (Fact 3).
4. **Compose.** Step t is evaluated at θ_t, which depends on the earlier noisy sums. RDP composition holds for such adaptive sequences, so the T steps together have RDP curve $T\varepsilon_{q,\sigma}(\alpha)$.
5. **Convert.** Equation 39.2 turns the composed curve into (ε, δ). Every iterate is a function of the released noisy sums, so releasing all of them, or only the last, is covered.

39.3.4. Interpretation

What the proof assumes, and how implementations break it. Each step of the derivation is a condition on the code.

- *Step 1 needs per-example independence.* Batch normalization computes means and variances over the batch, so one record changes every other record's activations and gradients, and the sum can move by much more than C. Private models use normalizations that act on one example at a time, such as group or layer normalization.

- *Step 1 needs a fixed C.* Choosing C as, say, the median gradient norm of the current batch makes the noise scale depend on the data. Choose C in advance, from public data or a private estimate.
- *Step 2 needs Poisson sampling.* Shuffling the data and cutting it into fixed batches is a different mechanism, which Amplification by subsampling shows can be much less private than the Poisson accountant reports.
- *Step 3 needs a public denominator.* Dividing by the actual batch size $|S_t|$, which reveals how many records were drawn and changes when z is added, is not post-processing of G_t. Divide by B, or release a noisy count and spend budget on it.
- *Step 4 needs the accountant to see every step*, including the steps of runs that were discarded during tuning: that is the subject of Hyperparameter tuning.

What it does not cover. The guarantee is for one record. A person with many records needs user-level privacy. Preprocessing that uses the data, such as normalizing features by their mean, must itself be private or use public statistics.

39.3.5. Example: the running example

With $q = 0.01$, $\sigma = 1$, $T = 10{,}000$ and $\delta = 10^{-5}$, the accountant gives $\varepsilon = 6.71$, attained at order $\alpha = 4.1$, the same value Part 4 reports. Table 39.2 gives the noise multiplier that the same q and T need for other budgets.

Table 39.2.: The noise multiplier that DP-SGD with $q = 0.01$ and $T = 10{,}000$ steps needs for each budget, from the RDP accountant.

ε at $\delta = 10^{-5}$	0.5	1	2	4	6.71	8
Noise multiplier σ	7.72	4.13	2.28	1.36	1	0.917

How large is the noise? The averaged update G_t/B carries noise with standard deviation $\sigma C/B = 1 \times 0.5/100 = 0.005$ on each of the 3,329 coordinates. A Gaussian vector with d independent coordinates of standard deviation s has length close to $s\sqrt{d}$, so the noise has length about $0.005 \times \sqrt{3{,}329} = 0.288$. The averaged clipped gradient has length at most $C = 0.5$, and in the run it is 0.070 at the first step and between 0.015 and 0.027 from step 1,000 on. The noise in every step is about ten times longer than the signal.

Training works anyway, because the signal points in roughly the same direction from one step to the next, while the noise is independent. Over t steps, the signals add up to about t times their length, and the noise to about $\sqrt{t}$ times its length, since independent vectors add in squares. Signal overtakes noise when $t \cdot 0.026 > \sqrt{t} \cdot 0.288$, that is after $t > (0.288/0.026)^2 \approx 123$ steps. The final model reaches test accuracy 0.9589, against 0.9627 for non-private SGD.

39.3.6. Check yourself

- A colleague's implementation divides each noisy sum by the number of records actually in the batch. Which step of the derivation fails? *(Step 3: the divisor depends on the data, so the update is no longer a function of the noisy sum alone, and the accountant's analysis does not apply to it.)*

- Does changing C from 0.5 to 5 change ε? *(No. The sum's sensitivity and the noise both scale with C, so their ratio $1/\sigma$ and the accountant's input are unchanged. It changes accuracy.)*

39.4. Clipping: bias, noise and the choice of C

39.4.1. Context

The clipping norm does not affect privacy, but it controls both forms of cost. Small C clips more gradients, which biases the update; large C adds more noise, because the noise is σC. What does the update estimate, and how should C be chosen?

39.4.2. Statement

Averaged over the sampling and the noise, the update direction is a **reweighted gradient**:

$$\mathbb{E}\Big[\frac{G_t}{B}\Big] = \frac{1}{n}\sum_{i=1}^{n} \min\Big(1, \frac{C}{\|g_i\|}\Big) g_i, \tag{39.3}$$

the true average gradient $\frac{1}{n}\sum_i g_i$ with each record weighted by $\min(1, C/\|g_i\|)$. Its noise has standard deviation $\sigma C/B$ per coordinate.

Scale invariance. If every per-example gradient in a run is clipped, that is $\|g_i\| \geq C$ at every step, then the update is

$$\theta_{t+1} = \theta_t - \frac{\eta C}{B}\Big(\sum_{i\in S_t} \frac{g_i}{\|g_i\|} + \sigma\zeta_t\Big), \qquad \zeta_t \sim \mathcal{N}(0, I), \tag{39.4}$$

which depends on η and C only through their product ηC.

39.4.3. Derivation

1. **Average over the sampling.** Each record is in the batch with probability q, so $\mathbb{E}\sum_{i\in S_t} \bar{g}_i = \sum_{i=1}^{n} q\,\bar{g}_i$. The noise has mean zero.
2. **Divide by $B = qn$.** The q cancels and leaves $\frac{1}{n}\sum_i \bar{g}_i$, which is Equation 39.3 by the definition of $\bar{g}_i$. This is why the denominator is the expected batch size: with it, the update is an unbiased estimate of the average clipped gradient.
3. **The noise.** ξ_t/B has standard deviation $\sigma C/B$ per coordinate.
4. **Scale invariance.** If $\|g_i\| \geq C$, then $\bar{g}_i = C g_i/\|g_i\|$. Write the noise as $\sigma C\zeta_t$ with ζ_t standard normal. Then $G_t = C(\sum_i g_i/\|g_i\| + \sigma\zeta_t)$, and $\eta G_t/B$ is Equation 39.4. Two runs with the same ηC, the same seed and every gradient clipped produce the same parameters.

39.4.4. Interpretation

Below the gradient norms, only ηC matters. When C is smaller than every per-example gradient, DP-SGD is normalized SGD, which averages unit vectors, plus noise, and its behaviour depends on the product ηC. Lowering C further changes nothing once η is scaled up to match. This is why practitioners often clip aggressively and tune only the learning rate; De et al. (2022) report that small clipping norms work well, which this explains.

Above them, noise grows and signal does not. Once C exceeds most gradient norms, the clipped average stops growing with C, but the noise $\sigma C/B$ keeps growing in proportion. The signal-to-noise ratio falls like $1/C$. A large C is never better than the smallest C that clips almost nothing.

The bias reweights records, not uniformly. Equation 39.3 gives each record a weight that falls as its gradient grows. Records the model fits badly, such as rare examples, members of small groups or mislabelled points, have large gradients and are down-weighted, while well-fitted records keep their full weight. The update is not the gradient of the training loss but of a reweighted one, whose weights change as training proceeds. Disparate impact measures who pays for this.

Gradient norms change during training. In the DP-SGD run of the running example the median per-example gradient norm is 3.592 at the first step, 0.006 at step 1,000, and rounds to 0.000 from step 3,000 on; non-private training behaves the same way (Figure 39.1, right). The logistic loss flattens on records that are classified with a wide margin, so their gradients vanish. With $C = 0.5$, every gradient is clipped at the start, and between 9% and 25% of the batch later: the few records still near the decision boundary. A fixed C is in the scale-invariant regime early and in the unbiased regime late.

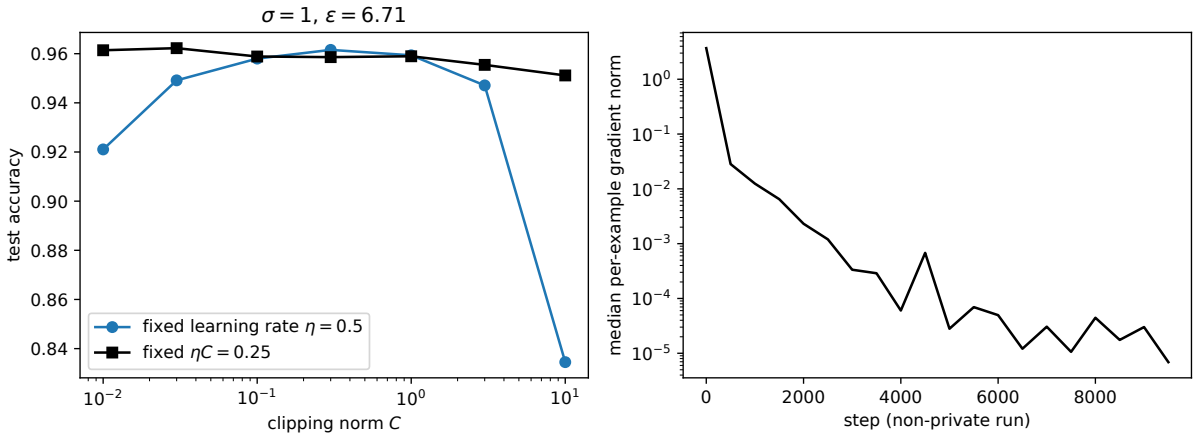

Figure 39.1.: Left: test accuracy of the running example at $\sigma = 1$ ($\varepsilon = 6.71$) against the clipping norm, with the learning rate fixed at $\eta = 0.5$ (circles) and with ηC fixed at 0.25 (squares). Right: the median per-example gradient norm during non-private training, on a log scale; it falls by about five orders of magnitude.

39.4.5. Example: sweeping C

Table 39.3 trains the running example at $\varepsilon = 6.71$ with seven clipping norms, once with the learning rate fixed at 0.5 and once with ηC fixed at $0.5 \times 0.5 = 0.25$.

Table 39.3.: Test accuracy of the running example at $\sigma = 1$ for seven clipping norms, one run each. With ηC fixed, small clipping norms all give the same accuracy.

C	0.01	0.03	0.1	0.3	1	3	10
Fixed $\eta = 0.5$	0.9244	0.9510	0.9567	0.9607	0.9583	0.9523	0.8347
Fixed $\eta C = 0.25$	0.9627	0.9623	0.9605	0.9599	0.9590	0.9558	0.9494

With the learning rate fixed, a small C is too slow (0.9244 at $C = 0.01$: every step has length proportional to $\eta C = 0.005$) and a large one too noisy (0.8347 at $C = 10$). With ηC fixed, accuracy is flat for $C \leq 0.3$, as scale invariance predicts, and falls slowly for large C, where the noise grows while the clipped gradients do not. The best accuracy, 0.9627 at $C = 0.01$, equals the non-private model's.

39.4.6. Check yourself

- You double C and halve η. When is the training run unchanged, and when not? *(Unchanged in distribution if every gradient is clipped under both values of C, by Equation 39.4. If some gradients are shorter than the new C, they now keep more of their length relative to the others, and the update changes.)*
- Why does dividing by B rather than $|S_t|$ make the expected update unbiased for the clipped average? *(Because $\mathbb{E}\sum_{i \in S_t} \bar{g}_i = q \sum_i \bar{g}_i$, and dividing by qn gives exactly the average. Dividing by $|S_t|$ is a ratio of random quantities, whose expectation is not the ratio of expectations.)*

39.5. Batch size and the number of steps at a fixed budget

39.5.1. Context

Suppose the privacy budget (ε, δ) and the compute budget, a number of epochs E, are fixed. Each epoch is $1/q$ steps, so $T = E/q$. Should you take many small steps or few large ones? The accountant answers how much noise each choice needs, and the noise per averaged gradient decides how useful each step is.

39.5.2. Statement

In the regime where the small-q approximation of Fact 2 holds, keeping ε fixed while changing q at a fixed number of epochs requires

$$\sigma \propto \sqrt{q}, \qquad \text{so} \qquad \frac{\sigma C}{B} \propto \frac{C}{\sqrt{qn}\,\sqrt{n}} = \frac{C}{\sqrt{Bn}} : \tag{39.5}$$

the noise on the averaged gradient falls like $1/\sqrt{B}$. Outside that regime, at small σ, small batches need even more noise than Equation 39.5 says, so large batches do better than $1/\sqrt{B}$.

39.5.3. Derivation

1. **Per-step cost.** By Fact 2, for small q the per-step RDP is about $\frac{\alpha}{2}q^2(e^{1/\sigma^2}-1)$, and for σ well above 1, $e^{1/\sigma^2}-1 \approx 1/\sigma^2$, so about $\frac{\alpha q^2}{2\sigma^2}$.
2. **Total cost.** $T = E/q$ steps add up to $\frac{E}{q}\cdot\frac{\alpha q^2}{2\sigma^2} = \frac{\alpha E q}{2\sigma^2}$. The conversion of Equation 39.2 depends only on this curve, so ε stays fixed when q/σ^2 does, that is $\sigma \propto \sqrt{q}$.
3. **Noise per averaged gradient.** $\sigma C/B$ with $B = qn$ and $\sigma \propto \sqrt{q}$ is proportional to $\sqrt{q}/q = 1/\sqrt{q}$, which is Equation 39.5.
4. **Small σ.** When σ is near or below 1, $e^{1/\sigma^2}-1$ is much larger than $1/\sigma^2$: the per-step cost is higher than step 1 says, by the factor $\sigma^2(e^{1/\sigma^2}-1)$. Small batches are in this regime, because they need small σ, so they pay this factor and need more noise than the $\sqrt{q}$ law predicts.

39.5.4. Interpretation

Amplification is most efficient at large σ. The ratio $\sigma/\sqrt{q}$, which Equation 39.5 says is constant, falls from 22.3 at $B = 10$ to 10.8 at $B = 10{,}000$ in Table 39.4. The factor $\sigma^2(e^{1/\sigma^2}-1)$ explains most of it: 3.23 at $\sigma = 0.704$, 1.33 at $\sigma = 1.36$ and 1.04 at $\sigma = 3.78$. Steps with little noise are expensive per unit of signal, because in the tail of the privacy loss, the high orders that the conversion uses, sampling buys little (Amplification by subsampling).

Large batches help, but not for free. For a fixed number of epochs, large batches give less noise per step and fewer steps. Fewer steps means less progress if the learning rate cannot grow in proportion, and the best learning rate grows with the batch: in Table 39.5 the best learning rate goes from 0.25 at $B = 30$ to between 1 and 2 at $B = 100$ to $B = 1{,}000$. De et al. (2022) and Anil et al. (2022) train with batches of thousands to hundreds of thousands, and report that large batches are a main ingredient of accurate private models. Large batches also parallelize well, which matters more on accelerators than in this small example.

39.5.5. Example: one budget, seven batch sizes

Table 39.4 fixes $\varepsilon = 4$, $\delta = 10^{-5}$ and 100 epochs on $n = 10{,}000$ records, and finds the noise multiplier for each sampling rate. For full batches, $q = 1$, there is no sampling and the 100 Gaussian steps compose exactly, like a single Gaussian with ratio $\sqrt{100}/\sigma$ (f-DP and Gaussian DP).

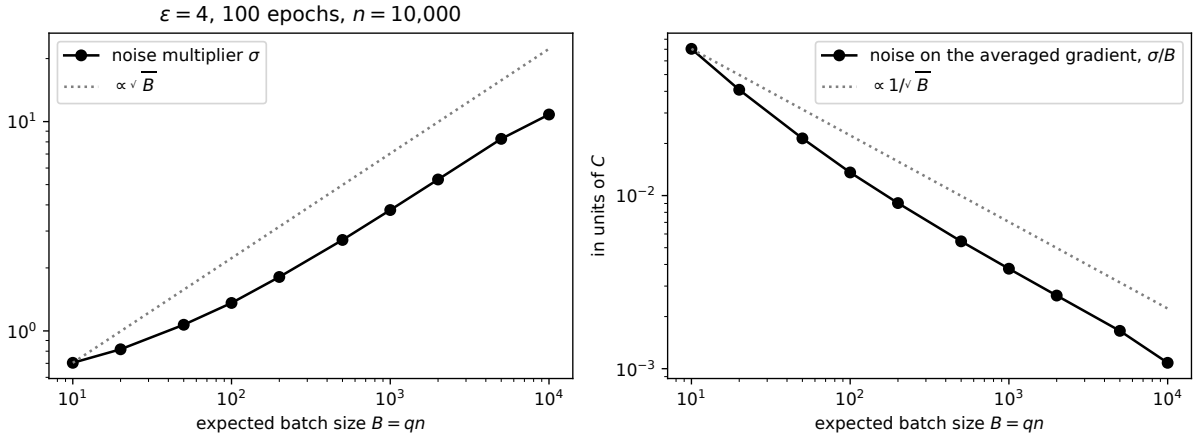

Figure 39.2.: DP-SGD at $\varepsilon = 4$, $\delta = 10^{-5}$, for 100 epochs on $n = 10{,}000$ records, as a function of the expected batch size. Left: the noise multiplier the accountant requires, against the $\sqrt{B}$ law of Equation 39.5. Right: the noise standard deviation on the averaged gradient, in units of C, against the $1/\sqrt{B}$ law. Small batches need more noise than the law predicts.

Table 39.4.: Noise needed for $\varepsilon = 4$ at $\delta = 10^{-5}$ over 100 epochs, for seven sampling rates. The noise on the averaged gradient, in units of C, falls faster than $1/\sqrt{B}$.

q	B	Steps T	σ	Noise per averaged gradient σ/B	$\sigma/\sqrt{q}$	$\sigma^2(e^{1/\sigma^2} - 1)$
0.001	10	100,000	0.704	0.0704	22.3	3.23
0.003	30	33,333	0.909	0.0303	16.6	1.95
0.01	100	10,000	1.36	0.0136	13.6	1.33
0.03	300	3,333	2.16	0.0072	12.5	1.12
0.1	1,000	1,000	3.78	0.00378	12	1.04
0.3	3,000	333	6.44	0.00215	11.8	1.01
1	10,000	100	10.8	0.00108	10.8	1

From $B = 10$ to $B = 1{,}000$, a hundredfold increase, the noise per averaged gradient falls from 0.0704 to 0.00378, a factor of 18.6, against the factor of 10 that $1/\sqrt{B}$ predicts. Table 39.5 trains four of these configurations with three learning rates each.

Table 39.5.: Test accuracy of the running example at $\varepsilon = 4$ and 100 epochs, for four batch sizes and three learning rates each, one run each.

B	Learning rates and test accuracy
30	$\eta = 0.25$: 0.9544; 0.5: 0.9487; 1: 0.9453
100	$\eta = 0.5$: 0.9522; 1: 0.9569; 2: 0.9465
300	$\eta = 1$: 0.9591; 2: 0.9565; 4: 0.9577

B	Learning rates and test accuracy
1,000	$\eta = 2$: 0.9589; 4: 0.9565; 8: 0.9576

At its best learning rate, each batch size reaches between 0.9544 and 0.9591, and the two largest batches do best, with 100 and 30 times fewer steps than $B = 10$ would take. (Choosing the best of three learning rates after looking at test accuracy is itself a leak; it is done here to compare batch sizes, and Hyperparameter tuning shows how to do it privately.)

39.5.6. Check yourself

- At a fixed number of epochs and fixed ε, you multiply the batch size by 4. Roughly how does the noise multiplier change in the regime of Equation 39.5, and the noise on the averaged gradient? *(The noise multiplier doubles, $\sigma \propto \sqrt{q}$, and the noise on the averaged gradient halves, $\propto 1/\sqrt{B}$.)*
- Why does the full-batch row not need the subsampling accountant? *(With $q = 1$ every record is in every step, the steps are plain Gaussian mechanisms, and Gaussian mechanisms compose exactly into one with ratio $\sqrt{T}/\sigma$.)*

39.6. Per-example gradient norms without per-example gradients

39.6.1. Context

Ordinary backpropagation computes the gradient of the *sum* of the batch's losses, never the gradient of each record. Clipping needs each record's gradient norm. Forming all B per-example gradients costs B times the memory of the model's gradient, which for large models is prohibitive. Can the norms, and the clipped sum, be had more cheaply?

39.6.2. Statement

For a dense layer with inputs a_i and back-propagated errors v_i, record i's gradient is $v_i a_i^\top$ (Fact 4), and

$$\left\| v_i a_i^\top \right\|_F = \|v_i\| \, \|a_i\|. \tag{39.6}$$

The whole network's per-example gradient norm is the square root of the sum of these squared norms over layers. The clipped sum is $\sum_i c_i v_i a_i^\top = (c \circ V)^\top A$, where $c_i = \min(1, C/\|g_i\|)$, V and A stack the errors and inputs as rows, and $c \circ V$ multiplies row i of V by c_i. For a layer applied to a sequence of length N, the number of tokens, record i's gradient is $\sum_t v_{it} a_{it}^\top$, where t now indexes the tokens, and

$$\Big\| \sum_t v_{it} a_{it}^\top \Big\|_F^2 = \sum_{t,s} (a_{it} \cdot a_{is})(v_{it} \cdot v_{is}). \tag{39.7}$$

39.6.3. Derivation

1. **One token.** The squared Frobenius norm is the sum of squared entries: $\sum_{j,k} v_j^2 a_k^2 = (\sum_j v_j^2)(\sum_k a_k^2) = \|v\|^2 \|a\|^2$.
2. **Layers.** The full gradient is the concatenation of the layers' gradients, so its squared length is the sum of theirs.
3. **The clipped sum.** $\sum_i c_i v_i a_i^\top$ is linear in the errors: scale each record's error by c_i and do the usual batch product of errors and inputs. One backward pass computes the errors, the norms come from Equation 39.6, and one more matrix product per layer gives the clipped sum.
4. **Sequences.** Expand the square: $\| \sum_t v_t a_t^\top \|_F^2 = \sum_{t,s} \operatorname{tr}(a_t v_t^\top v_s a_s^\top) = \sum_{t,s} (v_t \cdot v_s)(a_s \cdot a_t)$, using $\operatorname{tr}(uv^\top) = v \cdot u$. This is the entrywise product of two $N \times N$ Gram matrices, summed.

39.6.4. Interpretation

This is **ghost clipping** (Goodfellow 2015 for the norms of single inputs; Lee & Kifer 2021 for clipping with them; Li et al. 2022 for sequences): the per-example gradients are "ghosts" that are never formed. For one token per record it stores $B(d_{\text{in}} + d_{\text{out}})$ numbers per layer instead of $Bd_{\text{in}}d_{\text{out}}$. For sequences the Gram matrices cost $2BN^2$, which beats the explicit $Bd_{\text{in}}d_{\text{out}}$ only when $2N^2 < d_{\text{in}}d_{\text{out}}$, so long sequences in narrow layers favour forming the gradients. Bu, Mao & Xu (2022) choose per layer. Either way, privacy is untouched: these are exact computations of the same quantities.

39.6.5. Example: the running example and a transformer layer

For the 256 records of a test batch, the norms from Equation 39.6 agree with explicitly formed per-example gradients to a relative difference of 2.2×10^{-16}, rounding error. For a random 16-token sequence, Equation 39.7 gives 33.144228 and the explicit gradient's norm is the same. Table 39.6 compares the memory for several layers.

Table 39.6.: Numbers stored to clip one dense layer, explicitly and with ghost norms.

Layer	Explicit $Bd_{\text{in}}d_{\text{out}}$	Ghost	Ratio
Running example, first layer: $B = 100$, $d = 51 \to 64$	326,400	11,500	28.4
$B = 32$, one token, $768 \to 768$	18,874,368	49,152	384.0
$B = 32$, 512 tokens, $768 \to 768$	18,874,368	16,777,216	1.1
$B = 32$, 512 tokens, $768 \to 3{,}072$	75,497,472	16,777,216	4.5
$B = 8$, 4,096 tokens, $4{,}096 \to 4{,}096$	134,217,728	268,435,456	0.5

39.6.6. Check yourself

- Why does ghost clipping need a second pass, or a second matrix product, after the norms are known? *(The clipping factors c_i depend on the norms, which need the errors of the whole network. Only then can the errors be rescaled and multiplied by the inputs.)*
- For a convolutional layer, is the per-example gradient an outer product? *(Not of one pair of vectors. It is a sum over spatial positions of outer products, like the sequence case, so Equation 39.7 applies with positions in place of tokens.)*

39.7. Microbatches and vectorized per-example gradients

39.7.1. Context

Deep-learning frameworks are built to compute the gradient of a batch's summed loss in one parallel pass, and per-example clipping breaks that pattern. Computed naively, one record at a time, DP-SGD can run tens or hundreds of times slower than ordinary training. Ghost norms (Section 39.6), which compute each record's gradient length without forming the gradient, are one remedy. Two others are common in practice. One computes the per-example gradients in parallel after all. The other, **microbatching**, clips groups of records instead of single records. The first changes nothing about privacy or accuracy, so the question is what the second costs.

39.7.2. Statement

Fix in advance a rule that assigns every record to one of $K = B/m$ groups, for example a hash of a record identifier taken modulo K, so that a Poisson batch of expected size B splits into about K **microbatches** of about m records each. Microbatched DP-SGD clips the mean gradient of each microbatch, not each record's gradient, and adds Gaussian noise to the sum of the clipped means. Under add/remove neighbours that sum has sensitivity $2C$ as soon as a record can share its group with others, against C for per-example clipping. The accountant assumes noise σ times the sensitivity, so with the same q, σ and T it gives the same ε only if the noise is $2\sigma C$. The update divides the noisy sum by the expected number of microbatches, B/m, so its noise has standard deviation

$$\frac{2\sigma C}{B/m} = 2m \cdot \frac{\sigma C}{B} \tag{39.8}$$

per coordinate, $2m$ times that of per-example clipping.

39.7.3. Derivation

1. **One record touches one microbatch.** The assignment of records to groups is fixed before training and does not depend on which other records are present. A position in the dataset would not do, because adding a record shifts the positions of the records after it. So adding or removing record z changes only the microbatch of z's group. Every other microbatch, and its clipped mean, is the same on both datasets.

2. **That microbatch's clipped mean moves by up to $2C$.** If the group had other sampled records, its clipped mean changes from one vector of length at most C to another, and the two can point in opposite directions, so they differ by up to $2C$. Only when z is alone in its group does the change shrink to C, the per-example case. A worst-case bound must take $2C$.
3. **The accountant.** Step 2 of Section 39.3 needs the noise to be σ times the sensitivity, so the noise must be $\sigma \cdot 2C$. The rest of the derivation is unchanged.
4. **Per coordinate.** The update divides the noisy sum by a public number, the expected number of microbatches B/m. Dividing $2\sigma C$ by it gives Equation 39.8.

39.7.4. Interpretation

Microbatching trades accuracy for speed, at a steep rate. Each microbatch is now the unit that is clipped, so a batch has only B/m clipped terms to carry signal instead of B, while the total noise has doubled to $2\sigma C$. The mean gradient of a microbatch is also shorter than its records' gradients when they disagree, so clipping removes less of it, but that does not make up for a factor $2m$ in the noise.

Check what your library assumes. Some libraries offer microbatches as a speed option. Whether their accounting uses sensitivity C or $2C$ for a microbatch, and whether their microbatches are fixed in advance or cut from the shuffled batch, decides whether the reported ε is valid. If microbatches are cut by position within each sampled batch, adding one record shifts every later record into a different microbatch, and the bound of step 1 fails.

Vectorization costs nothing. The other remedy keeps per-example clipping and computes the per-example gradients in parallel. JAX's `vmap` does it by vectorizing the gradient computation over the examples of a batch, and Opacus does it by attaching hooks that record the per-example quantities during back-propagation. These are exact computations of the same per-example gradients, so they change neither the privacy nor the accuracy. Subramani, Vadivelu & Kamath (2021) show that vectorization combined with just-in-time compilation in many cases brings DP-SGD's running time close to that of ordinary training.

39.7.5. Example: microbatches on the running example

At the running example's $\sigma = 1$, $C = 0.5$ and $B = 100$, the noise on the averaged update is 0.0050 per coordinate with per-example clipping. With microbatches of $m = 4$ records it is 0.0400, eight times more, and with $m = 16$ it is 0.1600, thirty-two times more, at the same $\varepsilon = 6.71$. The test accuracy falls with it, from 0.9589 for per-example clipping (Section 39.3) to 0.9336 with microbatches of 4 and 0.7459 with microbatches of 16, one run each.

39.7.6. Check yourself

- Why is the sensitivity $2C$ rather than C, when one record changes only one microbatch? *(Its microbatch's clipped mean changes from one vector of length at most C to another, which may point the opposite way. Per-example clipping avoids this because, under add/remove, the record's term goes from absent to present, a change of at most C.)*

- Does computing per-example gradients with `vmap` instead of a loop change ε? *(No. It computes exactly the same clipped sum, only faster.)*

39.8. The running example: privacy against accuracy

39.8.1. Context

Put the pieces together: for the running example, how much accuracy does each budget cost, and where does it go?

39.8.2. Statement

Table 39.7 trains the running example with $q = 0.01$, $C = 0.5$, $\eta = 0.5$ and $T = 10{,}000$ steps, at each budget's noise multiplier from Table 39.2, three times each.

Table 39.7.: Test accuracy of the running example under DP-SGD at five budgets, with $\delta = 10^{-5}$.

	Noise multiplier	Test accuracy (mean ± standard deviation over 3 runs)
$\varepsilon = 0.5$	7.72	0.8209 ± 0.0180
$\varepsilon = 1$	4.13	0.9175 ± 0.0161
$\varepsilon = 2$	2.28	0.9441 ± 0.0051
$\varepsilon = 4$	1.36	0.9548 ± 0.0019
$\varepsilon = 8$	0.917	0.9604 ± 0.0019
Clipped, no noise	0	0.9649 ± 0.0009
Non-private SGD, 1,000 steps	—	0.9610 ± 0.0005

39.8.3. Derivation

Each row runs the algorithm of Section 39.3 from a fresh random initialization, with the noise multiplier from the accountant (Fact 2). The non-private baseline uses the same sampling and learning rate with neither clipping nor noise; its accuracy is already at its best after 1,000 steps (0.9627) and stays there (0.9617 after 10,000).

39.8.4. Interpretation

Clipping costs nothing here, noise costs everything. Clipping without noise reaches 0.9649, slightly above non-private SGD: on this problem clipping only limits the influence of the few records with large gradients. The whole loss comes from the noise, and it is steeply non-linear in ε. From $\varepsilon = 8$ to 4 the accuracy drops by half a point, from 2 to 1 by 2.7 points, and from 1 to 0.5 by almost 10.

Why the collapse at small ε. At $\varepsilon = 1$ the noise multiplier is 4.13, so the noise on the averaged gradient has length about $4.13 \times 0.5/100 \times \sqrt{3{,}329} = 1.19$, against a signal of about 0.026. By the argument of Section 39.3, signal overtakes noise only after about $(1.19/0.026)^2 \approx 2{,}100$ steps, so the 10,000 steps contain only a few independent "useful" moves. Figure 39.4 shows the result: with $\sigma = 4$ the model reaches its accuracy early and then wanders.

Run-to-run variation grows with the noise. The standard deviation over runs is 0.0019 at $\varepsilon = 8$ and 0.018 at $\varepsilon = 0.5$. A single private run is a sample from a wide distribution, and comparing two configurations by one run each, as Table 39.3 does, is reliable only for differences well above that spread.

Architecture choices change under privacy. The running example uses tanh units, and that is deliberate. Papernot, Thakurta, Song, Chien & Erlingsson (2021) find that bounded activations such as tanh train better than ReLU under DP-SGD. With the same privacy guarantee, $(2.93, 10^{-5})$ on the handwritten digits of MNIST, their tanh network reaches 98.1% test accuracy against 96.6% for ReLU. On the CIFAR-10 images at $(7.53, 10^{-5})$ it reaches 66.2% against 61.6%. Model size changes too. The noise vector has length about $\sigma C\sqrt{d}/B$, growing with the number of parameters d, while the clipped signal cannot exceed C. So the best private model is often smaller than the best non-private one, unless pretraining on public data has already done most of the work (Public data and private fine-tuning).

What the papers report. Larger models can still win when the other knobs scale with them. De, Berrada, Hayes, Smith & Balle (2022) train a 40-layer wide residual network from scratch on CIFAR-10 to 81.4% test accuracy at $(8, 10^{-5})$, with very large batches and small clipping norms, the two practices that Section 39.4 and Section 39.5 explain, among several others. These numbers come from the papers, not from this chapter's script.

39.8.5. Example: what $\varepsilon = 6.71$ buys

Part 4 asked how private the configuration $q = 0.01$, $\sigma = 1$, $T = 10{,}000$ is, and answered $\varepsilon = 6.71$. This chapter adds the other half: on this task it costs 0.4 points of accuracy, 0.9589 against 0.9627. To halve ε to about 3 you would need σ between 1.36 and 2.28 and accept about one more point of loss; to reach $\varepsilon = 1$, four points. Choosing ε asks which of these trades is worth making, and Auditing checks whether the trained model is as private as the accountant says.

39.8.6. Check yourself

- Why does the non-private baseline use 1,000 steps rather than 10,000? *(Its accuracy is the same, 0.9627 against 0.9617, and the shorter run is the fair comparison: it is the non-private model at its best, not one that was given more steps.)*
- The training curve at $\sigma = 4$ is flat after the first few hundred steps. Would more steps at the same σ help? *(They would add signal, but they would also raise ε. At a fixed budget, more steps require more noise per step, and the break-even calculation of the interpretation gets worse, not better.)*

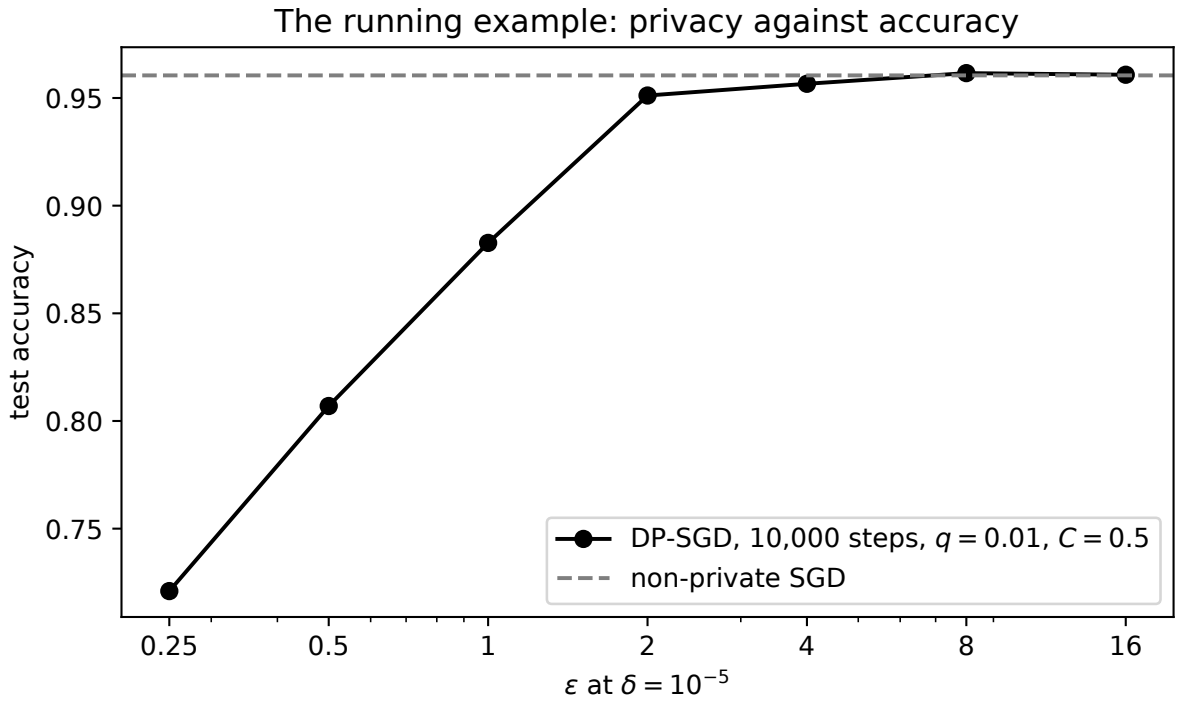

Figure 39.3.: Test accuracy of DP-SGD on the running example at $\delta = 10^{-5}$ against ε (log scale), with the non-private model dashed. Accuracy is close to non-private above $\varepsilon = 4$ and falls steeply below $\varepsilon = 1$.

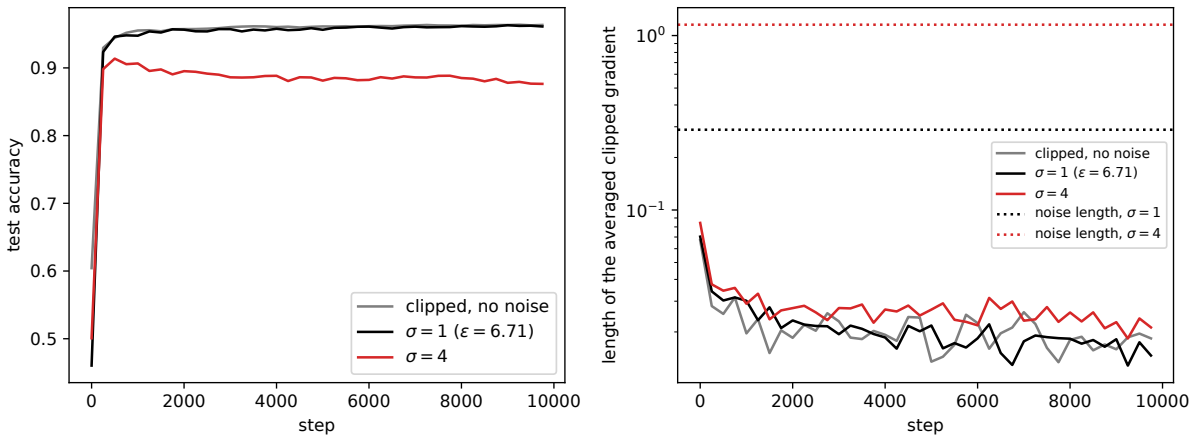

Figure 39.4.: Left: test accuracy during training with clipping alone, with $\sigma = 1$ ($\varepsilon = 6.71$) and with $\sigma = 4$. Right: the length of the averaged clipped gradient at each step (solid, log scale) against the length of the noise on it (dotted). The noise is about ten times longer than the signal at $\sigma = 1$, and about forty times at $\sigma = 4$.

39.9. Code: check every number by computation

The script code/dp_sgd.py implements the two-layer network, its per-example gradients by ghost norms, DP-SGD with Poisson sampling and optional microbatches, and the RDP accountant of Part 4, rewritten in a few dozen lines so the part stands on its own. From the repository root:

```
uv run python code/part05-dp-ml/dp_sgd.py
```

Later chapters import its model and accountant: `make_task()`, `train_dpsgd(rng, data, config)`, `accuracy`, `clipped_grad_sum`, `dpsgd_epsilon(q, sigma, steps, delta)` and `noise_multiplier_for(q, steps, eps, delta)`.

Output (seed 0), summarized in Table 39.8:

Table 39.8.: The script's output with the default seed.

Experiment	Result
Accountant, $q = 0.01$, $\sigma = 1$, 10,000 steps	$\varepsilon = 6.71$ at $\alpha = 4.1$, as in Part 4
Noise on the averaged gradient	0.005 per coordinate, length about 0.288; signal 0.015 to 0.027
Ghost norms	Agree with explicit gradients to 2.2×10^{-16}
Microbatches of 4 and 16	Noise 8 and 32 times larger; accuracy 0.9336 and 0.7459
Running example, $\varepsilon = 6.71$	0.9589 against 0.9627 non-private
Clipping sweep	With ηC fixed, 0.9599 to 0.9627 for $C \leq 0.3$
Batch sweep, $\varepsilon = 4$	Noise per averaged gradient falls 18.6 times from $B = 10$ to 1,000
Privacy against accuracy	From 0.8209 at $\varepsilon = 0.5$ to 0.9604 at $\varepsilon = 8$

tests/test_dp_sgd.py checks that the output still matches.

What to take from it. DP-SGD is short: sampling, clipping, a noisy sum and a step take about twenty lines, and the accountant a few dozen more. What takes care is everything around it, the conditions of Section 39.3 and the choice of knobs. On this task the clipping norm hardly matters once ηC is tuned, the batch size matters a little, and the noise multiplier, set by the budget, matters most.

39.11. Cheat sheet

n records, d parameters, clipping norm C, noise multiplier σ, sampling rate q, expected batch $B = qn$, T steps, learning rate η, add/remove neighbours. Table 39.9 collects the results.

Table 39.9.: Every result of the chapter.

Result	Formula	Conditions
Update	$\theta_{t+1} = \theta_t - \frac{\eta}{B}\big(\sum_{i\in S_t} g_i \min(1, \frac{C}{\|g_i\|}) + \mathcal{N}(0, \sigma^2 C^2 I)\big)$	Poisson batches, per-example clipping

Result	Formula	Conditions
Privacy	RDP $T\varepsilon_{q,\sigma}(\alpha)$, converted by Equation 39.2	Fixed C, public B, no batch statistics
Running example	$\varepsilon = 6.71$ at $\delta = 10^{-5}$	$q = 0.01$, $\sigma = 1$, $T = 10{,}000$
Expected update	$\frac{1}{n}\sum_i \min(1, C/\|g_i\|)g_i$	Divide by B, not $\|S_t\|$
Noise	$\sigma C/B$ per coordinate, length about $\sigma C\sqrt{d}/B$	—
Scale invariance	Depends on ηC only	Every gradient clipped
Batch size	$\sigma \propto \sqrt{q}$, noise $\propto 1/\sqrt{B}$	Fixed ε and epochs, small q, $\sigma \gtrsim 1$
Ghost norms	$\|v_i a_i^\top\|_F = \|v_i\|\|a_i\|$; sequences: $\langle AA^\top, VV^\top\rangle$	Dense layers
Microbatches of m	Sensitivity $2C$; noise per coordinate $2m\sigma C/B$ at the same ε	Groups fixed in advance, add/remove
Signal against noise	Signal overtakes noise after about (noise length/signal length)^2 steps	Signal roughly constant in direction

Rules of thumb

- Only σ, q and T set ε. C and η are free for accuracy.
- Clip small, tune ηC. Below the typical gradient norm, the clipping norm stops mattering.
- Prefer large batches at a fixed number of epochs; scale the learning rate up with them.
- Check the implementation against Section 39.3: Poisson sampling, per-example gradients, no batch statistics, a public denominator, a fixed C.
- Speed up per-example clipping by vectorizing or by ghost norms, not by microbatches, which multiply the noise by $2m$.
- Expect accuracy to be close to non-private at large ε and to collapse below some threshold; locate that threshold for your task before promising a budget.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

40. Hyperparameter tuning and private selection

40.1. Why this matters

The previous chapter proved a guarantee for one training run. Stochastic gradient descent (SGD) with per-example clipping and Gaussian noise, run once with a fixed learning rate, clipping norm, batch size and number of steps, satisfies differential privacy (DP) with the (ε, δ) that the accountant reports; this algorithm is DP-SGD. Nobody trains once. A practitioner tries a grid of learning rates, perhaps several clipping norms and architectures, scores each trained model on a validation set, and ships the best one. The validation set and the training set are private data, and every run touched them. **How much does the search leak, and how do you pay for it honestly?**

The question has a sharp answer, and it is not "nothing" and not always "the sum of all runs". Releasing the best of k private runs can cost exactly k times one run: there are mechanisms for which the best-of-k release is no better than releasing all k runs. That is what composition, the bound that adds up the costs of all runs in Rényi differential privacy (RDP), charges anyway, and for a grid of 10 DP-SGD runs of the running example it turns $\varepsilon = 6.71$ into 27.23. But a small change to the procedure changes the answer completely. If the *number* of runs is random, drawn from a suitable distribution before the search starts, the best-of release costs a constant factor (two or three times one run for pure DP) plus a term that grows only with the logarithm of the expected number of runs. For 10 runs in expectation, the cost falls from 27.23 to between 10.08 and 13.67 depending on the distribution, and for 1,000 runs from 1,035.93 to 13.46.

40.1.1. The one idea: the release is a function of every run, but a random number of runs hides which ones

The model you ship was chosen by comparing all the runs, so it is a function of all of them, and post-processing says its privacy is at most that of all the runs together. That is the composition bound. It can be tight because a fixed number of runs gives the adversary a sharp event to test for: "every one of the k runs came out badly", whose probability multiplies k per-run likelihood ratios together. A random number of runs blurs that event. If K is random, the adversary does not know how many runs failed, and the event "all runs failed" is mostly explained by "there were few runs" rather than by the data. The mathematics of this is the **generating function** $\mathbb{E}[x^K]$ of the number of runs, which turns "the best of K draws" into a formula, and the right choice of its distribution trades a slightly worse search for a much cheaper guarantee.

Table 40.1 lists the results and where each is used.

Table 40.1.: The results of this chapter and where each is used.

Result	Where it is used
The best of k private runs can cost k runs	Why tuning must be accounted for; the common reporting bug
Composition: k runs cost k times the RDP curve	The baseline; small grids
Random stopping: the best of a geometric number of runs is 3ε-DP	Pure-DP candidates; the idea behind everything that follows
Rényi bounds for a random number of runs (Poisson, truncated negative binomial)	Tuning DP-SGD with sublinear cost
Selecting by a noisy validation score	Choosing among fixed candidates; protecting the validation set
Tuning the running example, and what to report	Every private training project; Choosing ε and Auditing

Notation. One **run** is a randomized algorithm Q that trains a model on the private data with hyperparameters drawn from a fixed set of **candidates**, and outputs the model together with its **score**, a number used to rank runs, such as a validation accuracy. The outputs of Q are totally ordered by score, so "the best" is well defined. $Q(D)$ also denotes the distribution of one run's output on dataset D, and $D \sim D'$ are neighbours. K is the number of runs, fixed ($K = k$) or random, and $f(x) = \mathbb{E}[x^K]$ its generating function. The **best-of-K** algorithm M draws K, runs Q independently K times, and releases the best output. $\varepsilon(\alpha)$ is an RDP curve at order α (the papers this chapter follows write λ for the order), and ε_M the curve of M. The distribution of K has its own parameters. A Poisson number of runs is described by its mean $\mathbb{E}[K]$. A geometric number of runs stops after each run with a probability $\omega \in (0, 1)$, which is also a parameter of the truncated negative binomial distribution, and ν denotes the shape of that distribution. Papernot & Steinke write the Poisson mean μ, the stopping probability γ and the shape η. The running example is that of DP-SGD: a network with 3,329 parameters trained on $n = 10{,}000$ records, with a sampling rate q of 0.01, a clipping norm C of 0.5 and $\delta = 10^{-5}$.

How to read this chapter. The toolkit has the two facts every derivation uses, post-processing and the distribution of a maximum. Section 40.3 shows why tuning is not free, and Section 40.4 what the obvious fix costs. Section 40.5 is the key idea, in its simplest form, and Section 40.6 its version for DP-SGD; read the statements and the examples first, the derivations on a second pass. Section 40.7 covers the classical selection mechanisms, Section 40.8 runs everything on the running example, and Section 40.9 says what to do and what to report.

40.2. Toolkit: four facts every derivation uses

40.2.1. Fact 1 — RDP curves add, and convert to (ε, δ)

A mechanism M satisfies $(\alpha, \varepsilon(\alpha))$-**Rényi differential privacy** if, for all neighbours $D \sim D'$, the Rényi divergence of order $\alpha > 1$ between its output distributions is at most $\varepsilon(\alpha)$:

$$D_\alpha(M(D) \,\|\, M(D')) = \frac{1}{\alpha - 1} \ln \sum_y \Pr_D[y]^\alpha \Pr_{D'}[y]^{1-\alpha} \le \varepsilon(\alpha), \tag{40.1}$$

where $\Pr_D[y]$ is the probability that $M(D)$ outputs y. The sum is the average of the likelihood ratio $\Pr_D[y]/\Pr_{D'}[y]$ raised to the power $\alpha - 1$, averaged over outputs drawn from D; large orders weight the rare, large ratios more. As $\alpha \to \infty$ the divergence becomes the largest log ratio, so pure ε-DP is the point $\alpha = \infty$. Three properties are used here (Rényi differential privacy). Running mechanisms in sequence, even adaptively, adds their curves. The divergence grows with the order, so a bound at order α_2 also holds at every $\alpha_1 < \alpha_2$. And a curve converts to (ε, δ)-DP at the best order,

$$\varepsilon = \min_\alpha \Big[\varepsilon(\alpha) + \ln \frac{\alpha - 1}{\alpha} - \frac{\ln \delta + \ln \alpha}{\alpha - 1} \Big], \tag{40.2}$$

or, read the other way, $(\alpha, \varepsilon(\alpha))$-RDP gives $(\hat{\varepsilon}, \hat{\delta})$-DP for every $\hat{\varepsilon}$ with $\hat{\delta} = e^{(\alpha-1)(\varepsilon(\alpha)-\hat{\varepsilon})}(1 - 1/\alpha)^{\alpha-1}/\alpha$ (From RDP to (ε, δ)). DP-SGD with $q = 0.01$, $\sigma = 1$ and 10,000 steps has $\varepsilon = 6.71$ at $\delta = 10^{-5}$ by this conversion.

40.2.2. Fact 2 — Post-processing, and why "the best" is a post-processing of all runs

A computation that uses only a private output, and not the data, is as private as that output (Post-processing, group privacy and composition). The best of k runs is computed from the k outputs alone: compare their scores and keep the winner. So the best-of-k release is a post-processing of the k runs, and it is at least as private as releasing all of them, which by composition costs k times one run. The question of this chapter is whether it can be *more* private than that. Post-processing never makes things worse, but it does not promise to make them better.

40.2.3. Fact 3 — The best of K draws, and the generating function

Draw an output Y from a distribution Q on outcomes ordered from best to worst. The best of k independent draws is no better than y exactly when every draw is no better than y, so

$$\Pr[\text{best of } k \preceq y] = Q(\preceq y)^k, \tag{40.3}$$

where $Q(\preceq y)$ is the probability that one draw is no better than y and $Q(\prec y)$ the probability that it is strictly worse. The best is exactly y when all draws are no better than y but not all are strictly worse: $Q(\preceq y)^k - Q(\prec y)^k$. Now let the number of draws K be random, independent of the draws. Averaging over K replaces x^k by $\mathbb{E}[x^K]$, which is the **generating function** of K, written $f(x) = \sum_k \Pr[K = k]\, x^k$. So

$$\Pr[M = y] = f(Q(\preceq y)) - f(Q(\prec y)). \tag{40.4}$$

A fixed $K = k$ has $f(x) = x^k$; a Poisson number of runs with mean $\mathbb{E}[K]$ has $f(x) = e^{\mathbb{E}[K](x-1)}$; a geometric number on $\{1, 2, \dots\}$, $\Pr[K = k] = \omega(1-\omega)^{k-1}$, has $f(x) = \omega x/(1-(1-\omega)x)$, by summing the geometric series.

A die. The best of two rolls of a fair die is a 6 unless both rolls are below 6: $1-(5/6)^2 = 11/36 = 0.3056$. In the form of Equation 40.4 with outcome $y = 6$ the best, $Q(\preceq 6) = 1$ and $Q(\prec 6) = 5/6$, so $P = 1^2 - (5/6)^2$. If instead you roll once or twice with probability $\frac{1}{2}$ each, $f(x) = \frac{1}{2}x + \frac{1}{2}x^2$ and $\Pr[\text{best} = 6] = f(1) - f(5/6) = 1 - \frac{1}{2}\cdot\frac{5}{6} - \frac{1}{2}\cdot\frac{25}{36} = 17/72 = 0.2361$, the average of the one-roll answer $1/6$ and the two-roll answer $11/36$.

40.2.4. Fact 4 — Disjoint parts of the data cost the larger of their costs

Suppose a dataset is split into two disjoint parts, a training set and a validation set, and each record lives in exactly one of them. An algorithm that is ε_1-DP in the training records (with the validation set fixed) and ε_2-DP in the validation records (with the training set fixed) is $\max(\varepsilon_1, \varepsilon_2)$-DP for neighbours that add or remove one record anywhere, because a pair of neighbours differs in one record, which sits in one part only. The same holds order by order for RDP curves: the curve is the pointwise maximum. This is the idea of **parallel composition**, and it is why a held-out validation set does not add its cost to training's cost: it adds its own cost only where it is larger.

40.3. Best of k is k times worse

40.3.1. Context

The intuitive argument for ignoring tuning goes: the release is one model, chosen among a handful by one comparison, and a choice among eight learning rates carries at most three bits. That argument is wrong in two ways. The released model is not the choice; it is a whole private run, picked *because* of how it came out. And the comparison is a function of every run. How bad can it be?

40.3.2. Statement

Let one run be **randomized response** on two outcomes, "good" and "bad" (best first). On D the run comes out good with probability $\frac{1}{1+e^\varepsilon}$, and on its neighbour D' with probability $\frac{e^\varepsilon}{1+e^\varepsilon}$. One run is exactly ε-DP. Releasing the best of k runs is exactly $k\varepsilon$-DP:

$$\frac{\Pr_D[\text{best of } k \text{ is bad}]}{\Pr_{D'}[\text{best of } k \text{ is bad}]} = \frac{\left(e^\varepsilon/(1+e^\varepsilon)\right)^k}{\left(1/(1+e^\varepsilon)\right)^k} = e^{k\varepsilon}. \tag{40.5}$$

In RDP, Papernot & Steinke (2022, Proposition 17) show that the same release has $D_\alpha \geq k\varepsilon - k\ln(1+e^{-\varepsilon})/(\alpha-1)$, so at large orders it also costs about k times one run.

40.3.3. Derivation

1. **Best of k is bad only if every run is bad.** By Fact 3 with outcome "bad" the worst, $\Pr[\text{best is bad}] = Q(\text{bad})^k$.
2. **Each run's ratio is e^ε.** $Q_D(\text{bad}) = e^\varepsilon/(1+e^\varepsilon)$ and $Q_{D'}(\text{bad}) = 1/(1+e^\varepsilon)$, a ratio of e^ε.
3. **The k ratios multiply.** Raising both to the power k gives Equation 40.5. The other outcome, "good", has the ratio $(1-Q_D(\text{bad})^k)/(1-Q_{D'}(\text{bad})^k)$, which is between $e^{-\varepsilon}$ and 1, so the largest log ratio over outcomes is $k\varepsilon$.
4. **The Rényi version.** Keep only the "bad" term in the sum of Fact 1: $e^{(\alpha-1)D_\alpha} \geq \Pr_D[\text{bad}]^\alpha \Pr_{D'}[\text{bad}]^{1-\alpha} = e^{k\varepsilon\alpha}(1+e^\varepsilon)^{-k}$, which is $(e^{k\varepsilon})^\alpha$ times $\Pr_{D'}[\text{bad}]$. Taking logarithms and dividing by $\alpha-1$ gives $D_\alpha \geq (k\varepsilon\alpha - k\ln(1+e^\varepsilon))/(\alpha-1) = k\varepsilon - k\ln(1+e^{-\varepsilon})/(\alpha-1)$, using $\ln(1+e^\varepsilon) = \varepsilon + \ln(1+e^{-\varepsilon})$.

40.3.4. Interpretation

Where the loss comes from. The whole loss sits on one event: every run failed. Its probability is small on both datasets, but its ratio is the product of k per-run ratios, because the runs are independent and the event requires all of them. Figure 40.1 (right) shows the privacy loss distribution for $\varepsilon = 1$: one run has losses ± 1; the best of 10 has a loss of -0.0446 with probability 0.9564 and a loss of 10 with probability 0.0436. A test that looks for "the released model is bad" detects membership with a likelihood ratio of e^{10} whenever it fires.

This is not an artefact of a contrived mechanism. A DP-SGD run that sometimes diverges, a learning rate that sometimes produces a useless model, a candidate that rarely clears a threshold: each is a run with a "bad" outcome whose probability depends a little on the data. Best-of-k multiplies those small dependences. The example is extreme because it puts all of each run's privacy loss on a single binary outcome. A particular DP-SGD search may leak much less, but no analysis that knows only each run's guarantee can promise it, so the general bound for a fixed k is composition, which grows linearly (Section 40.4).

The bound for a fixed k is tight, so the procedure must change. Composition says best-of-k costs at most $k\varepsilon$, and Equation 40.5 says some mechanism attains it. No better analysis of "the best of exactly k runs" exists for all mechanisms. A better guarantee needs a different procedure, and the next sections change one thing: the number of runs.

Non-private tuning leaks too. If you tune without any noise and then train privately once with the chosen hyperparameters, the hyperparameters are a non-private function of the data, and the final run's ε does not cover them. Papernot & Steinke (2022, Section 2) build a support vector machine whose best regularization weight changes when a few outliers are added, so the chosen value reveals whether the outliers were in the training set, a membership inference through a single number.

40.3.5. Example: the numbers for $\varepsilon = 1$

With $\varepsilon = 1$ a run is good with probability 0.2689 on D and 0.7311 on D'. The script computes the best-of-k distributions exactly. The largest log ratio is 2.0000 for $k = 2$, 3.0000 for $k = 3$ and 10.0000 for $k = 10$, exactly $k\varepsilon$. At order $\alpha = 2$, the Rényi divergence of the best of 10 is 6.8683, between the lower bound of step 4, 6.8674, and composition's upper bound, ten times one run's

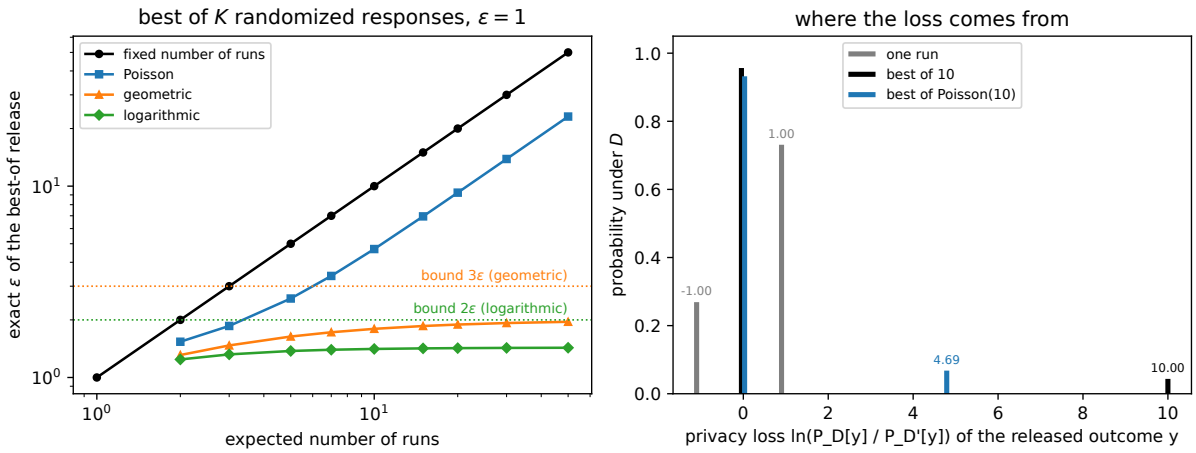

Figure 40.1.: Left: the exact ε of releasing the best of K randomized-response runs, each 1-DP, against the expected number of runs, for a fixed number of runs, a Poisson, a geometric and a logarithmic number. A fixed number grows linearly; the geometric and logarithmic numbers stay below their bounds 3ε and 2ε. Right: the privacy loss of the released outcome under D for one run, the best of 10 runs and the best of a Poisson number with mean 10; the best of 10 puts a loss of 10 on an event of probability 0.0436.

0.7353, which is 7.3533. Composition overstates the exact value by 7%; at order 2 it is nearly tight, as at order ∞.

40.3.6. Check yourself

- Releasing only the index of the best run, not the trained model, would it fix Equation 40.5? *(No. In the example the output is "good" or "bad", and the index of the best run carries the same event: if all runs are bad, every index is a bad run, and the chosen one reveals it. What matters is that the release depends on every run.)*
- Suppose each run is ε-DP and you release the best of k runs together with all k scores. What is the cost? *(At most $k\varepsilon$ by composition, the same as the best alone in the worst case; releasing more does not cost more here because the best of k already attains the bound.)*

40.4. Paying by composition

40.4.1. Context

The safe answer is to charge for every run. What does it cost on the running example, and how much more noise does each run need to keep the total fixed?

40.4.2. Statement

If each of k runs has RDP curve $\varepsilon(\alpha)$, releasing anything computed from all of them, in particular the best, has curve at most

$$\varepsilon_M(\alpha) \le k\,\varepsilon(\alpha), \tag{40.6}$$

converted to (ε, δ) by Equation 40.2. For DP-SGD, k runs of T steps at noise multiplier σ cost the same as one run of kT steps, so keeping the total at a target ε means choosing σ for kT steps.

40.4.3. Derivation

1. **The release is a post-processing of the k runs** (Fact 2).
2. **The k runs compose.** Each run uses fresh randomness, and RDP curves add (Fact 1), so their joint output has curve $k\varepsilon(\alpha)$. This holds even if the candidates are chosen adaptively, each after seeing the earlier results, since RDP composition covers adaptive sequences.
3. **DP-SGD.** One run of T steps has curve $T\varepsilon_{q,\sigma}(\alpha)$, where $\varepsilon_{q,\sigma}$ is one subsampled Gaussian step. k runs give $kT\varepsilon_{q,\sigma}(\alpha)$, the curve of one run of kT steps.

40.4.4. Interpretation

Composition is cheaper than $k\varepsilon$, but still grows like k. In (ε, δ) terms, k runs cost less than k times one run's ε, because the conversion of Equation 40.2 pays its $\ln(1/\delta)$ term once, and because adding curves behaves like advanced composition, roughly $\sqrt{k}$ at small ε. On the running example, Table 40.2, 10 runs cost 4.06 times one run, not 10. But the curve grows linearly, and so does ε once the budget is large: from 30 to 100 runs, ε grows by a factor 2.5.

Raising the noise is the honest way to keep the budget. To keep the total at $\varepsilon = 6.71$, each of 10 runs needs $\sigma = 2.45$ instead of 1. DP-SGD showed what that costs on this task: more noise per step means fewer useful steps, and accuracy falls steeply below some budget.

When composition is the right tool. For a handful of candidates, two or three, composition costs little more than the alternatives below and needs no change to the procedure. Figure 40.2 shows that the random-K methods only pull away from composition from a few runs on.

40.4.5. Example: the running example's grid

Table 40.2 takes the running example, $q = 0.01$, $\sigma = 1$, 10,000 steps, one run $\varepsilon = 6.71$ at $\delta = 10^{-5}$, and composes k runs. The values for 10 and 100 runs are those Choosing an accountant reported.

Table 40.2.: Composition of k DP-SGD runs of the running example, at $\delta = 10^{-5}$.

Runs k	1	3	10	30	100
ε of k runs at $\sigma = 1$	6.71	12.73	27.23	58.25	145.17
Ratio to one run	1.00	1.90	4.06	8.68	21.63

Runs k	1	3	10	30	100
σ per run for a total of 6.71	1	1.46	2.45	4.12	7.44

40.4.6. Check yourself

- Why does k runs of T steps cost exactly as much as one run of kT steps, if the runs start from different initializations? *(The accountant does not look at the parameters. Each step costs $\varepsilon_{q,\sigma}(\alpha)$ whatever it is applied to, and curves add.)*
- Your team ran 30 configurations, each at $\varepsilon = 6.71$, and reports 6.71. What does composition say the release costs? *(58.25. The best-of release can be at most that; Section 40.3 shows that without more structure no smaller number is guaranteed.)*

40.5. Random stopping: the best of a geometric number of runs

40.5.1. Context

Liu & Talwar (2019) asked whether the best of many ε-DP runs can cost a constant multiple of ε, independent of how many runs are made. They found that it can, with one change: after each run, flip a coin and stop with probability ω. The number of runs is then geometric with mean $1/\omega$, and releasing the best run seen is 3ε-DP whatever ω is.

40.5.2. Statement

Algorithm (random stopping). Repeat: run Q on the data and keep its output; with probability ω, stop and release the best output kept so far.

If Q is ε-DP, the release is 3ε-DP (Liu & Talwar 2019, Theorem 3.2). Its output distribution is explicit: for an outcome y with probability p under one run, $p_>$ the probability that one run is strictly better than y and $p_\geq = p_> + p$ the probability that it is at least as good,

$$\Pr[M = y] = \frac{\omega\, p}{(\omega + (1-\omega)p_>)(\omega + (1-\omega)p_\geq)}. \tag{40.7}$$

Its utility: for any fraction π, the release falls below the top π-quantile of one run's score with probability

$$\Pr[\text{miss}] = \frac{\omega(1-\pi)}{\omega + (1-\omega)\pi} \leq \frac{\omega}{\pi}. \tag{40.8}$$

40.5.3. Derivation

The idea: the probability of each output is a ratio built from three probabilities of one run, p, $p_>$ and $p_\geq$. Each moves by at most e^ε between neighbours, and the parameter ω enters in a way that cannot amplify those moves.

1. **The number of runs.** The algorithm stops after run j with probability $\omega(1-\omega)^{j-1}$: it continued $j-1$ times and stopped once. So K is geometric with mean $1/\omega$ and generating function $f(x) = \omega x/(1-(1-\omega)x)$ (Fact 3).
2. **Apply Equation 40.4.** One run is no better than y with probability $1-p_>$ and strictly worse with probability $1-p_\geq$. So $\Pr[M=y] = f(1-p_>) - f(1-p_\geq)$. Since $1-(1-\omega)(1-p_>) = \omega + (1-\omega)p_>$, this is
$$\frac{\omega(1-p_>)}{\omega+(1-\omega)p_>} - \frac{\omega(1-p_\geq)}{\omega+(1-\omega)p_\geq}. \tag{40.9}$$
3. **Simplify.** Over the common denominator, the numerator is ω times $(1-p_>)(\omega+(1-\omega)p_\geq) - (1-p_\geq)(\omega+(1-\omega)p_>)$. Expanding, the terms with ω give $\omega(p_\geq - p_>) = \omega p$, and the terms with $1-\omega$ give $(1-\omega)(p_\geq - p_>p_\geq - p_> + p_\geq p_>) = (1-\omega)p$. Their sum is p, which gives Equation 40.7.
4. **Bound each factor.** Write primes for the same quantities on D'. Each of p, $p_>$ and $p_\geq$ is the probability of an event about one run's output, so ε-DP of Q gives $p \leq e^\varepsilon p'$, $p'_> \leq e^\varepsilon p_>$ and $p'_\geq \leq e^\varepsilon p_\geq$. The first bounds the numerator ratio. For the denominators, $\omega + (1-\omega)p'_> \leq e^\varepsilon(\omega + (1-\omega)p_>)$, because $\omega \leq e^\varepsilon\omega$ and $p'_> \leq e^\varepsilon p_>$; the same for $p_\geq$.
5. **Multiply.** $\Pr[M(D)=y]/\Pr[M(D')=y] = \frac{p}{p'} \cdot \frac{\omega+(1-\omega)p'_>}{\omega+(1-\omega)p_>} \cdot \frac{\omega+(1-\omega)p'_\geq}{\omega+(1-\omega)p_\geq} \leq e^{3\varepsilon}$. This holds for every outcome, so the release is 3ε-DP.
6. **Utility.** The release is below the top π-quantile only if every run is: $\sum_j \omega(1-\omega)^{j-1}(1-\pi)^j = \omega(1-\pi)/(1-(1-\omega)(1-\pi))$, by the geometric series, which is the equality in Equation 40.8. It is at most ω/π because $\pi(1-\pi) \leq \omega(1-\pi) + \pi$.

40.5.4. Interpretation

Why the fixed-k disaster disappears. In Equation 40.4 with $f(x) = x^k$, the ratio for the worst outcome is $(Q(\preceq y)/Q'(\preceq y))^k$, a k-th power. The geometric generating function is a ratio of linear functions of x, so the ratio of outputs is a product of three ratios of linear functions, each moved by at most e^ε. The event "every run was bad" is now mostly the event "the coin stopped early", which does not depend on the data.

The 3 is real. The bound is attained in the limit. Take three outcomes, best first, with probabilities $(a, b, 1-a-b)$ on D and $(ae^\varepsilon, be^{-\varepsilon}, \dots)$ on D', with $\omega \ll b \ll a$ small. For the middle outcome, the numerator ratio $p/p' = e^\varepsilon$ and, since ω is negligible next to $p_>$ and $p_\geq \approx p_>$, both denominator ratios approach e^ε. The example below computes it.

Two outcomes give only 2ε. On randomized response, the "good" outcome has $p_> = 0$, so one denominator factor is ω on both datasets, and only two factors can move. Figure 40.1 (left) shows the exact ε of geometric stopping on randomized response rising toward 2ε as the mean number of runs grows.

The utility guarantee is about quantiles, and it costs runs. Equation 40.8 does not promise the best candidate. It promises that, with probability at least $1-\omega/\pi$, the release is at

least as good as the top π fraction of a single run's outcomes. To find a candidate in the top $1/m$ of a grid of m with probability 0.9, you need $\omega/\pi \leq 0.1$, so $\omega = 0.1/m$, a mean of $10m$ runs, ten times the grid. The exact miss probability is smaller than the bound, but not by much when π is small. This is the price of the method: you buy a constant privacy cost with extra runs, and the geometric distribution often stops after one or two.

Approximate DP and threshold variants. Liu & Talwar also give a version with a known score threshold, which stops as soon as a run clears it and costs 2ε plus a small term (their Theorem 3.1), and versions for (ε, δ)-DP runs and with a hard cap on the number of runs (Theorems 3.4 and 3.5). For DP-SGD, which is analysed in RDP, Section 40.6 is the version to use.

40.5.5. Example: a 3ε pair, and the utility of stopping

On randomized response with $\varepsilon = 1$, geometric stopping gives an exact ε of 1.3106 at $\omega = 0.5$, 1.7957 at $\omega = 0.1$, 1.9769 at $\omega = 0.01$ and 1.9977 at $\omega = 0.001$, approaching 2. On the three-outcome pair, with $\varepsilon = 1$ for one run, Table 40.3 shows the exact ε of the release approaching 3, and the logarithmic distribution of Section 40.6 approaching 2.

Table 40.3.: Exact ε of the best-of release on a three-outcome mechanism that is exactly 1-DP, computed from Equation 40.4. The middle outcome attains the maximum, and Equation 40.7 gives the same value.

a	b	ω	Geometric stopping	Logarithmic number, same ω
0.01	0.001	0.1	1.2598	1.1299
0.01	0.0001	0.01	2.2316	1.6158
0.01	10^{-6}	10^{-4}	2.9874	1.9937
0.001	10^{-9}	10^{-6}	2.9987	1.9994

For utility, suppose a grid of 8 candidates with one best. With $\omega = 1/8$, a mean of 8 runs, the chance of never trying the top eighth is 0.4667, and the bound $\omega/\pi = 1$ says nothing. With $\omega = 1/80$, a mean of 80 runs, the chance falls to 0.0805 against a bound of 0.1. To have the same chance of hitting a top 1/80 fraction you would again need ten times more runs: with $\omega = 1/80$ the miss probability for $\pi = 1/80$ is 0.4969.

40.5.6. Check yourself

- In step 4, why does $\omega \leq e^{\varepsilon}\omega$ matter? *(The denominator is a mixture of the constant ω, which does not depend on the data, and $p_>$, which does. Each part grows by at most e^{ε}, so the sum does. The constant part is what blurs the "all runs failed" event.)*
- If you wanted to run exactly 8 candidates, could you emulate it by setting $\omega = 1/8$? *(Only in mean. The geometric distribution stops after one run with probability 1/8 and after more than 16 runs with probability $(7/8)^{16} = 0.118$; Figure 40.3 shows how spread out it is. That spread is what buys the privacy.)*

40.6. Rényi bounds for a random number of runs

40.6.1. Context

DP-SGD is not usefully ε-DP for any small ε; its guarantee is an RDP curve that converts to (ε, δ). Papernot & Steinke (2022) extended random stopping to RDP and to a family of distributions for K, which lets you choose between more runs and less privacy cost. What do their bounds say, and what do they cost on the running example?

40.6.2. Statement

The generic bound (Papernot & Steinke 2022, Lemma 7). Let K have generating function f, and let M release the best of K independent runs of Q (if $K = 0$, an output that does not depend on the data). For neighbours with run distributions Q, Q' and best-of distributions M, M',

$$D_\alpha(M\|M') \le D_\alpha(Q\|Q') + \frac{1}{\alpha-1}\ln\Big[f'(s)^\alpha f'(s')^{1-\alpha}\Big] \tag{40.10}$$

for some numbers $s, s' \in [0,1]$ that are the probabilities of one and the same randomized test accepting a run's output, on D and on D'.

Poisson (Theorem 6). If K is Poisson with mean $\mathbb{E}[K]$, and Q is $(\alpha, \varepsilon(\alpha))$-RDP and $(\hat\varepsilon, \hat\delta)$-DP with $e^{\hat\varepsilon} \le 1 + \frac{1}{\alpha-1}$, then

$$\varepsilon_M(\alpha) \le \varepsilon(\alpha) + \mathbb{E}[K]\hat\delta + \frac{\ln \mathbb{E}[K]}{\alpha-1}. \tag{40.11}$$

Truncated negative binomial (Theorem 2). For $\nu > -1$ and $\omega \in (0,1)$, let K on $\{1, 2, \dots\}$ have $\Pr[K=k] = \frac{(1-\omega)^k}{\omega^{-\nu}-1}\prod_{i=0}^{k-1}\frac{i+\nu}{i+1}$, and for $\nu = 0$ the **logarithmic distribution** $\Pr[K=k] = \frac{(1-\omega)^k}{k\ln(1/\omega)}$. The case $\nu = 1$ is the geometric distribution. If Q is $(\alpha, \varepsilon(\alpha))$-RDP and $(\hat\alpha, \varepsilon(\hat\alpha))$-RDP, then

$$\varepsilon_M(\alpha) \le \varepsilon(\alpha) + (1+\nu)\Big(1 - \frac{1}{\hat\alpha}\Big)\varepsilon(\hat\alpha) + \frac{(1+\nu)\ln(1/\omega)}{\hat\alpha} + \frac{\ln \mathbb{E}[K]}{\alpha-1}, \tag{40.12}$$

for every $\hat\alpha \ge 1$, with $\mathbb{E}[K] = \frac{\nu(1-\omega)}{\omega(1-\omega^\nu)}$ $(\nu \ne 0)$ or $\frac{1/\omega - 1}{\ln(1/\omega)}$ $(\nu = 0)$. For an ε-DP run, letting both orders go to infinity gives $(2+\nu)\varepsilon$-DP (their Corollary 3): 3ε for the geometric distribution, as in Section 40.5, and 2ε for the logarithmic.

40.6.3. Derivation

The generic bound comes from writing the best-of distribution of Fact 3 as a derivative, then pulling the derivative out of the Rényi sum. The Poisson bound then follows in a few lines. Take outputs finite and $\Pr[K=0] = 0$ for simplicity (the paper handles the general case).

1. **The best-of probability is an average of f'.** By Equation 40.4 and the fundamental theorem of calculus, $M(y) = f(Q(\preceq y)) - f(Q(\prec y)) = \int_{Q(\prec y)}^{Q(\preceq y)} f'(x)\,\mathrm{d}x$. The interval has length $Q(y)$, so $M(y) = Q(y)\,c(y)$, where $c(y)$ is the average of f' over that interval, the expectation of $f'(X)$ for X uniform on it. Likewise $M'(y) = Q'(y)\,c'(y)$.
2. **Put it in the Rényi sum.** $e^{(\alpha-1)D_\alpha(M\|M')} = \sum_y A(y)^\alpha M'(y)^{1-\alpha} = \sum_y Q(y)^\alpha Q'(y)^{1-\alpha}\,c(y)^\alpha c'(y)^{1-\alpha}$.

3. **Bound the averages by a worst case.** Couple X and X' at the same relative position $t \in [0,1]$ in their intervals. The function $(u,v) \mapsto u^\alpha v^{1-\alpha}$ is jointly convex for $\alpha > 1$, so by Jensen's inequality $c(y)^\alpha c'(y)^{1-\alpha} \le \mathbb{E}[f'(X)^\alpha f'(X')^{1-\alpha}]$, which is at most the largest value of $f'(s)^\alpha f'(s')^{1-\alpha}$ over t, with $s = Q(\prec y) + tQ(y)$ and $s' = Q'(\prec y) + tQ'(y)$.
4. **Pull the worst case out of the sum.** Bounding every $c^\alpha c'^{1-\alpha}$ by the largest one over y and t leaves $\sum_y Q(y)^\alpha Q'(y)^{1-\alpha} = e^{(\alpha-1)D_\alpha(Q\|Q')}$ times that maximum. Taking logarithms and dividing by $\alpha - 1$ gives Equation 40.10.
5. **s and s' come from one test.** The test "accept an output worse than y; accept y itself with probability t; reject anything better" accepts with probability s on Q and s' on Q'. Any privacy guarantee of Q therefore constrains the pair, by post-processing (Fact 2).
6. **Poisson: compute f'.** $f(x) = e^{\mathbb{E}[K](x-1)}$, so $f'(x) = \mathbb{E}[K]e^{\mathbb{E}[K](x-1)}$ and $\ln[f'(s)^\alpha f'(s')^{1-\alpha}] = \ln \mathbb{E}[K] + \mathbb{E}[K]\big[\alpha(s-1) + (1-\alpha)(s'-1)\big] = \ln \mathbb{E}[K] + \mathbb{E}[K]\big[(\alpha-1)(1-s') - \alpha(1-s)\big]$.
7. **Use $(\hat\varepsilon, \hat\delta)$-DP on the rejection event.** $1 - s'$ and $1 - s$ are the probabilities that the test of step 5 rejects, on D' and D, so $1 - s' \le e^{\hat\varepsilon}(1-s) + \hat\delta$. The bracket is at most $(1-s)\big[(\alpha-1)e^{\hat\varepsilon} - \alpha\big] + (\alpha-1)\hat\delta$.
8. **The condition on $\hat\varepsilon$ kills the first term.** $e^{\hat\varepsilon} \le 1 + \frac{1}{\alpha-1}$ is the same as $(\alpha-1)e^{\hat\varepsilon} \le \alpha$, so the first term is not positive and the bracket is at most $(\alpha-1)\hat\delta$. Divide by $\alpha - 1$ and add $D_\alpha(Q\|Q') \le \varepsilon(\alpha)$: that is Equation 40.11.
9. **Truncated negative binomial.** Here $f'(x) = \omega^{\nu+1}\mathbb{E}[K]\,(1-(1-\omega)x)^{-\nu-1}$. The same steps apply, except that step 7 bounds the probabilities $1 - s$ and $1 - s'$ through the run's RDP guarantee at a second order $\hat\alpha$, again by post-processing, which gives Equation 40.12; Papernot & Steinke (2022, Appendix B.2) carry out the algebra, and Section M.3 in the appendices does it step by step, with their Corollaries 3 and 4.

40.6.4. Interpretation

What each term pays for. In Equation 40.11 and Equation 40.12 the first term, $\varepsilon(\alpha)$, is one run: you never pay less than one run, since the release contains a run. The last term, $\ln \mathbb{E}[K]/(\alpha-1)$, is the price of the number of runs, and it is logarithmic: multiplying the expected number of runs by 10 adds $\ln 10/(\alpha-1)$. The middle terms are the price of the tail of K: how much the distribution of K lets the adversary tell "many runs, all bad" from "few runs". For the truncated negative binomial it is a constant times the run's own privacy at another order, so the total is a constant multiple of one run plus the logarithm. For the Poisson distribution it is $\mathbb{E}[K]\hat\delta$, which is linear in $\mathbb{E}[K]$ but multiplied by the run's $\hat\delta$ at a small $\hat\varepsilon$, and so is small only when one run is very private.

Choosing ν: privacy against the shape of K. Smaller ν means a smaller multiple, $(1+\nu)$, of the second term, so better privacy; the logarithmic distribution ($\nu = 0$) is the best of the family that keeps $K \ge 1$ with a finite mean. But smaller ν also means a more skewed distribution of K. With mean 10, the logarithmic distribution has $\omega = 0.02692$ and stops after a single run with probability 0.2692, against 0.1000 for the geometric ($\nu = 1$) and 0.1562 for $\nu = 0.5$. The Poisson distribution is the limit $\nu \to \infty$ at a fixed mean, and is concentrated near its mean: with mean 10, $\Pr[K \le 1] = 4.99 \times 10^{-4}$. Figure 40.3 shows the four distributions with mean 8. A skewed K often runs few candidates, which Section 40.8 shows costs accuracy.

How tight are the bounds? They are upper bounds for every run with the given curve, so they can be loose for a particular one. On randomized response with $\varepsilon = 0.5$ and a logarithmic

number of runs with mean 10, Table 40.4 compares the exact Rényi divergence of the release with Equation 40.12 and with composition of 10 runs. Randomized response is pure DP, so the bound keeps falling as $\hat{\alpha}$ grows, and the table gives its limit, in which the two middle terms become $(1+\nu)\varepsilon = 0.5$. At order 2, Equation 40.12 is worse than composition, because its constant terms dominate at small orders. At orders 5 and 20, where conversions to (ε, δ) usually land, it is 2.6 and 4.3 times below composition, and 3.7 and 1.7 times above the exact value.

Table 40.4.: Randomized response with $\varepsilon = 0.5$, best of a logarithmic number of runs with mean 10: the exact Rényi divergence against the bound and against composition.

Order α	Exact D_α	Bound Equation 40.12	Composition of 10 runs
2	0.1438	3.0299	2.2734
5	0.3912	1.4599	3.8424
20	0.6379	1.0962	4.7505

For the Poisson bound on the same mechanism with mean 10, randomized response is $\hat{\delta} = 0$ at $\hat{\varepsilon} = 0.5$, so Equation 40.11 applies at the order where $e^{0.5} = 1 + 1/(\alpha - 1)$, $\alpha = 2.5415$. There the exact divergence is 0.4421, the bound 1.7654 and composition 2.7165.

What the theorems do not cover. Each run must draw its candidate independently from a fixed distribution, typically uniform on the grid: this is random search. Adaptive methods that pick the next candidate from the scores so far, such as Bayesian optimization, are not covered and need adaptive composition (Adaptive composition). The score must be part of each run's private output: if it is computed on private validation data, it must be private too (Section 40.7). And for zero-concentrated DP runs, whose curve is a line $\varepsilon(\alpha) = \rho\alpha$, the paper's Corollary 4 gives the closed form $\varepsilon_M(\alpha) \le 2\sqrt{\rho \ln \mathbb{E}[K]} + 2(1+\nu)\sqrt{\rho \ln(1/\omega)} - \nu\rho$ for orders up to $1 + \sqrt{\ln \mathbb{E}[K]/\rho}$, when $\rho \le \ln(1/\omega)$: the overhead grows like the square root of the logarithm of the expected number of runs.

40.6.5. Example: the running example

The script evaluates Equation 40.11 and Equation 40.12 on the RDP curve of one DP-SGD run of the running example, at every order of the accountant, takes the best $\hat{\alpha}$ for Equation 40.12 and, for Equation 40.11, the best $\hat{\delta}$ that the curve gives at $\hat{\varepsilon} = \ln(1 + 1/(\alpha - 1))$ by the conversion of Fact 1, uses that a bound at a larger order holds at a smaller one, and converts with Equation 40.2. Table 40.5 and Figure 40.2 show the result.

Table 40.5.: The ε at $\delta = 10^{-5}$ of tuning with DP-SGD runs of the running example (one run: $\varepsilon = 6.71$), by the number of runs and how it is chosen.

Expected runs	3	10	30	100	1,000
Composition	12.73	27.23	58.25	145.17	1035.93
Poisson	8.93	13.67	26.43	67.77	302.57
Geometric ($\nu = 1$)	9.22	11.31	12.85	14.32	16.76
$\nu = 0.5$	9.03	10.75	11.98	13.15	15.09

Expected runs	3	10	30	100	1,000
Logarithmic ($\nu = 0$)	8.75	10.08	11.04	11.95	13.46

For 10 runs in expectation, the logarithmic distribution costs 10.08, 1.5 times one run, against 27.23 for composition. From 10 to 1,000 runs it adds only 3.38 more. The Poisson bound starts well, 8.93 for 3 runs, but grows nearly linearly, because one run at $\varepsilon = 6.71$ is far from private enough to make $\mathbb{E}[K]\hat{\delta}$ small: at the orders the conversion uses, $\hat{\varepsilon}$ must be small and the run's $\hat{\delta}$ there is not. At a smaller per-run budget the Poisson bound does much better, as the experiment of Section 40.8 shows.

40.6.6. Check yourself

- In Equation 40.12, why can't the cost fall below one run, $\varepsilon(\alpha)$, however few runs are expected? *(The release is the output of one run. If $K = 1$ it is exactly one run, so no bound can be below one run's divergence.)*
- The Poisson distribution has $\Pr[K = 0] = e^{-\mathbb{E}[K]}$. What must the algorithm release then, and why does it not matter much? *(Something that does not depend on the data, such as the untrained initialization. With $\mathbb{E}[K] = 8$ this happens with probability 3.35×10^{-4}.)*

40.7. Selecting by a noisy validation score

40.7.1. Context

The methods so far treat each run as a black box that outputs a model and its score. A different situation is common too: the candidates are already fixed, for example public pretrained checkpoints or models whose training is accounted for separately, and only the choice among them uses private data, a held-out validation set. That is a **selection** problem, and Selection solved it with the exponential mechanism and report-noisy-max. How do those tools apply to tuning, and what do they leave out?

40.7.2. Statement

Let the score of candidate r be its number of correct predictions $u(r)$ on a private validation set of m records. Adding or removing one validation record changes every count by at most $\Delta u = 1$. The **exponential mechanism** picks candidate r in $\mathcal{R}$, the set of candidates, with probability proportional to $e^{\varepsilon u(r)/(2\Delta u)}$; it is ε-DP for the validation records, and its expected gap to the best count is at most $\frac{2\Delta u}{\varepsilon}(\ln|\mathcal{R}| + 1)$, an accuracy gap of $\frac{2}{\varepsilon m}(\ln|\mathcal{R}| + 1)$. Report-noisy-max, which adds Laplace or Gumbel noise to each count and releases the index of the largest, has the same guarantee (with Gumbel noise it is the same mechanism).

If the candidates were trained on the private training set, with k runs whose RDP curves are $\varepsilon_1(\alpha), \ldots, \varepsilon_k(\alpha)$, and the validation set is disjoint from it, releasing the selected model costs

$$\varepsilon_M(\alpha) \le \max\Big(\sum_{j=1}^{k} \varepsilon_j(\alpha),\ \varepsilon_{\text{sel}}(\alpha)\Big), \tag{40.13}$$

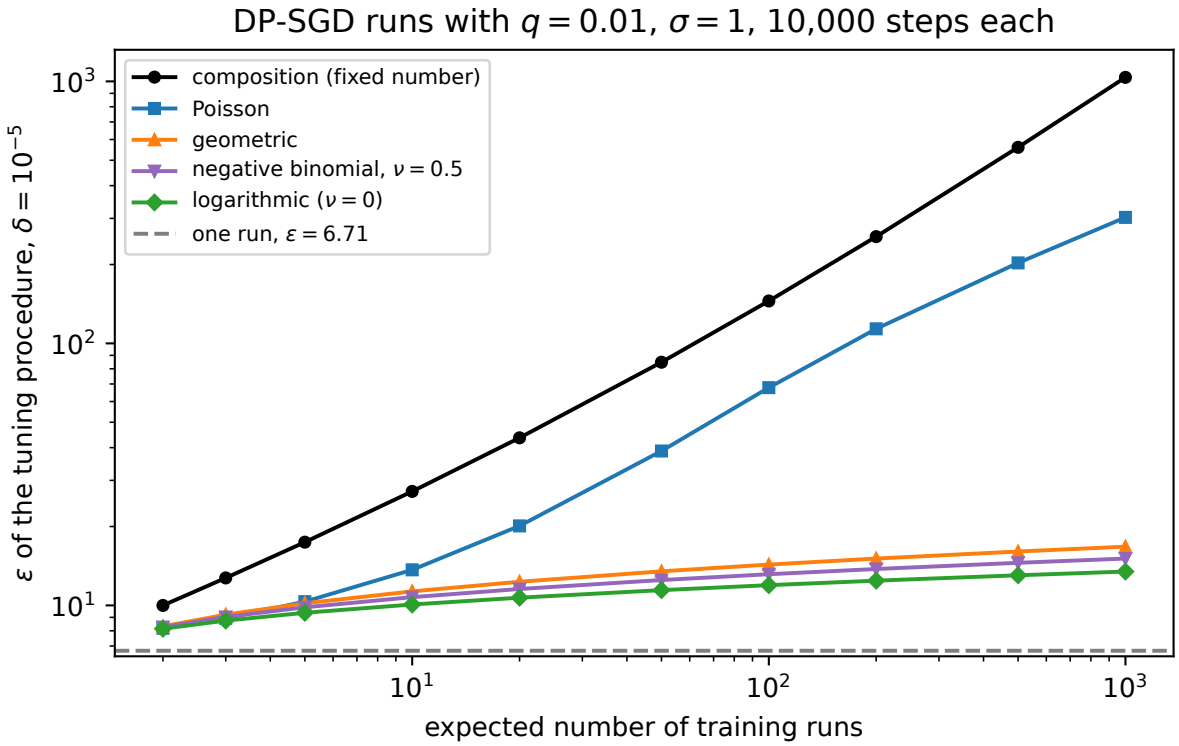

Figure 40.2.: The ε at $\delta = 10^{-5}$ of releasing the best of several DP-SGD runs of the running example ($q = 0.01$, $\sigma = 1$, 10,000 steps, one run $\varepsilon = 6.71$), against the expected number of runs, by composition, by the Poisson bound and by the truncated negative binomial bound with $\nu = 1$ (geometric), 0.5 and 0 (logarithmic). Both axes are logarithmic.

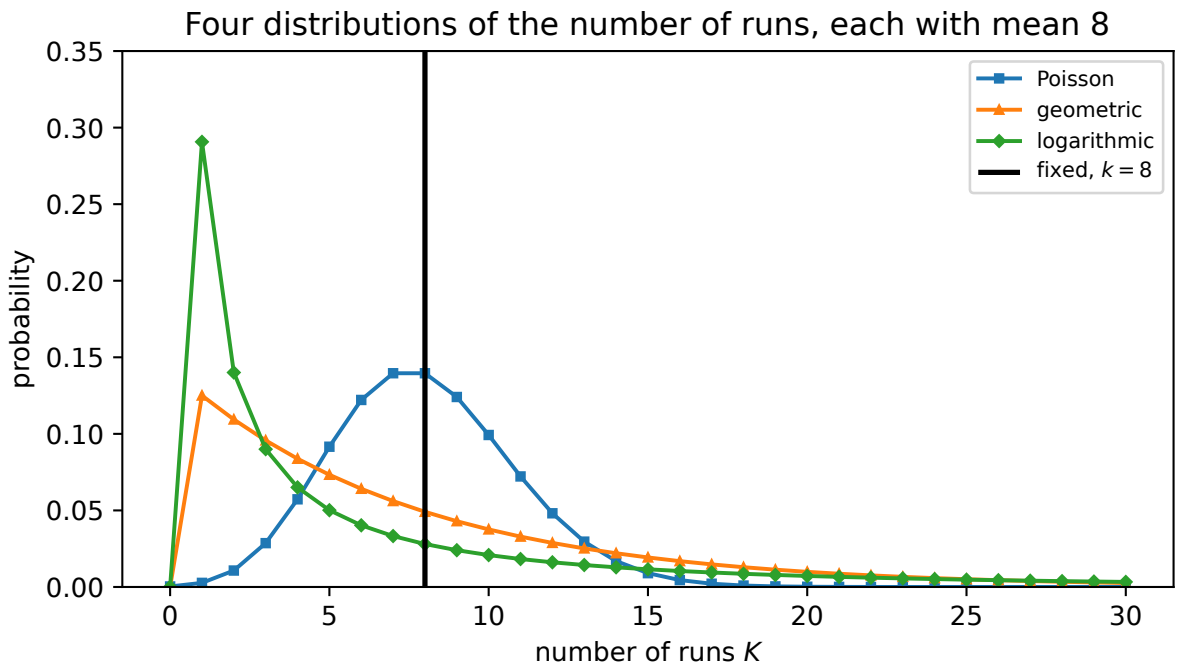

Figure 40.3.: Four distributions of the number of runs, each with mean 8: Poisson, geometric, logarithmic and a fixed 8. The logarithmic distribution stops after one run with probability 0.29.

where ε_{sel} is the selection mechanism's curve in the validation records.

40.7.3. Derivation

1. **The exponential mechanism.** One record changes each count by at most 1, so each weight $e^{\varepsilon u(r)/2}$ by at most $e^{\varepsilon/2}$ and the normalizing sum by at most $e^{\varepsilon/2}$; the ratio of probabilities is at most e^{ε} (Selection). Candidates more than c below the best have weight at most $e^{-\varepsilon c/2}$ times the best's, so the probability of picking one is at most $|\mathcal{R}|e^{-\varepsilon c/2}$, and integrating the tail gives the expected gap (Utility of the exponential mechanism).
2. **Training records.** For a training record, the validation set and the selection noise are fixed and independent of it. The released model and index are a post-processing of the k trained models (Fact 2), which compose (Fact 1): $\sum_j \varepsilon_j(\alpha)$.
3. **Validation records.** For a validation record, the trained models do not depend on it, and the release is the selection mechanism applied to fixed candidates: $\varepsilon_{\text{sel}}(\alpha)$.
4. **Combine.** Each record is in one of the two sets, so Fact 4 gives the maximum.

40.7.4. Interpretation

Selection is cheap; training is not. On a validation set of thousands of records, selecting privately costs almost nothing: the scores differ by tens of correct predictions and the mechanism's temperature, $2/\varepsilon$, is a few. The expensive part of tuning is that each candidate was *trained* on

private data, and Equation 40.13 still charges for all k trainings by composition. The exponential mechanism has nothing to say about it, because a trained model is not a low-sensitivity score: Liu & Talwar's starting point was exactly that the candidates' quality is only known through private, randomized runs.

When the classical tools are the right ones. If the candidates do not depend on the private training data, the training term in Equation 40.13 vanishes. Choosing which public checkpoint to fine-tune, which public model to deploy, or which hyperparameters to use from a list validated elsewhere, by their accuracy on a private validation set, is a pure selection problem, and the exponential mechanism or report-noisy-max is the tool, with $\ln|\mathcal{R}|$ utility cost and no linear privacy cost.

The validation set needs protection under every method. The best-of methods of Section 40.5 and Section 40.6 assume that the score is part of each run's private output. If it is an exact validation accuracy, the validation records are not protected at all: the choice and the released score depend on them with no noise. Adding Gaussian noise of standard deviation σ_{val} to each validation count makes each run's score a Gaussian mechanism with RDP curve $\alpha/(2\sigma_{\text{val}}^2)$, and by Fact 4 a run's curve is the larger of its training curve and this one.

A cheaper score is not a cheaper run. Each noisy count adds to the cost in validation records, but by Fact 4 it adds nothing as long as it stays below the training curve at every order. With $\sigma_{\text{val}} = 20$ correct predictions, one noisy count alone has $\varepsilon = 0.182$ and eight composed have 0.546, well below the training runs in the example below.

40.7.5. Example: choosing a learning rate on 5,000 validation records

In the experiment of Section 40.8, eight DP-SGD runs at $\sigma = 2.07$, with learning rates from 0.0625 to 8, get these counts out of $m = 5{,}000$: 4,486, 4,604, 4,681, 4,694, 4,600, 4,470, 4,232 and 4,123. The best, learning rate 0.5, beats the second, 0.25, by 13 correct predictions. Table 40.6 selects among them with the exponential mechanism.

Table 40.6.: The exponential mechanism selecting among eight trained models by their correct predictions on 5,000 private validation records.

ε_{sel}	Pr[best]	Expected gap (correct predictions)	Accuracy gap	Bound $2(\ln 8 + 1)/\varepsilon_{\text{sel}}$
0.01	0.2478	87.62	1.752%	615.9
0.1	0.6484	5.61	0.112%	61.6
1	0.9985	0.02	0.000%	6.2

At $\varepsilon_{\text{sel}} = 0.1$ the selection costs about a tenth of a point of accuracy, and at 1 nothing measurable. The training costs much more: each run at $\sigma = 2.07$ and 1,000 steps has $\varepsilon = 0.657$, and the eight together 1.994. Adding the eight noisy validation counts, run by run, changes nothing: the total stays at 1.994, because the counts' curve is below the training curve at the orders that matter.

40.7.6. Check yourself

- Why is the sensitivity of a count of correct predictions 1 under add/remove, while an accuracy has a sensitivity that depends on m? *(Adding a record adds one prediction, which is right or wrong, so the count moves by at most 1. The accuracy is the count divided by the number of records, and both change; the count avoids dividing by a private number.)*
- Fifty public checkpoints, a private validation set of 2,000 records and $\varepsilon = 0.5$: what expected accuracy gap does the exponential mechanism guarantee? *(At most* $2(\ln 50 + 1)/(0.5 \times 2{,}000) = 0.0098$*, about one point.)*

40.8. Tuning the running example

40.8.1. Context

Put the strategies side by side on the running example: tune the learning rate of DP-SGD over a grid of eight values, at the same total budget, and compare what each strategy delivers. The budget must cover the training runs and the validation scores.

40.8.2. Statement

Each run trains the running example's network with DP-SGD ($q = 0.01$, $C = 0.5$) for **1,000 steps instead of the 10,000 of DP-SGD**, to keep the script's runtime at a few minutes, with one of eight learning rates $\eta \in \{0.0625, 0.125, \dots, 8\}$. The first 5,000 of the 20,000 held-out records are a private validation set, and the other 15,000 the test set. A run's score is its number of correct validation predictions plus Gaussian noise with $\sigma_{\text{val}} = 20$. The total budget is $\varepsilon = 2$ at $\delta = 10^{-5}$, and each strategy chooses its noise multiplier σ so that the whole procedure meets it, by the accountant of Section 40.4 or Section 40.6.

Table 40.7.: Tuning the learning rate of the running example (1,000 steps per run) at a total budget of $\varepsilon = 2$, $\delta = 10^{-5}$. Test accuracy of the released model, mean and standard deviation over repetitions of the whole procedure, estimated by resampling from three runs per learning rate; runs on private data is the average number of training runs.

Strategy	σ	ε of one run	Total ε	Test accuracy	Runs on private data
No tuning: learning rate 0.5 from DP-SGD	1.03	1.97	1.97	0.9509 ± 0.0015	1
Grid of 8, single-run ε reported	1.03	1.97	5.60	0.9479 ± 0.0030	8
Tune on proxy data, then one run	1.03	1.97	1.97	0.9487 ± 0.0025	1

Strategy	σ	ε of one run	Total ε	Test accuracy	Runs on private data
Grid of 8, composition	2.07	0.66	1.99	0.9430 ± 0.0022	8
Random search, Poisson, mean 8	1.53	0.98	1.99	0.9433 ± 0.0060	8.01
Random search, logarithmic, mean 8	1.36	1.17	2.00	0.9372 ± 0.0200	7.95

40.8.3. Derivation

The rows are computed as follows; each uses the facts and results named.

1. **No tuning.** One run with the learning rate the previous chapter used, at the noise multiplier for $\varepsilon = 2$, $\sigma = 1.03$ (the accountant rounds up, so the run costs 1.97).
2. **The reporting bug.** The same eight runs at $\sigma = 1.03$, one per learning rate, best noisy validation count released, and the single-run ε reported. Its honest cost is the composition of eight runs, 5.60 (Equation 40.6).
3. **Proxy data.** A second task built the same way with a different random teacher stands in for public data from a related distribution. The grid is run there, the best learning rate by validation on the proxy task is kept, and one private run is trained with it at $\sigma = 1.03$. The proxy runs touch no private data, so they cost nothing (Fact 2).
4. **Composition.** The eight runs at the σ for which eight runs together cost 2, which is 2.07 (Equation 40.6 with Fact 4 for the noisy counts).
5. **Random search.** K runs, each with a learning rate drawn uniformly from the grid, with K Poisson or logarithmic with mean 8, σ chosen by Equation 40.11 or Equation 40.12 so that the procedure costs 2.
6. **Estimating accuracy.** Training is the slow part, so the script trains three independent runs per learning rate for each σ, and repeats each tuning procedure 4,000 times by drawing runs from this pool, with fresh validation noise and, for random search, a fresh K. Drawing with replacement from three runs understates the variety of a real search a little.

40.8.4. Interpretation

The honest strategies cost about a point of accuracy here, and the bug hides it. At the same total budget, composition reaches 0.9430 and Poisson random search 0.9433, against 0.9509 without tuning. Reporting the single-run budget makes the grid search look free: it claims 1.97 and spends at most 5.60.

Tuning did not pay on this task, for an instructive reason. Even with the budget misreported, the grid search, 0.9479, is below the untuned learning rate of 0.5, 0.9509. The

learning rate 0.5 is the best of the grid here, and the noisy validation count sometimes picks a neighbour. It is the best because DP-SGD chose its running example's settings with knowledge of this very task, a leak of exactly the kind this chapter is about, which no accountant in the book has charged for. On a new task, you would not have such a guess, and a search would be needed.

Random search with a Poisson number of runs beats composition only slightly here. At a total of $\varepsilon = 2$ and a mean of 8 runs, Poisson random search allows $\sigma = 1.53$ instead of 2.07, each run costing 0.98 instead of 0.66. But it tries a given learning rate with probability only $1 - e^{-1}$, since a candidate is missed with probability 0.3679, and its accuracy varies more from one search to the next, 0.0060 against 0.0022. The two effects roughly cancel at this small grid. With more candidates, Table 40.5 says the gap in σ grows.

The logarithmic distribution has the cheapest bound and the worst search. It allows the least noise of the honest strategies, $\sigma = 1.36$, but with mean 8 it stops after a single run with probability 0.2907, and then releases a random learning rate. That is why its accuracy is lowest and most variable, 0.9372 ± 0.0200. Papernot & Steinke report the same trade-off, and found the Poisson distribution best in their own small search. Figure 40.4 repeats the comparison at $\varepsilon = 1$ and 4 (one run per learning rate, so those points are noisier).

Tuning on proxy data is nearly free, when proxy data exist. The proxy task has a different teacher, so its best learning rate is not always the private task's, and the released model reaches 0.9487 for a total cost of one private run. Its quality depends on how close the proxy is.

40.8.5. Example: what the bug changes in a paper's table

A paper reports "test accuracy 0.948 at $\varepsilon = 1.97$" for a model chosen from eight learning rates. A reader comparing it with a paper that reports 0.943 at $\varepsilon = 1.99$ after an honest grid search concludes that the first method is better at the same budget. In Table 40.7 both rows are the same algorithm; the difference is the accounting. At its honest cost of 5.60, the first row should be compared with other methods at $\varepsilon = 5.60$, not at 1.97; DP-SGD shows how much accuracy a budget that large buys.

40.8.6. Check yourself

- Why does the composition row use $\sigma = 2.07$ while the logarithmic row can use 1.36, both at a total of 2? *(Composition charges eight full runs; Equation 40.12 charges one run plus a constant multiple of one run at another order plus* $\ln 8/(\alpha - 1)$*, which is less than seven more runs.)*
- The bootstrap draws runs with replacement from three per learning rate. Which strategy's accuracy does this distort most? *(Those that run the same learning rate many times, random search with large K: repeated draws of the same three runs make the best of many runs look less good than independent runs would. With a mean of 8 runs over 8 learning rates, the effect is small.)*

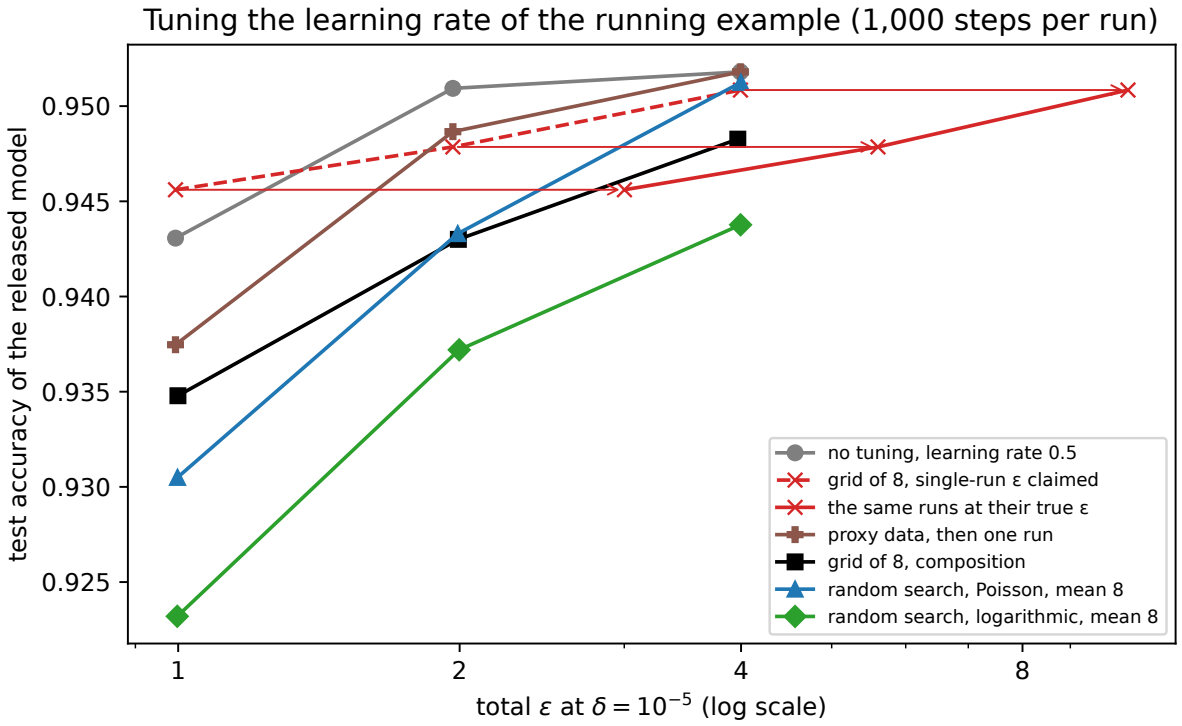

Figure 40.4.: Test accuracy of the model released by each tuning strategy against the total ε at $\delta = 10^{-5}$ it costs (1,000 DP-SGD steps per run). The red dashed line places the grid search at the single-run ε that the reporting bug claims, and the arrows move each point to its honest cost by composition. Points at $\varepsilon = 2$ use three runs per learning rate; those at 1 and 4 one run.

40.9. What to do and what to report

40.9.1. Context

The results of this chapter turn into a short procedure. What should a team training a private model actually do about hyperparameters, and what must a reported ε cover for a reader to rely on it?

40.9.2. Statement

1. **Spend private runs only where you must.** Tune on public data or on proxy data from a related distribution when it exists. Reuse hyperparameters that worked on similar tasks. Shrink the search: DP-SGD showed that below the typical gradient norm only the product of learning rate and clipping norm matters, so one of the two need not be searched.
2. **Fix the search before touching the private data.** Write down the candidate set, the distribution of the number of runs, the score and the validation set.
3. **Make the score private.** Use a held-out validation set and a noisy count, or spend part of the budget on a private score.
4. **Account for the whole search.** For a few candidates, compose. For more, run random search with a random number of runs and use Equation 40.11 (small per-run budget, moderate number of runs) or Equation 40.12 (many runs). Account for every run on the private data, including runs that crashed, runs for debugging, and evaluations used for early stopping.
5. **Report both numbers.** The ε of the released run, and the ε of the whole procedure with how it was computed: the candidate set, the distribution of K, the accountant, δ and the neighbouring relation.

40.9.3. Derivation

Each item follows from a result above.

1. Runs on public data cost nothing (Fact 2), and every private run costs something by Section 40.4 and Section 40.6. A smaller candidate set gives the same utility with fewer runs, which lowers $\ln \mathbb{E}[K]$ or k.
2. The theorems of Section 40.5 and Section 40.6 require that the candidates are drawn from a fixed distribution and that K is drawn from its distribution independently of the data. Choosing them after looking at results makes them functions of the data that no theorem covers.
3. Every best-of theorem assumes that the score is part of a private output (Section 40.7). An exact validation score makes the validation records unprotected.
4. Composition and the random-K bounds are both valid; which is smaller depends on the number of runs and the per-run budget (Table 40.5, Table 40.7). A crashed run still computed on the data, and if its failure influenced what was done next, it is part of the adaptive sequence.

5. The released run's ε says how much the final model alone leaks if the hyperparameters were public; the procedure's ε is what the release actually guarantees. Papernot & Steinke (2022) suggest stating both when the second is much larger.

40.9.4. Interpretation

The cheapest fix is usually upstream. In Table 40.7, the strategies that spend the whole budget on one private run, no tuning and proxy tuning, beat every honest search. That will not always hold, since a poor guess can be far worse than a noisy search, but it says where to start: get good hyperparameters without the private data, and search privately only over what remains uncertain.

Pre-registration is part of the guarantee. The random-K theorems are statements about a procedure. An engineer who looks at the first few results and decides to "try a few more" has changed the procedure, and the theorem no longer applies. Logging the search configuration before it runs is to tuning what fixing the clipping norm in advance is to DP-SGD.

Reporting standards exist. Ponomareva et al. (2023, Section 5.3.3) ask for the formal guarantee of the final model and of the tuning, and Choosing an accountant lists tuning among the checks of a reported ε. Auditing cannot catch the bug: an audit tests the trained model, not how it was chosen.

40.9.5. Example: the report for the running example

For the Poisson row of Table 40.7, a complete report reads: "DP-SGD with Poisson sampling rate 0.01, clipping norm 0.5, noise multiplier 1.53, 1,000 steps; one run satisfies $(0.98, 10^{-5})$-DP. The learning rate was selected by random search over $\{0.0625, 0.125, \dots, 8\}$ with a Poisson number of runs with mean 8, scored by correct predictions on a disjoint validation set of 5,000 records with Gaussian noise of standard deviation 20; the whole procedure satisfies $(1.99, 10^{-5})$-DP by the Rényi bound of Papernot & Steinke (2022, Theorem 6), add/remove neighbours, record level."

40.9.6. Check yourself

- A colleague tunes on the private data, then retrains the chosen configuration from scratch with fresh noise and releases only the retrained model. Does the retraining make the tuning free? *(No. The chosen hyperparameters are a function of the tuning runs, so the release is a post-processing of the tuning runs plus the new run; the tuning must be accounted for, and the new run adds its own cost.)*
- Why can't an audit of the released model detect that tuning was not accounted for? *(An audit estimates how much the trained model reveals about its training records. The best-of-k leak is in the event "every run was bad", which an audit of one released model at one fixed configuration does not replicate unless it reruns the whole search on neighbouring datasets.)*

40.10. Code: check every number by computation

The script code/hyperparameter_tuning.py computes the exact best-of-K distributions of Equation 40.4 for randomized response and the three-outcome mechanism, evaluates the bounds of Liu & Talwar and Papernot & Steinke on the RDP accountant of DP-SGD, whose model and accountant it imports from code/dp_sgd.py, and runs the tuning experiment. From the repository root:

```
uv run python code/part05-dp-ml/hyperparameter_tuning.py
```

It trains about 200 DP-SGD runs of 1,000 steps each and takes two to four minutes. Its accountants are reusable: `tuned_epsilon(q, sigma, steps, strategy)` gives the total ε of a search with `strategy` one of `("fixed", k)`, `("poisson", mean)` or `("tnb<η>", mean)`, and `sigma_for_tuning(q, steps, eps, strategy)` the noise multiplier that keeps a search within a budget. The `<η>` of the last strategy is the shape ν.

Output (seed 0), summarized in Table 40.8:

Table 40.8.: The script's output with the default seed.

Experiment	Result
Best of 10 randomized responses, $\varepsilon = 1$	Exactly $\varepsilon = 10$; loss 10 with probability 0.0436
Composition, running example	27.23 for 10 runs, 145.17 for 100
Geometric stopping, three outcomes	Exact ε up to 2.9987, below the bound 3
Logarithmic number of runs, running example	10.08 for 10 runs, 13.46 for 1,000
Exponential mechanism over 8 models	Pr[best] = 0.6484 at $\varepsilon = 0.1$
Tuning at $\varepsilon = 2$	Honest search 0.9430 to 0.9433; bug claims 1.97 and spends 5.60

tests/test_hyperparameter_tuning.py checks that the output still matches.

What to take from it. The exact computations show that the bounds are attained in the worst case: $k\varepsilon$ for a fixed number of runs, 3ε and 2ε for the geometric and logarithmic numbers. The accountant shows that for DP-SGD the random-K bounds grow logarithmically while composition grows linearly. The experiment shows that on a small grid the accuracy gained by tuning can be smaller than the accuracy lost by paying for it, and that the cheapest strategy is to need fewer private runs.

40.12. Cheat sheet

K runs of a private algorithm Q with RDP curve $\varepsilon(\alpha)$, best output released, generating function $f(x) = \mathbb{E}[x^K]$. Table 40.9 collects the results.

Table 40.9.: Every result of the chapter.

Result	Formula	Conditions
Best of K	$\Pr[M = y] = f(Q(\preceq y)) - f(Q(\prec y))$	Independent runs, K independent of them
Fixed k	$\varepsilon_M(\alpha) \le k\varepsilon(\alpha)$; attained for $\alpha = \infty$	Always valid
Random stopping	3ε-DP; misses top π fraction w.p. $\le \omega/\pi$	ε-DP runs, K geometric with mean $1/\omega$
Generic	$\varepsilon_M(\alpha) \le \varepsilon(\alpha) + \frac{1}{\alpha-1}\ln[f'(s)^\alpha f'(s')^{1-\alpha}]$	s, s' from one test
Poisson	$\varepsilon(\alpha) + \mathbb{E}[K]\hat{\delta} + \frac{\ln \mathbb{E}[K]}{\alpha-1}$	$(\hat{\varepsilon}, \hat{\delta})$-DP with $e^{\hat{\varepsilon}} \le 1 + \frac{1}{\alpha-1}$
Truncated negative binomial	$\varepsilon(\alpha) + (1+\nu)(1-\frac{1}{\hat{\alpha}})\varepsilon(\hat{\alpha}) + \frac{(1+\nu)\ln(1/\omega)}{\hat{\alpha}} + \frac{\ln \mathbb{E}[K]}{\alpha-1}$	Any $\hat{\alpha} \ge 1$; pure DP: $(2+\nu)\varepsilon$
Selection among fixed candidates	Exponential mechanism, gap $\le \frac{2}{\varepsilon m}(\ln \lvert\mathcal{R}\rvert + 1)$ in accuracy	Count score on m validation records
Trained candidates, disjoint validation	$\max(\sum_j \varepsilon_j(\alpha), \varepsilon_{\text{sel}}(\alpha))$	Each record in one set

Rules of thumb

- The best of k runs is not cheaper than k runs unless k is random. Report the cost of the search, not of the released run.
- For DP-SGD, random search with a Poisson number of runs suits small searches at small per-run budgets; the logarithmic or $\nu = 0.5$ distributions suit large searches, at the price of often running few candidates.
- Validation scores on private data must be noisy; a few thousand validation records make the noise cheap.
- The best tuning is the tuning you do not do on private data: public or proxy data, reused settings, fewer knobs.
- Fix the candidate set and the distribution of the number of runs in advance; adaptive searches need adaptive composition.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

41. DP-FTRL and matrix factorization

41.1. Why this matters

Stochastic gradient descent (SGD) with differential privacy (DP), the DP-SGD of the previous chapter, gets its privacy from two sources. Clipping and Gaussian noise make each step a Gaussian mechanism, and **Poisson sampling** makes each step much more private than that: a record is in the batch only with probability q, and the accountant credits the run for the uncertainty about whether the record was used. For the running example of this part, with $q = 0.01$, that amplification is what turns a noise multiplier of 1 into $\varepsilon = 6.71$ over 10,000 steps.

Many training pipelines cannot honestly claim Poisson sampling. Data loaders shuffle the dataset once, or once per epoch, and cut it into fixed batches; streaming pipelines read the data in the order it arrives; and in federated learning, where the records live on phones, the server cannot choose which devices check in, so it cannot sample them independently with a known probability. Amplification by subsampling shows that applying the Poisson accountant to such pipelines can understate ε considerably. The honest alternative is to give up amplification. Each step is then a plain Gaussian mechanism, and on the running example, for $\varepsilon = 2$ over five passes through the data, the noise multiplier has to grow from 0.928 to 4.458, and test accuracy falls from 0.9460 to 0.8941.

This chapter asks: **how do you train privately without trusting random batches, and can correlated noise beat independent noise?** It can, by a lot, and the reason is a change of viewpoint. The first algorithm to exploit it ran the follow the regularized leader (FTRL) algorithm on noisy gradient sums and is called DP-FTRL; it adds its noise through a binary tree, a construction from the theory of private counters. The modern form, the **matrix factorization mechanism**, contains the tree as a special case, and on the running example it closes nearly all of the gap to amplified DP-SGD without any sampling at all.

41.1.1. The one idea: training releases prefix sums, so put the noise where the prefix sums need it

Gradient descent without momentum adds up its steps. After t steps the weights are the starting point minus the learning rate times the **prefix sum** $S_t = x_1 + \cdots + x_t$ of the clipped gradient sums x_s of the batches seen so far. What the models reveal about the data is what these prefix sums reveal, and the error in a model is the error in its prefix sum. SGD with independent noise on every step, DP-SGD without amplification, makes the noise in S_t a random walk, whose standard deviation grows like $\sqrt{t}$. Nothing forces the noise to be independent. If the noise added at step t partly cancels the noise added before it, the prefix sums stay accurate. The price is that each record's gradient must then be hidden in several noisy quantities at once.

The bookkeeping is linear algebra. Releasing all T prefix sums is the linear map $x \mapsto Ax$, with A the lower-triangular matrix of ones. Write $A = LR$, add Gaussian noise to Rx, and release $L(Rx + z) = Ax + Lz$. The **encoder** R sets the privacy, because the noise must hide one record's effect on Rx; the **decoder** L sets the error, because it is what multiplies the noise. Independent noise, the binary tree and the best known mechanisms are all choices of this factorization, and the question "how much noise does private training need without amplification?" becomes "how small can the sensitivity of R times the size of L be?". Table 41.1 lists the results.

Table 41.1.: The results of this chapter and where each is used.

Result	Where it is used
Training as a prefix-sum workload; the two naive mechanisms	Why DP-SGD without amplification is noisy; what DP-FTRL releases
The matrix mechanism: privacy from the columns of R, error from the rows of L, and a lower bound	Comparing any two correlated-noise schemes; streaming and adaptivity
Tree aggregation and DP-FTRL	The first practical mechanism; federated training
The square-root factorization and the optimal one	The default correlated-noise mechanism; how close it is to optimal
Several participations: sensitivity as the norm of a sum of columns; banded factorizations	Training for more than one epoch; why the data order matters
The running example: matrix mechanisms against DP-SGD	When to use which; user-level privacy in federated learning

Notation. A run has T steps with a fixed batch size B. At step t the model has parameters $\theta_t \in \mathbb{R}^d$, and the clipped per-example gradients of the batch are summed into $x_t \in \mathbb{R}^d$, one entry per weight; stacking the x_t as rows gives the $T \times d$ matrix x. C is the clipping norm, so each record adds a vector of length at most C to each x_t it takes part in. $S_t = \sum_{s \le t} x_s$ is the t-th prefix sum and $\hat{S}_t$ its private estimate. A is the $T \times T$ lower-triangular matrix of ones. A **factorization** is $A = LR$, with R an $m \times T$ encoder and L a $T \times m$ decoder; r_j is the j-th column of R and ℓ_t the t-th row of L. The noise z is $m \times d$ with independent $\mathcal{N}(0, s^2C^2)$ entries; s is the **noise scale**, in units of C like DP-SGD's noise multiplier σ. μ is the ratio of sensitivity to noise standard deviation of a Gaussian mechanism, and E the number of epochs.

The running example. The part's network from DP-SGD: 50-dimensional inputs, labels from a fixed random teacher network, a student with 64 tanh hidden units and $d = 3{,}329$ weights, $n = 10{,}000$ training and 20,000 test records, clipping norm C of 0.5, $\delta = 10^{-5}$. The **fixed-order** runs use one public random permutation of the record slots, drawn independently of the data and kept for every epoch, cut into 100 batches of $B = 100$. Each epoch is 100 steps, and each record participates once per epoch, exactly 100 steps apart. The DP-SGD runs use Poisson sampling with $q = 0.01$, so their expected batch is also 100.

How to read this chapter. Read the toolkit and Section 41.3, which sets up the problem, then Section 41.4, the general framework. Section 41.5 and Section 41.6 are two instances, the

historical one and the one to use. Section 41.7 is needed as soon as you train for more than one epoch. Section 41.8 puts the pieces together on the running example.

41.2. Toolkit: four facts every derivation uses

41.2.1. Fact 1 — A Gaussian mechanism is described by one ratio

Release $f(D) + Z$, where f takes values in $\mathbb{R}^{m\times d}$ and Z has independent $\mathcal{N}(0, \varsigma^2)$ entries. Let $\Delta_2 f$ be the largest change of f between neighbouring datasets, measured in the Frobenius norm: the square root of the sum of squared entries, the Euclidean length of the matrix read as one long vector. The privacy of the release depends only on $\mu = \Delta_2 f/\varsigma$, because rotating the output space puts the shift on one axis, and the noise on every other axis has the same distribution under both datasets (The Laplace and Gaussian mechanisms). Such a mechanism is μ-Gaussian differential privacy (GDP), and it is (ε, δ)-DP exactly when

$$\delta \geq \Phi\Big(\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) - e^{\varepsilon}\,\Phi\Big(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big), \tag{41.1}$$

with Φ the standard normal distribution function (f-DP and Gaussian DP). The right side grows with μ, so each (ε, δ) has a largest admissible ratio $\mu(\varepsilon, \delta)$. At $\delta = 10^{-5}$, $\mu(2, \delta) = 0.502$ and $\mu(8, \delta) = 1.666$. The noise standard deviation for sensitivity $\Delta_2 f$ is then $\varsigma = \Delta_2 f/\mu(\varepsilon, \delta)$.

41.2.2. Fact 2 — Post-processing

Any computation on a private output that does not touch the data again is as private as the output (Post-processing, group privacy and composition). Multiplying a noisy matrix by a fixed matrix, and taking gradient steps with the result, are post-processing.

41.2.3. Fact 3 — A linear combination of independent Gaussian noise

If z has independent $\mathcal{N}(0, \varsigma^2)$ entries and ℓ is a fixed row vector, then ℓz, one number for each of the d columns, has independent coordinates, each normal with variance

$$\varsigma^2 \|\ell\|^2 = \varsigma^2 \sum_j \ell_j^2, \tag{41.2}$$

because a weighted sum of independent normals is normal and the variances of independent terms add, each multiplied by its weight squared. Applied to the rows ℓ_t of a decoder, the error of the t-th released prefix sum has standard deviation $\varsigma\|\ell_t\|$ in each coordinate. Two rows give correlated errors, with covariance $\varsigma^2\, \ell_t \cdot \ell_u$.

41.2.4. Fact 4 — Adaptive Gaussian steps compose into one Gaussian

If each of k steps is a Gaussian mechanism with ratio μ_i, and each step may depend on the outputs of the earlier ones, the run is $\sqrt{\mu_1^2 + \cdots + \mu_k^2}$-GDP (f-DP and Gaussian DP; Private empirical risk minimization restates the argument). Conditionally on the earlier outputs, each step's privacy loss is normal with the mean and variance of a one-step Gaussian loss, so the losses add like independent normals, and their variances, which are the μ_i^2, add.

41.3. Training is a stream of prefix sums

41.3.1. Context

What does a training run actually have to release, and what does privacy cost when the data order is fixed and nothing is sampled? Pinning this down turns training into a classic problem, the private release of running sums, for which much better mechanisms exist than fresh noise on every step.

41.3.2. Statement

Run gradient descent with a constant learning rate η (also called the step size) and no momentum, $\theta_{t+1} = \theta_t - \frac{\eta}{B}\hat{x}_t$, where $\hat{x}_t$ is the possibly noisy clipped gradient sum of step t. Then

$$\theta_{t+1} = \theta_0 - \frac{\eta}{B}\hat{S}_t, \qquad \hat{S}_t = \sum_{s \le t} \hat{x}_s, \tag{41.3}$$

so the whole run is a post-processing of the prefix sums $\hat{S}_1, \dots, \hat{S}_T$, and the noise in θ_{t+1} is η/B times the noise in $\hat{S}_t$. **FTRL** with linearized losses and a quadratic regularizer, $\theta_{t+1} = \arg\min_\theta \left(\langle \hat{S}_t, \theta\rangle + \frac{B}{2\eta}\|\theta - \theta_0\|^2\right)$, produces the same weights. Releasing all prefix sums is the linear workload

$$S = Ax, \qquad A = \begin{pmatrix} 1 & & & \\ 1 & 1 & & \\ \vdots & & \ddots & \\ 1 & 1 & \cdots & 1 \end{pmatrix} \in \mathbb{R}^{T \times T}, \tag{41.4}$$

where row t of Ax is S_t. For a record that takes part in one step, two mechanisms suggest themselves, each with the noise that makes it μ-GDP for its own sensitivity:

- **Independent noise on each step**, $\hat{S}_t = \sum_{u \le t}(x_u + z_u)$: sensitivity C, and error standard deviation $\sqrt{t}$ in units of C/μ for $\hat{S}_t$.
- **Independent noise on each prefix sum**, $\hat{S}_t = S_t + z_t$: sensitivity $\sqrt{T}C$, and error standard deviation $\sqrt{T}$ in the same units, for every t.

41.3.3. Derivation

1. **Unroll the recursion.** Adding the updates $\theta_{u+1} - \theta_u = -\frac{\eta}{B}\hat{x}_u$ for $u = 1, \dots, t$ telescopes to Equation 41.3. The weights at every step are a fixed function of the released prefix sums, so releasing the prefix sums privately makes every model private (Fact 2).
2. **FTRL.** The FTRL objective is a linear term plus a quadratic; setting its gradient $\hat{S}_t + \frac{B}{\eta}(\theta - \theta_0)$ to zero gives $\theta = \theta_0 - \frac{\eta}{B}\hat{S}_t$, the same point.
3. **Independent noise on each step: privacy.** The record changes only x_τ, its step, by a vector of length at most C. The released noisy gradients $x_u + z_u$ are one Gaussian mechanism per step, and only step τ moves, so the run is a Gaussian mechanism with sensitivity C; the prefix sums are post-processing of the noisy gradients. Noise $z_u \sim \mathcal{N}(0, C^2/\mu^2)$ per coordinate gives μ-GDP.

4. **Its error.** $\hat{S}_t - S_t = z_1 + \cdots + z_t$, a sum of t independent normals with variance C^2/μ^2 each, so its standard deviation is $\sqrt{t}C/\mu$ (Fact 3 with $\ell = (1, \ldots, 1, 0, \ldots, 0)$).
5. **Independent noise on each prefix sum: privacy.** The record's gradient appears in every S_t with $t \geq \tau$, so $T - \tau + 1$ of the released vectors move by the same vector of length up to C. The total Frobenius change is $\sqrt{T - \tau + 1}\, C$, at most $\sqrt{T}C$ for $\tau = 1$. By Fact 1 the noise must be $\sqrt{T}C/\mu$, and that is the error of every $\hat{S}_t$.

41.3.4. Interpretation

DP-SGD without amplification is the first mechanism. Fixed-order noisy SGD adds independent noise to every step, so its model at step t carries a random walk of t noise vectors. At the end of a run of T steps the walk has standard deviation $\sqrt{T}$ times the per-step noise. The second mechanism makes every prefix sum equally noisy, but no better than the worst prefix sum of the first. Neither exploits the structure of A: the first ignores that the noise accumulates, the second ignores that most of S_t was already released in S_{t-1}.

Why prefix sums, and not just the last model? If only the final model were released, one prefix sum, S_T, would suffice, with sensitivity C and error C/μ. But training is adaptive: the gradient x_t is computed at θ_t, which depends on the earlier noisy prefix sums. The mechanism has to produce all the intermediate models anyway, and each must be private, because the later gradients are functions of them. So the workload is all T rows of A, released one at a time as the stream arrives.

Other optimizers are other workloads. With momentum or a learning-rate schedule the weights are still fixed linear combinations of the noisy gradients, only with a different lower-triangular matrix in place of A. Denisov, McMahan, Rush, Smith & Thakurta (2022) factor those matrices too. This chapter keeps plain gradient descent, so the workload is always A.

41.3.5. Example: one epoch of the running example

Take one epoch, $T = 100$ steps, and normalize $\mu = 1$, $C = 1$. Independent noise on each step gives a final prefix sum with error standard deviation $\sqrt{100} = 10$ and a root-mean-square error over the 100 prefix sums of $\sqrt{(1 + 2 + \cdots + 100)/100} = \sqrt{50.5} = 7.11$. Independent noise on each prefix sum has error 10 on every one. At $\varepsilon = 2$, $\mu = 0.502$, so the first mechanism's noise scale is $1/0.502 = 1.994$ per step, in units of C, and its final prefix sum carries noise of standard deviation 19.94 in units of C. DP-SGD with Poisson sampling at the same ε and T needs only $\sigma = 0.827$, and its final prefix sum carries $0.827\sqrt{100} = 8.27$: amplification buys a factor of 2.4 here. The rest of the chapter shows that correlated noise can beat even that, without any sampling.

41.3.6. Check yourself

- Why is the noise in the model after t steps of fixed-order noisy SGD of order $\sqrt{t}$ and not t? *(The per-step noises are independent with mean zero, so their variances add: the sum of t of them has variance t times one, and standard deviation $\sqrt{t}$ times one.)*

- With momentum, are the weights still a post-processing of the prefix sums of noisy gradients? *(Yes. Momentum combines the past noisy gradients linearly with fixed coefficients, and the noisy gradients are the differences of consecutive noisy prefix sums. A factorization of the momentum matrix itself can do better than going through prefix sums.)*

41.4. The matrix mechanism

41.4.1. Context

The two naive mechanisms put noise at opposite ends: on the inputs, or on the answers. The **matrix mechanism** of Li, Hay, Rastogi, Miklau & McGregor (2010) puts it in between, on some linear transformation Rx of the inputs from which the answers can be recovered linearly. How private is such a release, how accurate, and what does it need to work on a stream whose inputs are chosen adaptively?

41.4.2. Statement

Let $A = LR$, with $R \in \mathbb{R}^{m\times T}$ and $L \in \mathbb{R}^{T\times m}$, and release

$$\hat{S} = L(Rx + z) = Ax + Lz, \qquad z_{jk} \sim \mathcal{N}(0, s^2C^2) \text{ independent.} \tag{41.5}$$

Privacy. If a record takes part in one step, at a position fixed in advance, the release is μ-GDP with

$$\mu = \frac{\Delta_2 R}{s}, \qquad \Delta_2 R = \max_j \|r_j\|, \tag{41.6}$$

the largest Euclidean length of a column of R. This holds even when each x_t is chosen after seeing $\hat{S}_1, \dots, \hat{S}_{t-1}$, provided L and R are lower-triangular (streaming).

Error. Each coordinate of $\hat{S}_t - S_t$ is normal with mean zero and standard deviation $sC\|\ell_t\|$. At a fixed privacy level μ this is

$$\frac{C}{\mu}\, e_t, \qquad e_t = \Delta_2 R\, \|\ell_t\|, \tag{41.7}$$

and e_t, the **error per unit of privacy**, is unchanged if R is multiplied by any number $c > 0$ and L divided by it. Two summaries are used below: the root-mean-square error $\left(\frac{1}{T}\sum_t e_t^2\right)^{1/2} = \Delta_2 R\, \|L\|_F/\sqrt{T}$, and the maximum error $\max_t e_t$.

Lower bound. For every factorization,

$$\left(\frac{1}{T}\sum_t e_t^2\right)^{1/2} = \frac{\Delta_2 R\, \|L\|_F}{\sqrt{T}} \geq \frac{\|A\|_*}{T}, \tag{41.8}$$

where $\|A\|_* = \sum_k \nu_k(A)$ is the sum of the singular values $\nu_k(A)$ of A, its **trace norm**. For the prefix-sum matrix, $\nu_k(A) = 1/(2\sin\frac{(2k-1)\pi}{4T+2})$ for $k = 1, \dots, T$.

41.4.3. Derivation

1. **The release is a function of $Rx + z$.** L is fixed, so $\hat{S}$ is post-processing of $Rx + z$ (Fact 2), and $LRx = Ax$ by the factorization.
2. **Sensitivity, non-adaptive inputs.** Neighbouring streams differ in the record's contribution g to x_τ, a vector of length at most C: row τ of x changes by g and nothing else. Then Rx changes by $r_\tau g^\top$, column τ of R times the row g, whose Frobenius norm is $\|r_\tau\| \, \|g\| \le \|r_\tau\| C$ (each entry is $r_{j\tau} g_k$, and the sum of their squares factorizes). The worst position gives $\max_j \|r_j\| \, C$, and Fact 1 with noise sC gives Equation 41.6.
3. **Adaptive inputs, one participation.** In training, x_t is computed at θ_t, which depends on the earlier outputs. With L and R lower-triangular, row j of $Rx + z$ depends on $x_1, \ldots, x_j$ only, so the mechanism can release row j of $Rx + z$ at step j, and $\hat{S}_j$ with it. Compare the two streams step by step. Before step τ the record has contributed nothing, so the outputs before τ have the same distribution under both. Condition on them: they fix θ_τ, hence the record's contribution g. From then on, at any step, the other records' gradients are the same functions of the earlier outputs in both runs, and the record contributes nothing more, so given the same history the mean of each later row of $Rx + z$ differs between the two runs by the matching row of the fixed shift $r_\tau g^\top$. Released row by row, these are Gaussian mechanisms whose squared shifts add up to $\|r_\tau g^\top\|_F^2 \le \|r_\tau\|^2 C^2$, so by Fact 4 the rest of the run is Gaussian with ratio at most $\|r_\tau\| C/(sC)$, as in step 2. Averaging over the history before τ keeps the bound. Denisov et al. (2022, Theorem 2.1) prove the general statement: any factorization of a lower-triangular A that is μ-GDP, or (ε, δ)-DP, for fixed streams stays so for adaptively chosen ones, with the same parameters. Section H.5 in the appendices proves the Gaussian case, for several adaptive participations.
4. **Error.** $\hat{S}_t - S_t = \ell_t z$, so Fact 3 with noise sC gives standard deviation $sC\|\ell_t\|$; substituting $s = \Delta_2 R/\mu$ from Equation 41.6 gives Equation 41.7. Replacing R by cR and L by L/c multiplies $\Delta_2 R$ by c and $\|\ell_t\|$ by $1/c$.
5. **Lower bound, first half.** For any matrix U whose largest singular value is at most 1, $\operatorname{tr}(U^\top A) \le \|A\|_*$, with equality for U built from the singular vectors of A; this is the dual description of the trace norm, which Section H.3 in the appendices proves in three lines. Write $\operatorname{tr}(U^\top LR) = \langle L^\top U, R\rangle_F \le \|L^\top U\|_F \|R\|_F \le \|L\|_F \|R\|_F$: the first step is the Cauchy–Schwarz inequality for the Frobenius inner product. For the second, $\|L^\top U\|_F = \|U^\top L\|_F$, and $U^\top$ does not lengthen any vector, since its singular values are at most 1; applied to each column of L it gives $\|U^\top L\|_F \le \|L\|_F$. So $\|L\|_F \|R\|_F \ge \|A\|_*$.
6. **Second half.** R has T columns, each of length at most $\Delta_2 R$, so $\|R\|_F^2 \le T(\Delta_2 R)^2$. Combining, $\Delta_2 R \|L\|_F \ge \|A\|_*/\sqrt{T}$; dividing by $\sqrt{T}$ gives Equation 41.8. The singular values follow from A^{-1}, which has 1 on the diagonal and -1 just below it; the eigenvalues of $(A^{-1})^\top A^{-1}$ are $4\sin^2 \frac{(2k-1)\pi}{4T+2}$. Section H.3 in the appendices derives them: the product is the second-difference matrix with a 1 in its last diagonal entry, and its eigenvectors are sine waves. The script checks the closed form against a numerical singular value decomposition at $T = 256$: they agree to 2.0×10^{-13}.

41.4.4. Interpretation

Privacy lives in the columns, error in the rows. A column of R is where one step's gradient ends up in the noisy quantities; its length says how much noise is needed to hide it. A row of L says which noisy quantities one prefix sum is assembled from; its length says how much of the

noise lands in that answer. The best factorization balances the two, and the scale invariance of step 4 means only the product matters.

The two naive mechanisms are the extreme factorizations. Independent noise on each step is $R = I$, $L = A$: columns of length 1, rows of length $\sqrt{t}$. Noise on each prefix sum is $R = A$, $L = I$: the first column has length $\sqrt{T}$, rows have length 1. For $T = 100$ their root-mean-square errors are 7.11 and 10, while Equation 41.8 says no factorization can go below 2.18. The rest of the chapter is about factorizations near that bound.

Streaming needs lower-triangular factors. If L or R had entries above the diagonal, $\hat{S}_t$ would need noise or data from future steps. Honaker (2015) improved the tree's estimates by using all of its nodes at the end, which is not lower-triangular, and for that reason his estimator cannot be used during training (Denisov et al. 2022 make this point). For any factorization there is a lower-triangular one with the same distribution of $\hat{S}$ (Denisov et al. 2022, Proposition 2.2), so nothing is lost by insisting on it. Section H.5 in the appendices derives this by Gram–Schmidt and shows that the sensitivity does not grow.

When R is square and invertible, the mechanism is noisy SGD with correlated noise. Then $L = AR^{-1}$ and $\hat{S} = A(x + R^{-1}z)$: the mechanism adds the noise $\zeta = R^{-1}z$ to the gradients and then sums. Each step's noise ζ_t is a fixed combination of $z_1, \dots, z_t$, so implementations generate it on the fly from the stored z's, without forming any $T \times T$ matrix.

What neighbouring means here. The record's slot in the fixed order is public, and the neighbouring stream has the slot empty, contributing zero gradient. If neighbours instead replace the record by another, the contribution changes by up to $2C$, and every sensitivity doubles.

41.4.5. Example: the scale of the gap

Table 41.2 collects the error per unit of privacy, e_t of Equation 41.7, for one participation, for the mechanisms of this and the next two sections. The rows for the tree, the square root and the optimal factorization are derived in Section 41.5 and Section 41.6.

Table 41.2.: Error of each released prefix sum per unit of privacy ($\mu = 1$, $C = 1$), for one participation per record. The optimal factorization is normalized to columns of length 1 and was computed for $T \leq 256$ only.

Mechanism	$T = 100$: $\Delta_2 R$	root-mean-square e_t	max e_t	$T = 10{,}000$: $\Delta_2 R$	root-mean-square e_t	max e_t
Independent noise ($R = I$)	1	7.11	10.00	1	70.71	100.00
Noise on prefix sums ($R = A$)	10	10.00	10.00	100	100.00	100.00
Binary tree	2.828	5.05	6.93	3.873	9.84	13.96
Square root	1.591	2.37	2.53	2.000	3.84	4.00
Optimal (Frobenius)	1	2.24	2.45	—	—	—

Mechanism	$T = 100$: $\Delta_2 R$	root-mean-square e_t	max e_t	$T = 10{,}000$: $\Delta_2 R$	root-mean-square e_t	max e_t
Lower bound Equation 41.8	—	2.18	—	—	3.63	—

From $T = 100$ to $T = 10{,}000$, a hundredfold longer run, the independent-noise error grows tenfold, the tree's by a factor of 2 and the square root's by a factor of 1.6. At $T = 10{,}000$, independent noise is 18 times worse than the square root in root-mean-square error.

41.4.6. Check yourself

- You rescale an encoder by 2, $R \to 2R$, and the decoder by $1/2$. What happens to the noise scale needed for $\mu = 1$, and to the error? *(The sensitivity doubles, so the noise scale doubles; the decoder halves, so the error $sC\|\ell_t\|$ is unchanged.)*
- Why can the lower bound of Equation 41.8 not be reached by a factorization whose columns have very different lengths? *(Step 6 bounds $\|R\|_F^2$ by T times the largest squared column length, which is tight only when all columns are equally long. Unequal columns waste privacy on the short ones.)*

41.5. Tree aggregation and DP-FTRL

41.5.1. Context

The first mechanism with error far below $\sqrt{T}$ was the **binary tree**, found independently by Dwork, Naor, Pitassi & Rothblum (2010) and Chan, Shi & Song (2010) for counting events in a stream. Kairouz, McMahan, Song, Thakkar, Thakurta & Xu (2021) used it to release the prefix sums of gradients, with FTRL as the optimizer, and called the result DP-FTRL. How does it work, and how good is it?

41.5.2. Statement

Build a binary tree over the steps $1, \dots, T$. Level 0 has one node per step; each node at level l covers one of the blocks $1, \dots, 2^l$, then $2^l + 1, \dots, 2 \cdot 2^l$, and so on, of 2^l consecutive steps; there are $L_T = \lceil \log_2 T \rceil + 1$ levels. Release each node's sum of gradients plus independent noise. A prefix $1, \dots, t$ is the union of one node for each 1 in the binary expansion of t, so

$$\hat{S}_t = \sum_{\text{nodes in the decomposition of } t} (\text{node sum} + \text{noise}), \qquad \Delta_2 R = \sqrt{L_T}, \qquad e_t = \sqrt{L_T}\sqrt{\text{popcount}(t)}, \tag{41.9}$$

where $\text{popcount}(t)$ is the number of 1s in the binary expansion of t, at most $L_T - 1$ for $t \le T$. Both factors grow like $\sqrt{\ln T}$, so the error grows like $\ln T$.

41.5.3. Derivation

1. **The factorization.** R has one row per node, with 1 in the columns of the steps the node covers: R is $m \times T$ with m about $2T$. Row t of L has a 1 for each node of the decomposition of t. Then $LR = A$, because the decomposition's nodes cover each step $1, \dots, t$ exactly once.
2. **The decomposition.** Write t in binary. Going from the highest bit down, each 1 at bit l takes the next block of 2^l steps, which starts right after the sum of the higher bits, a multiple of 2^{l+1}, so the block is a node of the tree. For example $7 = 4 + 2 + 1$ uses the nodes covering steps 1 to 4, 5 and 6, and 7; 8 uses a single node covering 1 to 8.
3. **Sensitivity.** A step lies in exactly one node per level, so column j of R has L_T ones and length $\sqrt{L_T}$.
4. **Error.** Row t of L has popcount(t) ones, so $\|\ell_t\| = \sqrt{\text{popcount}(t)}$, and Equation 41.7 gives Equation 41.9.
5. **Privacy during training.** L and R can be ordered so that each node is released when its last step has arrived, and $\hat{S}_t$ uses only completed nodes: the factorization is a streaming one, and Section 41.4 applies.

41.5.4. Interpretation

Why the tree helps. Independent noise sums t noise terms for the t-th prefix; the tree sums at most $\log_2 t + 1$ of them, each somewhat larger because every step is hidden in L_T nodes. Trading a factor $\sqrt{L_T}$ in noise for a reduction from $\sqrt{t}$ terms to $\sqrt{\ln t}$ is a large win for long runs.

Why it is not the end. The tree's error jumps around: at $t = 127 = 1111111_2$ it uses seven nodes, at $t = 128$ one (Figure 41.2, left). Its encoder is also wasteful: the nodes at the top levels are used by few prefixes, yet every step pays for being in them. Honaker (2015) showed how to combine all nodes with weights to reduce the variance, but not in a streaming way (Section 41.4). The square-root factorization of the next section has smaller error everywhere.

DP-FTRL. Kairouz et al. (2021) run FTRL, which by Equation 41.3 is gradient descent from θ_0 on noisy prefix sums, with the prefix sums released by the tree; they also add momentum and restart the tree after a number of steps. They report that DP-FTRL, without any amplification, compares favourably with DP-SGD with amplification in their experiments, and that it allows much more flexible data access. Xu et al. (2023) describe training production language models for the Gboard keyboard with DP-FTRL in federated learning, where Poisson sampling of devices is not available.

41.5.5. Example: $T = 100$ and $T = 10{,}000$

For $T = 100$, the tree has $L_T = 8$ levels, so $\Delta_2 R = \sqrt{8} = 2.828$. The largest popcount up to 100 is 6 (at $t = 63$), so the largest error per unit of privacy is $\sqrt{8}\sqrt{6} = 6.93$, and the root-mean-square error is 5.05 (Table 41.2). For $T = 10{,}000$ there are 15 levels, $\Delta_2 R = 3.873$, the maximum error is 13.96 and the root-mean-square error 9.84, against 70.71 for independent noise.

41.5.6. Check yourself

- Which prefix sums does the tree release most accurately? *(Those whose length is a power of two, which use one node, such as $t = 64$; their error is $\sqrt{L_T}$ per unit of privacy.)*
- For $T = 8$, is the tree better than independent noise? *(No. With 4 levels, $\Delta_2 R = 2$, and the root-mean-square error is $2\sqrt{13/8} = 2.55$, against $\sqrt{4.5} = 2.12$ for independent noise. The tree only pays off for longer runs; Exercise 1 in the exercise book finds the crossover.)*

41.6. The square-root factorization

41.6.1. Context

The tree treats privacy and error asymmetrically: a tall, thin encoder and a sparse decoder. A natural symmetric choice is $L = R$, a matrix whose square is A. Is there a lower-triangular square root of A, what does it look like, and how close is it to the best possible factorization?

41.6.2. Statement

The lower-triangular matrix $R = A^{1/2}$ with $R^2 = A$ is the Toeplitz matrix (constant along each diagonal) with entries

$$R_{ij} = r_{i-j} \text{ for } i \geq j, \qquad r_k = \binom{2k}{k} 4^{-k} : \quad r = 1, \tfrac{1}{2}, \tfrac{3}{8}, \tfrac{5}{16}, \tfrac{35}{128}, \dots, \tag{41.10}$$

the coefficients of the power series $(1-x)^{-1/2} = \sum_k r_k x^k$, computed by $r_0 = 1$, $r_k = r_{k-1}\frac{2k-1}{2k}$. With $L = R$,

$$(\Delta_2 R)^2 = \|\ell_T\|^2 = \sum_{k<T} r_k^2, \qquad 1 + \frac{\ln \frac{2T+1}{3}}{\pi} \leq \sum_{k<T} r_k^2 \leq 1 + \frac{0.8 + \ln \frac{4T-3}{5}}{\pi}, \tag{41.11}$$

and the largest error per unit of privacy is $\max_t e_t = e_T = \sum_{k<T} r_k^2$, which grows like $\ln(T)/\pi$. As noisy SGD, the noise added to the gradients is $\zeta = R^{-1}z$, with R^{-1} the Toeplitz matrix of the coefficients h_k of $(1-x)^{1/2}$: $h = 1, -\frac{1}{2}, -\frac{1}{8}, -\frac{1}{16}, -\frac{5}{128}, \dots$.

41.6.3. Derivation

1. **Lower-triangular Toeplitz matrices are power series.** Identify the matrix with first column $(c_0, c_1, \dots, c_{T-1})$ with the series $c(x) = \sum_k c_k x^k$. The product of two such matrices has, in position (i, j), the sum $\sum_k a_{i-k} b_{k-j}$ over $j \leq k \leq i$, which is the coefficient of x^{i-j} in $a(x)b(x)$: products of matrices are products of series, truncated after x^{T-1}.
2. A **is the series** $1/(1-x)$, since its first column is all ones and $1 + x + x^2 + \cdots = 1/(1-x)$.
3. **A square root.** The series $r(x) = (1-x)^{-1/2}$ satisfies $r(x)^2 = 1/(1-x)$, so its Toeplitz matrix squares to A. Its coefficients follow from the binomial series, $(1-x)^{-1/2} = \sum_k \binom{-1/2}{k}(-x)^k$, with $(-1)^k\binom{-1/2}{k} = \frac{\frac{1}{2}\cdot\frac{3}{2}\cdots\frac{2k-1}{2}}{k!} = \frac{1\cdot 3\cdots(2k-1)}{2^k k!}$. Multiplying top and bottom by $2\cdot 4\cdots 2k = 2^k k!$ gives $\frac{(2k)!}{4^k (k!)^2} = \binom{2k}{k}4^{-k}$, and the ratio of consecutive terms is $\frac{2k-1}{2k}$.

4. **The inverse.** R^{-1} corresponds to $1/r(x) = (1-x)^{1/2}$, whose coefficients are $1, -\frac{1}{2}, -\frac{1}{8}, -\frac{1}{16}, -\frac{5}{128}, \ldots$, by the binomial series again; all after the first are negative.
5. **Sensitivity and error.** Column j of R holds $r_0, \ldots, r_{T-j}$, so the first column is the longest, with squared length $\sum_{k<T} r_k^2$. Row t of $L = R$ holds $r_{t-1}, \ldots, r_0$, so its squared length is $\sum_{k<t} r_k^2$, largest at $t = T$. The product of the two at $t = T$ is $\sum_{k<T} r_k^2$.
6. **Bounds.** A Wallis-type inequality gives $\frac{1}{\pi(k+1/2)} \le r_k^2 \le \frac{1}{\pi(k+1/4)}$ for $k \ge 1$ (Fichtenberger, Henzinger & Upadhyay 2023 quote it with a reference). Section H.3 in the appendices proves it for every k. Compare the sums with integrals of the decreasing functions $1/(x+\frac{1}{2})$ and $1/(x+\frac{1}{4})$: $\sum_{k=1}^{T-1} \frac{1}{k+1/2} \ge \int_1^T \frac{dx}{x+1/2} = \ln \frac{2T+1}{3}$, and $\sum_{k=1}^{T-1} \frac{1}{k+1/4} \le \frac{1}{5/4} + \int_1^{T-1} \frac{dx}{x+1/4} = 0.8 + \ln \frac{4T-3}{5}$. Adding the $k = 0$ term, 1, gives Equation 41.11.

41.6.4. Interpretation

Correlated noise that cancels. The noise added to step t's gradient is $z_t - \frac{1}{2} z_{t-1} - \frac{1}{8} z_{t-2} - \ldots$: fresh noise, minus a decaying share of the noise already injected. Each step's noise is a little larger than independent noise, with standard deviation $\sqrt{\sum_k h_k^2}$ times the noise scale, which tends to $\sqrt{4/\pi} = 1.128$ (the script sums 100,000 coefficients: $\sum h_k^2 = 1.2732 = 4/\pi$). But the running sums of the noise no longer drift: the negative coefficients pull the accumulated noise back toward zero. Figure 41.1 shows one coordinate at $\mu = 1$ for 1,000 steps. The per-step noises of the two mechanisms look alike; their running sums do not.

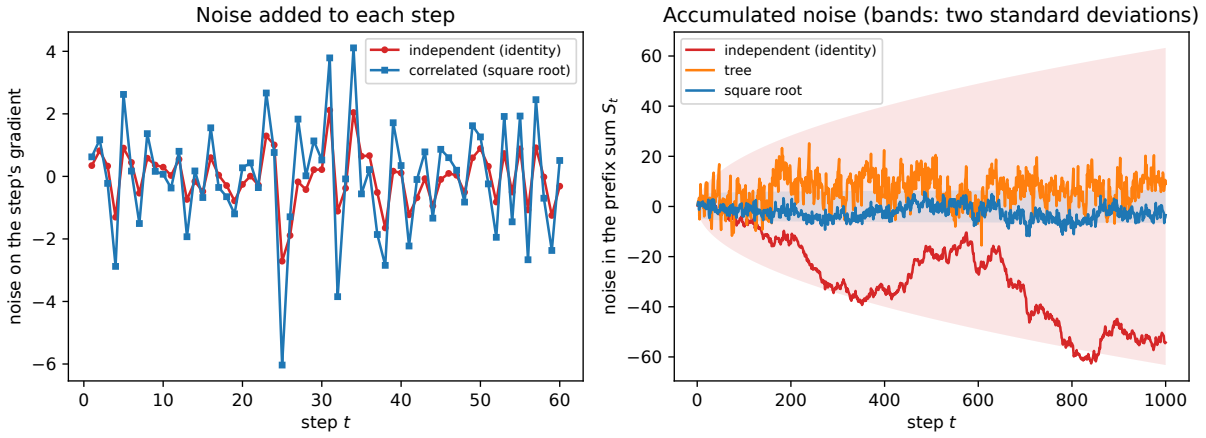

Figure 41.1.: Left: one coordinate of the noise added to each of the first 60 steps' gradients, independent (identity factorization) and square-root correlated, both calibrated to $\mu = 1$ for one participation. Right: the noise in the prefix sums over 1,000 steps, for independent noise, the binary tree and the square root, with bands of two standard deviations. Independent noise drifts like a random walk; the square root's stays within a narrow band.

How close to optimal. The lower bound Equation 41.8 is 2.18 at $T = 100$ and 3.63 at $T = 10{,}000$, and the square root's root-mean-square error is 2.37 and 3.84, within 9% and 6%. Section H.3 in the appendices proves that this ratio tends to 1 as T grows. Fichtenberger, Henzinger & Upadhyay (2023) bound its maximum error with explicit constants and compare it with a lower bound that holds for every factorization, and Henzinger, Upadhyay & Upadhyay (2023) give almost tight

bounds for its mean squared error; the factorization itself already appears in Bennett (1977), as they note. (The closed form printed in Theorem 1 of the arXiv version, $1 + \ln \frac{4T-3}{5}/\pi$, omits the first term of the integral comparison of step 6 and is slightly below the true sum, 2.392 against 2.531 at $T = 100$; the corrected form is the upper bound of Equation 41.11.) A finer expansion of r_k^2 around $1/(\pi k)$ gives the approximation $\sum_{k<T} r_k^2 \approx (\ln T + \gamma + 4 \ln 2)/\pi$, with γ Euler's constant, stated here without proof; the script finds 2.532 against the exact 2.531 at $T = 100$.

The optimal factorization. For the root-mean-square error, the best encoder minimizes $\|L\|_F$ subject to columns of length at most 1. Writing $X = R^\top R$, the problem is to minimize $\operatorname{tr}(A^\top A X^{-1})$ over positive definite X with diagonal at most 1, which is convex. Denisov et al. (2022, Theorem 3.2) show that the solution is $X = V^{-1/2}(V^{1/2} A^\top A V^{1/2})^{1/2} V^{-1/2}$, with V the diagonal matrix of a vector v that is the fixed point of $v \mapsto \operatorname{diag}\left((V^{1/2} A^\top A V^{1/2})^{1/2}\right)$, and they iterate that map. Setting the derivative of the Lagrangian $\operatorname{tr}(A^\top A X^{-1}) + \sum_i \lambda_i (X_{ii} - 1)$ to zero gives $X \Lambda X = A^\top A$, and the constraint $X_{ii} = 1$ turns that into exactly this fixed point. Section H.4 in the appendices gives the full argument: convexity, the balance condition, why it identifies the global optimum, and that the optimal value is $\sum_i v_i$. A lower-triangular R with $R^\top R = X$ comes from a Cholesky factorization of X with rows and columns reversed. The script's iteration converges in 155 steps at $T = 100$ and 193 at $T = 256$, to a root-mean-square error of 2.24 and 2.52, against 2.37 and 2.67 for the square root. The optimum costs a cubic-time computation per iteration, and the square root, which is free and nearly as good, is the usual default for long runs.

Figure 41.2 shows the error per unit of privacy across one run and against the horizon, and Figure 41.3 shows the factors for $T = 16$. The square root and the optimal factorization look alike: lower-triangular, largest on the diagonal, decaying away from it.

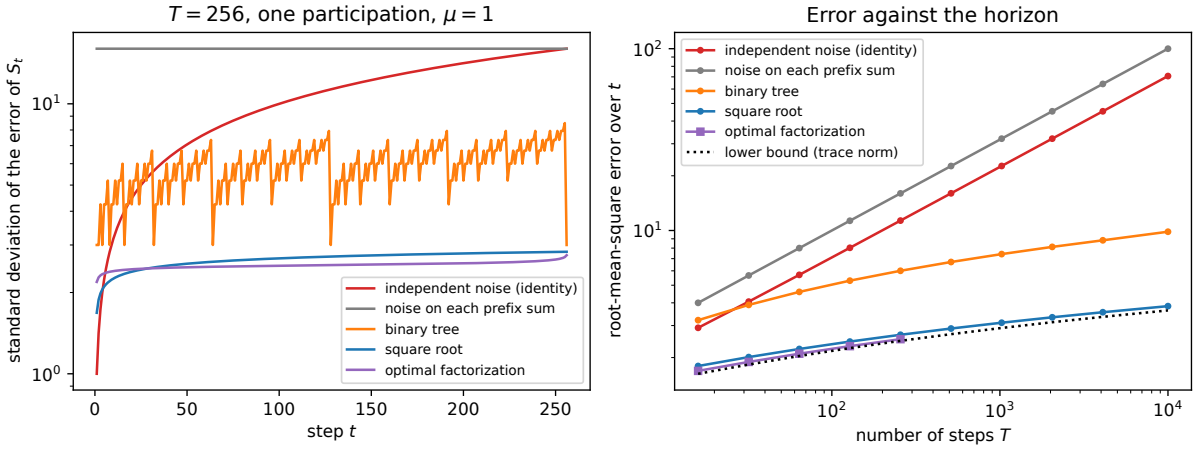

Figure 41.2.: Left: standard deviation of the error of each released prefix sum S_t for $T = 256$, one participation, at $\mu = 1$ and $C = 1$, for five factorizations. Right: the root-mean-square error over a run against its length T, with the trace-norm lower bound of Equation 41.8 dotted; the optimal factorization is computed up to $T = 256$.

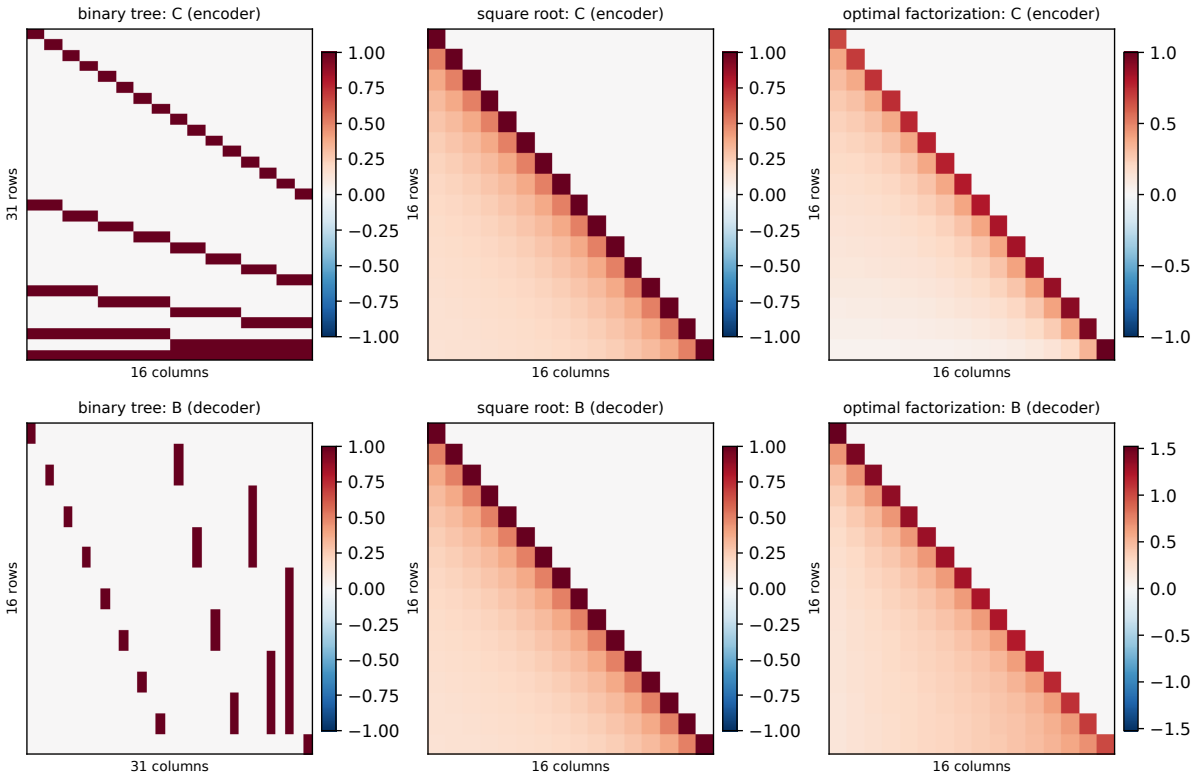

Figure 41.3.: The encoder R (top) and decoder L (bottom) of three factorizations of the 16×16 prefix-sum matrix. The tree's encoder has one row per node (31 rows), and its decoder picks the nodes of each prefix. The square root uses the same matrix for both; the optimal factorization's encoder has columns of length exactly 1.

41.6.5. Example: $T = 4$ by hand

With $r = (1, \frac{1}{2}, \frac{3}{8}, \frac{5}{16})$,

$$R = \begin{pmatrix} 1 & & & \\ \frac{1}{2} & 1 & & \\ \frac{3}{8} & \frac{1}{2} & 1 & \\ \frac{5}{16} & \frac{3}{8} & \frac{1}{2} & 1 \end{pmatrix}. \tag{41.12}$$

Row 3 times column 1 of R is $\frac{3}{8} + \frac{1}{2} \cdot \frac{1}{2} + \frac{3}{8} = 1$, and row 4 times column 1 is $\frac{5}{16} + \frac{3}{8} \cdot \frac{1}{2} + \frac{1}{2} \cdot \frac{3}{8} + \frac{5}{16} = 1$, as $R^2 = A$ requires; the script confirms $R^2 = A$ exactly. The first column has squared length $1 + \frac{1}{4} + \frac{9}{64} + \frac{25}{256} = \frac{381}{256} = 1.488$, so $\Delta_2 R = 1.220$, and the last prefix sum has error 1.488 per unit of privacy, against $\sqrt{4} = 2$ for independent noise. At $T = 100$ the same computation gives $\sum r_k^2 = 2.531$, so $\Delta_2 R = 1.591$ and the final prefix sum's error is 2.53, a quarter of independent noise's 10.

41.6.6. Check yourself

- Why are the noise coefficients h_k after the first all negative, and what would happen to the prefix-sum noise if they were positive? *(They are the coefficients of $(1 - x)^{1/2}$, whose binomial terms after the first are negative. Positive coefficients would add past noise again, so the prefix sums would drift faster than a random walk.)*
- The square root has $\Delta_2 R = 1.591$ at $T = 100$, so it needs 59% more noise per step than independent noise. Why is it still better? *(Its decoder rows have length at most 1.591 instead of up to 10: each prefix sum collects a decaying, partly cancelling combination of the noise, not t independent terms.)*

41.7. Several participations

41.7.1. Context

So far each record took part in one step, as in a single pass over the data. Training usually makes several passes, and then a record's gradient enters x at several steps, each time through a different column of R. How large is the sensitivity then, and how should the factorization change?

41.7.2. Statement

Let a record take part at steps $\tau_1 < \cdots < \tau_k$, contributing vectors $g_1, \ldots, g_k$ of length at most C, possibly chosen adaptively. Then the change in Rx is $\sum_i r_{\tau_i} g_i^\top$, and

$$(\Delta_2 R)^2 = \frac{1}{C^2} \max_{\text{patterns}} \sup_{\|g_i\| \le C} \Big\| \sum_i r_{\tau_i} g_i^\top \Big\|_F^2 = \max_{\text{patterns}} \Big\| \sum_i r_{\tau_i} \Big\|^2 \quad \text{if } R^\top R \ge 0 \text{ entrywise}, \tag{41.13}$$

the maximum over the possible participation patterns of the length of the sum of the participating columns. As before the sensitivity is in units of C, and the release is μ-GDP with $\mu = \Delta_2 R / s$. Two special cases:

- **Independent noise**, $R = I$: $\Delta_2 R = \sqrt{k}$.
- **Banded encoders.** If R is lower-triangular with nonzero entries only within b diagonals of the main one, $R_{ij} = 0$ for $i - j \geq b$, and any two participations are at least b steps apart (b-**min-separation**), then the columns of distinct participations do not overlap, and $\Delta_2 R = \left(\sum_i \|r_{\tau_i}\|^2\right)^{1/2} \leq \sqrt{k} \max_j \|r_j\|$.

41.7.3. Derivation

1. **The change in Rx.** Row τ_i of x changes by g_i, so Rx changes by $\sum_i r_{\tau_i} g_i^\top$, a sum of the same column-times-row products as in Section 41.4.
2. **Expand the norm.** $\|\sum_i r_{\tau_i} g_i^\top\|_F^2 = \sum_{i,j} (r_{\tau_i} \cdot r_{\tau_j})(g_i \cdot g_j)$, because the Frobenius inner product of $ab^\top$ and $cd^\top$ is $(a \cdot c)(b \cdot d)$.
3. **The worst gradients.** Each $g_i \cdot g_j$ lies in $[-C^2, C^2]$. If every $r_{\tau_i} \cdot r_{\tau_j}$ is nonnegative, the sum is largest when every $g_i \cdot g_j = C^2$, that is when all g_i are the same vector of length C; the sum is then $C^2 \sum_{i,j} r_{\tau_i} \cdot r_{\tau_j} = C^2 \|\sum_i r_{\tau_i}\|^2$. The entries of $R^\top R$ are exactly the inner products of columns, so the condition is $R^\top R \geq 0$, which holds for any R with nonnegative entries, such as the identity, the tree and the square root. Adaptive choices of the g_i cannot exceed this supremum; Denisov et al. (2022, Theorem 2.1) state their adaptive result for exactly this sensitivity, the supremum over neighbouring streams. Section H.5 in the appendices proves it for Gaussian noise and a lower-triangular R.
4. **Independent noise.** The columns of I are orthonormal, so $\|\sum_i e_{\tau_i}\|^2 = k$.
5. **Banded encoders.** Column τ of a b-banded R is nonzero only in rows $\tau, \ldots, \tau + b - 1$. Participations at least b apart have columns with disjoint supports, so their inner products are zero, the cross terms of step 2 vanish whatever the g_i, and the sum is $\sum_i \|r_{\tau_i}\|^2 \|g_i\|^2$.

41.7.4. Interpretation

Correlated noise makes repeated participation more expensive. Under independent noise, k participations cost $\sqrt{k}$, the usual composition of Gaussian mechanisms (Fact 4). Under the square root, the columns of nearby steps overlap and point in similar directions, so a record that appears again adds its contribution on top of its earlier one, and the sensitivity grows faster than $\sqrt{k}$. Under the tree it is worse still: a record in two steps shares all the high-level nodes covering both, and in those nodes its two contributions add.

Banding restores $\sqrt{k}$. Cutting the square root's encoder to its first b diagonals, with b the separation between participations, removes the overlaps. The decoder $L = AR^{-1}$ of the banded encoder is less accurate than the square root's for a single participation, because the band no longer spreads the noise across the whole run, but with many participations the sensitivity saving dominates. Choquette-Choo, McMahan, Rush & Thakurta (2023) optimize the factorization directly under a participation constraint for multi-epoch training, and Choquette-Choo, Ganesh, McKenna, McMahan, Rush, Thakurta & Xu (2023) show that banded factorizations can also use amplification by sampling, so that they match DP-SGD where it is strong and beat it elsewhere.

The data order is part of the mechanism. The sensitivity depends on which steps a record can occupy. A fixed permutation repeated every epoch guarantees a separation of exactly n/B steps; reshuffling every epoch can put a record at the end of one epoch and the start of the next,

one step apart, which breaks the banded bound. The order must be chosen independently of the data, and fixed in the analysis, but it need not be random.

41.7.5. Example: up to 20 epochs

Table 41.3 takes the running example's order: 100 steps per epoch, separation $b = 100$, E epochs, so $T = 100E$ and every record takes part E times. The banded encoder keeps the first 100 coefficients of the square root. The last column is the error of the final prefix sum per unit of privacy, e_T of Equation 41.7 with the multi-epoch sensitivity.

Table 41.3.: Sensitivity (in units of C) and error of the final prefix sum per unit of privacy, for E participations 100 steps apart, $T = 100E$.

Epochs E	Independent: $\Delta_2 R$ / final e_T	Tree	Square root	Banded square root
1	1.000 / 10.00	2.828 / 4.90	1.591 / 2.53	1.591 / 2.53
2	1.414 / 20.00	4.690 / 8.12	2.531 / 4.20	2.250 / 4.16
5	2.236 / 50.00	8.944 / 21.91	5.080 / 8.86	3.558 / 8.56
10	3.162 / 100.00	16.186 / 39.65	9.154 / 16.54	5.031 / 15.69
20	4.472 / 200.00	30.430 / 74.54	17.191 / 32.09	7.115 / 29.85

The banded sensitivity at 20 epochs is $\sqrt{20} \times 1.591 = 7.115$, as step 5 predicts. The full square root's is 17.191, more than twice as large, because its long columns overlap. Yet the final errors are close, 29.85 against 32.09, because the banded decoder is less accurate; both are between a sixth and a seventh of independent noise's 200.

41.7.6. Check yourself

- Does Equation 41.13 apply to the optimal factorization of Section 41.6? *(Only if its $R^\top R = X$ has no negative entries; otherwise the worst case over the g_i must be computed with signs, and can be larger than the aligned case.)*
- Why does the tree's sensitivity grow so fast with epochs? *(A node covering many steps contains several participations of the same record, and those add before the norm is taken: a top node with 20 participations contributes 20^2 to the squared sensitivity, not 20.)*

41.8. The running example: matrix mechanisms against DP-SGD

41.8.1. Context

The previous sections compared mechanisms by the error in released sums. Does that translate into accuracy when a network is trained, and how do correlated-noise mechanisms without sampling compare with DP-SGD with sampling at the same ε?

41.8.2. Statement

Table 41.4 gives the noise each method needs for $\varepsilon = 2$ and 8 at $\delta = 10^{-5}$, and the standard deviation of the noise carried by the final prefix sum, in units of C. Table 41.5 gives the test accuracy, at the better of two learning rates, 0.5 and 2, averaged over three runs.

Table 41.4.: Noise needed by each method at equal ε ($\delta = 10^{-5}$, 100 steps per epoch) and the resulting noise in the final prefix sum, all in units of C. DP-SGD uses Poisson sampling with $q = 0.01$ and the Rényi differential privacy (RDP) accountant; the others use a fixed order and exact Gaussian accounting.

ε, epochs	DP-SGD σ	Independent s	Tree s	Square root s	Banded s	Final prefix noise: DP-SGD / independent / tree / square root / banded
2, 1	0.827	1.994	5.639	3.172	3.172	8.27 / 19.94 / 9.77 / 5.05 / 5.05
2, 5	0.928	4.458	17.833	10.129	7.093	20.75 / 99.69 / 43.68 / 17.67 / 17.06
2, 10	1.03	6.305	32.273	18.251	10.031	32.57 / 199.38 / 79.05 / 32.98 / 31.28
8, 1	0.501	0.600	1.698	0.955	0.955	5.01 / 6.00 / 2.94 / 1.52 / 1.52
8, 5	0.573	1.342	5.369	3.049	2.135	12.81 / 30.01 / 13.15 / 5.32 / 5.14
8, 10	0.616	1.898	9.716	5.495	3.020	19.48 / 60.02 / 23.80 / 9.93 / 9.42

Table 41.5.: Test accuracy (mean ± standard deviation over three runs) at equal ε, $\delta = 10^{-5}$, batch 100, clipping norm 0.5, best of learning rates 0.5 and 2. Without noise, fixed-order training with clipping reaches 0.9420, 0.9580 and 0.9606 after 1, 5 and 10 epochs.

ε, epochs	DP-SGD (Poisson)	Independent	Tree	Square root	Banded square root
2, 1	0.9343 ± 0.0044	0.9066 ± 0.0031	0.9134 ± 0.0038	0.9361 ± 0.0046	0.9358 ± 0.0019
2, 5	0.9460 ± 0.0021	0.8941 ± 0.0071	0.9183 ± 0.0084	0.9430 ± 0.0011	0.9456 ± 0.0019
2, 10	0.9493 ± 0.0012	0.8641 ± 0.0130	0.9096 ± 0.0074	0.9398 ± 0.0029	0.9491 ± 0.0024
8, 1	0.9371 ± 0.0016	0.9395 ± 0.0018	0.9412 ± 0.0006	0.9461 ± 0.0022	0.9434 ± 0.0017
8, 5	0.9524 ± 0.0026	0.9420 ± 0.0029	0.9461 ± 0.0012	0.9497 ± 0.0025	0.9542 ± 0.0014
8, 10	0.9520 ± 0.0006	0.9410 ± 0.0032	0.9484 ± 0.0004	0.9530 ± 0.0015	0.9549 ± 0.0024

41.8.3. Derivation

Each entry is computed as the earlier sections prescribe. For DP-SGD, the RDP accountant of DP-SGD finds the smallest σ for $q = 0.01$, $T = 100E$ steps and the target ε; its final prefix sum carries T independent noises, $\sigma\sqrt{T}$. For the fixed-order methods, the sensitivity of Equation 41.13 for E participations 100 steps apart (Table 41.3) is divided by $\mu(\varepsilon, \delta)$ from Fact 1 to give the noise scale s; for independent noise this is Fact 4, $s = \sqrt{E}/\mu$. The final prefix sum's noise is s times the length of the last row of the decoder (Fact 3). Training then runs Equation 41.3 with the noise of each factorization: the per-step noise $R^{-1}z$ for the square-root and banded encoders, generated by a convolution in time, and the tree's node noises summed along the binary decompositions, with consecutive differences taken as the per-step noise.

41.8.4. Interpretation

Without amplification, correlated noise is essential. At $\varepsilon = 2$, fixed-order SGD with independent noise loses 2.8 points to DP-SGD after one epoch and 8.5 points after ten (0.8641 against 0.9493), and it gets worse with more epochs, because its noise grows like $\sqrt{E}$ per step and accumulates like $\sqrt{T}$. The tree recovers between a quarter and a half of the gap. The square root and the banded square root recover nearly all of it: at ten epochs the banded encoder reaches 0.9491, within 0.0002 of DP-SGD.

Matrix mechanisms can beat amplified DP-SGD. For short runs and large ε, amplification gains little. At $\varepsilon = 8$ and one epoch, DP-SGD needs $\sigma = 0.501$ and independent noise without sampling 0.600, barely more, and the square root, whose final prefix sum carries 1.52 against DP-SGD's 5.01, wins outright (0.9461 against 0.9371). At $\varepsilon = 8$ the banded encoder has the highest mean accuracy at five and ten epochs. At $\varepsilon = 2$ and one epoch the square root's final

noise, 5.05, is also below DP-SGD's 8.27, and its accuracy is the same within the run-to-run spread.

Where DP-SGD keeps its lead. At small ε over many epochs, amplification is strongest: DP-SGD's per-step noise grows only from 0.827 to 1.03 between one and ten epochs at $\varepsilon = 2$, while every fixed-order mechanism pays for ten participations. The full square root then falls behind (0.9398 against 0.9493), because its overlapping columns make repeated participation expensive, and only banding keeps up. The final-prefix noise is a good guide: the method with the least of it is the most accurate or within the spread of the most accurate in every row.

The comparison is slightly tilted. DP-SGD is accounted with the RDP accountant, which overstates ε somewhat compared with a numerical accountant (Choosing an accountant), while the fixed-order mechanisms use the exact Gaussian curve of Fact 1. A tighter DP-SGD accountant would lower its noise somewhat. The learning rate was chosen per method from two values by test accuracy, which is itself a leak that Hyperparameter tuning accounts for; here it serves only to compare methods at their best. The runs are short, at most 1,000 steps, to keep the script under a few minutes. The noise gaps of Table 41.3 keep widening with the number of epochs, so longer runs should separate the methods more, not less.

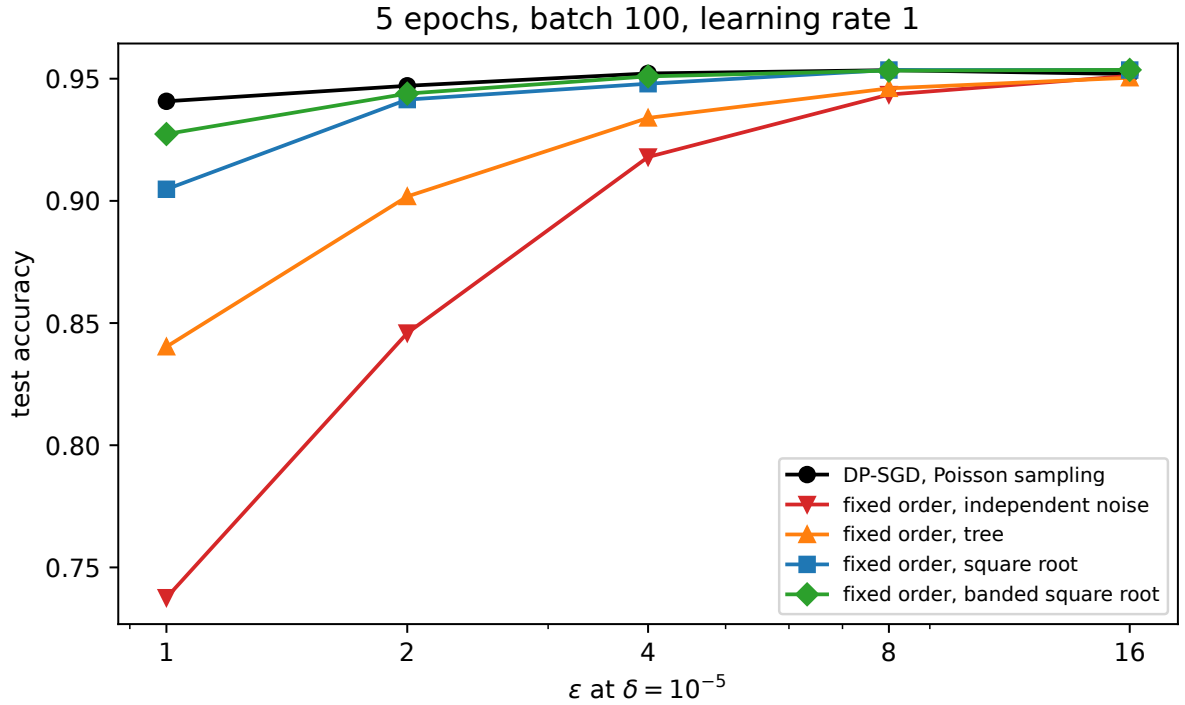

Figure 41.4.: Test accuracy of the running example after 5 epochs (500 steps of batch 100) at learning rate 1, against ε at $\delta = 10^{-5}$, one run per point. DP-SGD uses Poisson sampling; the other four use a fixed data order and differ only in how their noise is correlated.

Figure 41.4 shows the same pattern across budgets at five epochs: independent noise collapses at small ε, the tree is better, and the two square-root encoders track DP-SGD, with the banded one closest.

41.8.5. Example: what a federated deployment gains

In federated learning a "record" is a device, which checks in when it is idle, charging and on Wi-Fi; the server cannot sample devices independently with a known rate, so the Poisson accountant does not apply. Suppose the server can at least enforce that a device contributes at most once every b rounds, a b-min-separation. Then the banded matrix mechanism of Section 41.7 gives a provable guarantee with sensitivity $\sqrt{k}$ times one column for k participations, and on the running example's scale it is as accurate as DP-SGD with sampling would be. That is why production federated training of language models uses DP-FTRL (Xu et al. 2023), and why later work optimizes matrix factorizations for user-level training of language models (Choquette-Choo, McMahan, Rush & Thakurta 2023). The privacy unit there is a user, not an example, which User-level differential privacy treats.

41.8.6. Check yourself

- In Table 41.5, independent noise at $\varepsilon = 2$ gets worse from one epoch to ten. Why does more training hurt it? *(Each extra epoch adds a participation, so the noise scale grows like $\sqrt{E}$, from 1.994 to 6.305 between one and ten epochs: every update carries three times more noise, while each update's signal stays the same size or shrinks as the model converges.)*
- When would you still choose DP-SGD over a matrix mechanism? *(When you can implement Poisson sampling honestly and ε is small with many epochs, where amplification is strongest; or when the participation pattern is unknown, so no sensitivity for a correlated mechanism can be computed. Banded mechanisms with amplification combine both.)*

41.9. Code: check every number by computation

The script code/matrix_mechanisms.py builds the identity, prefix, tree, square-root and optimal factorizations, computes their sensitivities and errors (by structured formulas, checked against dense matrices at $T = 256$ to a relative difference of 3.3×10^{-16}), computes multi-epoch sensitivities, and trains the running example in a fixed order with each mechanism's correlated noise, against DP-SGD from code/dp_sgd.py. From the repository root:

```
uv run python code/part05-dp-ml/matrix_mechanisms.py
```

Output (seed 0), summarized in Table 41.6:

Table 41.6.: The script's output with the default seed.

Experiment	Result
Square-root coefficients and inverse	$r = 1, 0.5, 0.375, 0.3125, ...$; $h = 1, -0.5, -0.125, -0.0625, ...$; $R^2 = A$ exactly at $T = 4$
One participation, $T = 100$	Root-mean-square error 7.11 (independent), 5.05 (tree), 2.37 (square root), 2.24 (optimal), bound 2.18

Experiment	Result
One participation, $T = 10{,}000$	70.71, 9.84, 3.84; bound 3.63
20 epochs, sensitivity	4.472 (independent), 30.430 (tree), 17.191 (square root), 7.115 (banded)
Accuracy, $\varepsilon = 2$, 10 epochs	DP-SGD 0.9493, independent 0.8641, tree 0.9096, square root 0.9398, banded 0.9491
Accuracy, $\varepsilon = 8$, 1 epoch	DP-SGD 0.9371, independent 0.9395, square root 0.9461

tests/test_matrix_mechanisms.py checks that the output still matches. The script takes about two minutes of processor time, most of it for the 198 training runs behind Table 41.5.

What to take from it. A correlated-noise mechanism is a few lines on top of noisy SGD: store the past noise, and add a fixed combination of it to each step. What takes care is the sensitivity, which depends on the data order and the number of participations, and must be computed for the order you actually use.

41.11. Cheat sheet

T steps, clipping norm C, workload A (prefix sums), factorization $A = LR$, noise z with standard deviation sC, one participation unless stated. Table 41.7 collects the results.

Table 41.7.: Every result of the chapter.

Result	Formula	Conditions
Training releases prefix sums	$\theta_{t+1} = \theta_0 - \frac{\eta}{B}\hat{S}_t$	Gradient descent or FTRL, no momentum
Matrix mechanism	$\hat{S} = L(Rx + z) = Ax + Lz$	L, R lower-triangular for streaming
Privacy	$\mu = \Delta_2 R/s$, $\Delta_2 R = \max_j \|r_j\|$	One participation; adaptive inputs allowed
Error	$\mathrm{sd}(\hat{S}_t - S_t) = sC\|\ell_t\| = \frac{C}{\mu}\max_j \|r_j\|\,\|\ell_t\|$	Per coordinate
Lower bound	$\max_j \|r_j\|\,\|L\|_F/\sqrt{T} \geq \|A\|_*/T$	Any factorization
Independent noise	$R = I$: $\Delta_2 R = 1$, error $\sqrt{t}$	DP-SGD without amplification
Binary tree	$\Delta_2 R = \sqrt{\lceil \log_2 T \rceil + 1}$, error $\times\sqrt{\mathrm{popcount}(t)}$	DP-FTRL
Square root	$r_k = \binom{2k}{k}4^{-k}$; $(\Delta_2 R)^2 = \max$ error $= \sum_{k<T} r_k^2 \approx (\ln T + 3.35)/\pi$	$L = R = A^{1/2}$; noise $\zeta = R^{-1}z$
Several participations	$\Delta_2 R = \max \|\sum_i r_{\tau_i}\|$	$R^\top R \geq 0$
Banded encoder	$\Delta_2 R = \sqrt{\sum_i \|r_{\tau_i}\|^2}$	Band $\leq$ separation of participations

Rules of thumb

- If you cannot implement Poisson sampling, do not account as if you did. Fix the data order in advance and use a matrix mechanism.
- For one pass over the data, use the square-root factorization: it is within about 10% of the best possible error and costs nothing to compute.

- For several passes, fix the order so participations are evenly separated, and use a banded encoder whose band is at most the separation.
- Compute the sensitivity for the participation pattern you actually have; reshuffling every epoch changes it.
- Compare methods by the noise in the final prefix sum at equal ε: on the running example, the method with the least of it was the most accurate, or within the run-to-run spread of the most accurate, in every configuration.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

42. Private prediction: PATE and in-context learning

42.1. Why this matters

Training a model with differential privacy (DP) by stochastic gradient descent (SGD) with clipped and noisy gradients, DP-SGD (DP-SGD), makes the trained weights private. Every later use of the model is then free: anyone may download the weights and query them as often as they like, because releasing the weights was the private step and everything after it is post-processing. The price is paid during training. Every step adds noise to every gradient, the training code must compute and clip per-example gradients, and you must own the training loop.

Sometimes that price is the wrong one to pay, or cannot be paid at all. The model may be a large language model (LLM) behind an application programming interface, which you can prompt but not train. It may be a model that someone else trains, or one with no gradients, such as a forest of decision trees. Or it may answer only a few dozen questions in its whole life, a medical consultation tool for one study, for which a private training run is overkill. In each case there is another option: train ordinary, non-private models, **never release them**, and make each *answer* private instead. A query goes in, a differentially private answer comes out, and the models themselves stay behind a wall.

This chapter asks when that is the better choice and how to make it work. It answers with DP applied to predictions rather than to weights. Two questions organize it. How much does each private answer cost, and how many can you afford? And how do you turn a stream of private answers into a private model, so that the cost stops growing? The answer to the second question is private aggregation of teacher ensembles (PATE), introduced by Papernot, Abadi, Erlingsson, Goodfellow and Talwar (2017). Its modern descendant privatizes in-context learning: the private examples are placed in an LLM's prompt rather than used for training.

42.1.1. The one idea: one record, one vote

Split the private records into k disjoint shards, and train one model, a **teacher**, on each. To answer a query x, let every teacher vote for a label and release only the label with the most votes after adding noise to the counts. A record lives in exactly one shard, so it influences exactly one teacher, and that teacher casts exactly one vote. Adding or removing the record can therefore move at most one vote from one label to another, whatever the teachers are, however they were trained, and however badly one of them overfits its shard. The privacy proof stops there. It is the subsample-and-aggregate idea of Beyond global sensitivity, with a vote as the aggregator.

Everything else is about accuracy, and it comes down to one comparison: the **gap** between the top two vote counts against the noise. When the teachers agree, the gap is large and the noisy winner is almost always the true plurality. When they disagree, the noise decides. And the noise must grow like the square root of the number of answered queries, because each answer spends

budget. So private prediction is cheap for a few queries on which the teachers agree, and expensive otherwise. Table 42.1 lists the results.

Table 42.1.: The results of this chapter and where each is used.

Result	Where it is used
The noisy vote, LNMax and GNMax, and its cost per answer	Every private-prediction system; the noise needed for Q queries
The accuracy of a noisy vote: the gap against the noise	Choosing the number of teachers
Private answers against a private model: the break-even number of queries	Deciding between private prediction and DP-SGD
PATE: a student trained on privately labelled public data	Turning answers into a model whose use is free
Data-dependent analysis and Confident-GNMax	Paying less for answers the teachers agree on; what must be sanitized
Stable aggregation: distance to instability and sparse vector	Exact labels and a budget fixed in advance, paid only for contested queries
Private in-context learning	Prompting an LLM with private examples

Notation. A private dataset D has n records and is split into k disjoint shards of n/k records, one per teacher. A query x has m possible labels; $N_i(x)$ is the number of teachers that vote for label i, so $\sum_i N_i(x) = k$, and i^* is the label with the most votes, the **plurality**. The **gap** is the difference between the top count and the runner-up; on two labels it is $|N_1 - N_2|$. The noise on each count is $\mathcal{N}(0, \sigma^2)$ for GNMax and $\mathrm{Lap}(b)$ for LNMax. Q is the number of answered queries, $\alpha > 1$ an order of Rényi differential privacy (RDP), and $\tilde{\beta}$ an upper bound on the probability that the noisy winner differs from the plurality. Neighbouring datasets differ by **adding or removing** one record, as in DP-SGD, and $\delta = 10^{-5}$ throughout.

The running example. The part's neural-network task (DP-SGD): 50-dimensional standard normal inputs labelled ± 1 by a fixed random network, $n = 10{,}000$ private training records. Its 20,000 test records are split in two. The first 10,000 form a **public pool**: their inputs are treated as public and unlabelled, as PATE requires, and their labels are used only to measure how good the private labels are. The last 10,000 form the **evaluation set**, on which every accuracy in this chapter is measured. The teachers are regularized logistic regressions, the model of Private empirical risk minimization, each fitted on one shard of consecutive records. Logistic regression is cheap and, on this task, as accurate as the part's network on the same few records.

How to read this chapter. Read the toolkit and Section 42.3, which give the mechanism and its cost. Section 42.4 and Section 42.5 answer the question in the title: when private answers beat a private model. Section 42.6 builds PATE, and Section 42.7 the analysis that makes it competitive in practice; the second is the most technical section and can be skimmed for its statement and interpretation. Section 42.8 gives the alternative that needs no sanitizing, and why it is rarely used. Section 42.9 applies everything to in-context learning.

42.2. Toolkit: four facts every derivation uses

42.2.1. Fact 1 — One record changes one vote

Fix the partition of records into shards *before* looking at the data, by a hash of a record identifier rather than by position. Adding or removing a record then changes one shard, the one its hash points to, and leaves every other shard, and so every other teacher, exactly as it was. That teacher may now vote differently on a query: one count goes down by 1 and another goes up by 1, or nothing changes. The vote histogram $(N_1(x), \dots, N_m(x))$ therefore moves by at most 2 in ℓ_1 norm, the sum of absolute changes, and by at most $\sqrt{1^2 + 1^2} = \sqrt{2}$ in ℓ_2 norm, the Euclidean length of the change. This is the step of subsample-and-aggregate in Beyond global sensitivity: one record touches one block.

The partition rule matters. If shards were cut by position, inserting one record at the front would shift every later record into the next shard, change every shard, and possibly change every teacher. The derivations below assume a fixed hash; the script splits the records by position only because they are never added or removed in its experiments.

42.2.2. Fact 2 — The Gaussian mechanism in Rényi DP, and its accountant

Adding $\mathcal{N}(0, s^2)$ noise to every coordinate of a vector-valued function f whose value moves by at most $\Delta_2 f$ in ℓ_2 norm between neighbours gives a mechanism whose Rényi divergence of order α between neighbours is at most $\alpha(\Delta_2 f)^2/(2s^2)$ (Rényi DP). The **Rényi divergence** of order α between two distributions P and P' on a discrete set of outputs is

$$D_\alpha(P\|P') = \frac{1}{\alpha - 1} \ln \sum_y P(y)^\alpha P'(y)^{1-\alpha}, \tag{42.1}$$

and a mechanism is $(\alpha, \varepsilon(\alpha))$-RDP if this is at most $\varepsilon(\alpha)$ for every pair of neighbours. Three properties make RDP the accountant here. Any computation on a private output that does not touch the data again, **post-processing**, cannot increase the divergence. RDP curves **add** under composition, even when each mechanism is chosen after seeing the earlier outputs. And a composed curve converts to (ε, δ)-DP at the best order,

$$\varepsilon = \min_\alpha \left[\varepsilon(\alpha) + \ln \frac{\alpha - 1}{\alpha} - \frac{\ln \delta + \ln \alpha}{\alpha - 1} \right] \tag{42.2}$$

(Balle et al. 2020; From Rényi DP to (ε, δ)). When the curve is a line, $\varepsilon(\alpha) = \rho\alpha$, the result depends only on its slope ρ: at $\delta = 10^{-5}$, the largest slope that converts to $\varepsilon = 1$ is $\rho = 0.0306$, and to $\varepsilon = 4$ it is $\rho = 0.3731$. A pure Gaussian mechanism also has an exact conversion: its privacy is that of one Gaussian shift by $\mu = \Delta_2 f / s$ standard deviations, Gaussian differential privacy (GDP) with parameter μ, and composing Q of them gives $\mu\sqrt{Q}$ (f-DP and Gaussian DP).

42.2.3. Fact 3 — Report-noisy-max, and the RDP curve of any pure-DP step

Report-noisy-max adds independent Laplace noise $\mathrm{Lap}(b)$ to every candidate's score and releases only the index of the largest noisy score (Selection). If one record moves each score by at most Δu, it is $(2\Delta u/b)$-DP. The reason is that, with every other candidate's noise held fixed, candidate i wins exactly when its own noise clears a bar, the best of the others' noisy scores minus its own score. One record moves that bar by at most $2\Delta u$, Δu through the maximum of the others and Δu through candidate i's own score, and moving a Laplace threshold by s changes its tail probability by at most $e^{s/b}$. When all scores move in the same direction, the factor 2 disappears. A vote histogram is not of that kind: one count goes up while another goes down.

An ε_0-DP mechanism also has an RDP curve. The worst ε_0-DP mechanism at every order is randomized response, which reports a bit truthfully with probability $p = e^{\varepsilon_0}/(1 + e^{\varepsilon_0})$, so its curve,

$$\varepsilon_{\mathrm{RR}}(\alpha) = \frac{1}{\alpha - 1} \ln \left(p^\alpha (1-p)^{1-\alpha} + (1-p)^\alpha p^{1-\alpha}\right), \tag{42.3}$$

is a valid RDP curve for any ε_0-DP step (Concentrated differential privacy). This lets Laplace answers enter the same accountant as Gaussian ones.

42.2.4. Fact 4 — The difference of two independent Gaussians

If Z_1 and Z_2 are independent $\mathcal{N}(0, \sigma^2)$, then $Z_1 - Z_2$ is $\mathcal{N}(0, 2\sigma^2)$: variances of independent variables add, and subtracting does not change a variance. So $\Pr[Z_1 - Z_2 > t] = \Phi(-t/(\sqrt{2}\sigma))$, where Φ is the standard normal cumulative distribution function. In terms of the complementary error function erfc, which numerical libraries provide, $\Phi(-u) = \frac{1}{2}\,\mathrm{erfc}(u/\sqrt{2})$, so $\Pr[Z_1 - Z_2 > t] = \frac{1}{2}\,\mathrm{erfc}(t/(2\sigma))$. Every accuracy statement about GNMax uses this, because whether a noisy vote picks label i over label j depends only on the difference of their two noises.

42.3. The noisy vote: LNMax and GNMax

42.3.1. Context

A query arrives, the k teachers vote, and you must release one label. Which mechanism releases it, and how much does each answer cost? Two mechanisms are used in practice, and they differ in their noise: Laplace noise in the original PATE paper, Gaussian noise in its successor. The question is also how the cost of Q answers grows with Q, since that is what limits private prediction.

42.3.2. Statement

LNMax releases $\arg\max_i \left(N_i(x) + \mathrm{Lap}(b)\right)$ and **GNMax** releases $\arg\max_i \left(N_i(x) + \mathcal{N}(0, \sigma^2)\right)$, with independent noise on every count. Under add/remove neighbours and a fixed partition:

1. Each LNMax answer is $(2/b)$-DP (Papernot et al. 2017).
2. Each GNMax answer is $(\alpha, \alpha/\sigma^2)$-RDP for every $\alpha > 1$ (Papernot, Song, Mironov, Raghunathan, Talwar & Erlingsson 2018, Proposition 8).

3. Q GNMax answers, even with queries chosen adaptively, are $(\alpha, Q\alpha/\sigma^2)$-RDP. To meet a budget (ε, δ) the noise must therefore be

$$\sigma = \sqrt{\frac{Q}{\rho(\varepsilon, \delta)}}, \tag{42.4}$$

where $\rho(\varepsilon, \delta)$ is the largest slope whose line $\rho\alpha$ converts to (ε, δ) by Equation 42.2. The noise grows like $\sqrt{Q}$.

42.3.3. Derivation

1. **The histogram's sensitivity.** By Fact 1, one record moves the vote vector by at most 2 in ℓ_1 norm and $\sqrt{2}$ in ℓ_2 norm.
2. **LNMax is report-noisy-max.** The counts are the scores, each moves by at most $\Delta u = 1$, and they can move in opposite directions. Fact 3 with $\Delta u = 1$ gives $(2/b)$-DP.
3. **GNMax is post-processing of a Gaussian histogram.** Adding $\mathcal{N}(0, \sigma^2)$ to every count is the Gaussian mechanism on a vector with ℓ_2 sensitivity $\sqrt{2}$, so by Fact 2 its RDP is $\alpha(\sqrt{2})^2/(2\sigma^2) = \alpha/\sigma^2$. Taking the argmax and discarding the noisy counts is post-processing, which cannot increase it.
4. **Compose.** Each answer is $(\alpha, \alpha/\sigma^2)$-RDP whatever the earlier answers were, so Q answers add up to $Q\alpha/\sigma^2$ (Fact 2). This holds even if the analyst chooses query t after seeing answers $1, \ldots, t-1$.
5. **Calibrate.** The composed curve is the line $\rho\alpha$ with $\rho = Q/\sigma^2$, and its ε depends only on ρ. Setting $Q/\sigma^2 = \rho(\varepsilon, \delta)$ and solving for σ gives Equation 42.4.

42.3.4. Interpretation

The cost is per answer, not per teacher. Neither the number of teachers nor what they are enters the privacy cost. A teacher can be a neural network trained without any noise, a decision forest, or a human annotator who saw one shard. The cost is set by the noise and the number of answers, and the noise can be large in absolute terms because the counts themselves are large: with 250 teachers, noise of standard deviation 40 on each count is noticeable but not overwhelming.

Gaussian noise wins for many queries, Laplace for very few. A Laplace answer is analysed as a pure-DP step, which pays for the worst case of every answer; a Gaussian answer has a privacy loss that is itself Gaussian and composes exactly. For one answer the pure-DP analysis is cheap, and as answers accumulate the Gaussian's analysis wins. Table 42.2 compares the noise each needs, expressed as a standard deviation ($\sqrt{2}b$ for Laplace). For a single answer, Laplace needs less noise. From 100 answers on, Gaussian noise is smaller by a factor close to 2 at both budgets, and the gap persists, since both grow like $\sqrt{Q}$ once the composition is in its square-root regime.

Only the label is released. As in report-noisy-max, publishing the noisy counts as well would release a vector, and step 3 would no longer apply to the published output; the analysis would then have to pay for all m counts as a release in their own right. GNMax happens to have a valid analysis for the noisy counts too, since it is a Gaussian mechanism, but the data-dependent analysis of Section 42.7 needs the label alone.

How tight is the RDP accountant here? A Gaussian histogram has an exact conversion (Fact 2). At the σ the RDP accountant picks for $\varepsilon = 1$, the exact ε is 0.915, and for $\varepsilon = 4$ it is 3.698: the accountant overstates ε by about 9% and 8%. The ratio is the same for every Q because both depend only on Q/σ^2.

42.3.5. Example: the noise for Q answers

Table 42.2 gives the noise for four numbers of answers at $\varepsilon = 1$ and $\varepsilon = 4$.

Table 42.2.: Noise per count for Q answers at $(\varepsilon, 10^{-5})$, from the RDP accountant; Laplace answers are charged the randomized-response curve of Fact 3.

Budget	Answers Q	GNMax σ	LNMax b	LNMax standard deviation $\sqrt{2}b$
$\varepsilon = 1$	1	5.72	2.02	2.85
	100	57.2	79.7	113
	1,000	181	255	361
	10,000	572	809	1,140
$\varepsilon = 4$	1	1.64	0.501	0.709
	100	16.4	22.7	32.1
	1,000	51.8	73.1	103
	10,000	164	231	327

The $\sqrt{Q}$ law of Equation 42.4 is exact here: from 100 to 10,000 answers, a hundredfold increase, σ grows tenfold, from 57.2 to 572. That is what makes 10,000 answers at $\varepsilon = 1$ hopeless for any ensemble of fewer than a few thousand teachers: noise of standard deviation 572 on each count swamps any vote.

Figure 42.1 shows what the noise does to real votes. With $k = 100$ teachers on the running example and the noise for 1,000 answers at $\varepsilon = 4$, $\sigma = 51.8$, a query on which 98 teachers vote -1 and 2 vote $+1$, a gap of 96, gets the plurality label with probability 0.9051. A query split 70 to 30, gap 40, gets it with probability 0.7076, and one split 52 to 48, gap 4, with probability 0.5218, barely better than a coin. Across the public pool, the fraction of teachers voting $+1$ piles up near 0 and 1, but a large share of queries sits in between.

42.3.6. Check yourself

- You double the number of teachers and keep Q and ε. Does σ change? *(No. Equation 42.4 does not contain k: one record still moves one vote. What changes is the counts, which are now twice as large, so the same noise matters less if the teachers agree as much as before.)*
- Why would publishing the noisy winning count along with the label break the LNMax analysis? *(The report-noisy-max proof conditions on the other candidates' noise and integrates over the winner's own noise. Publishing the winner's noisy count publishes that noise, which the proof assumed stays hidden.)*

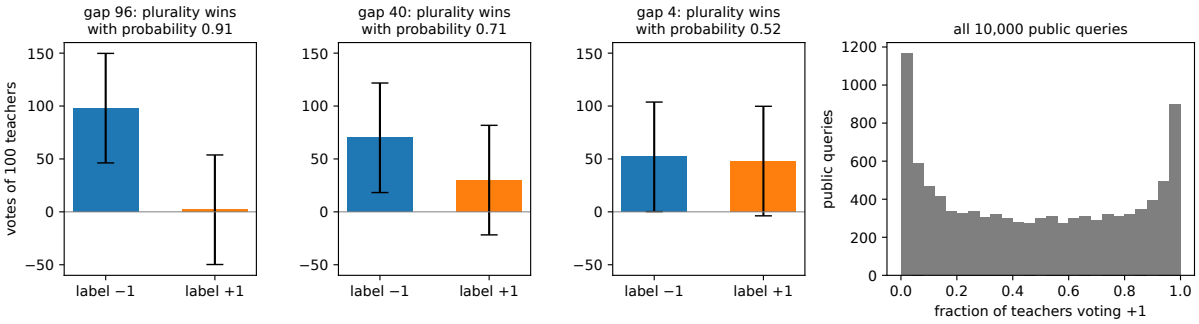

Figure 42.1.: Left three panels: the votes of 100 teachers on three public queries, with bars of one noise standard deviation ($\sigma = 51.8$, the GNMax noise for 1,000 answers at $\varepsilon = 4$); the title gives the probability that the noisy vote returns the plurality label. Right: across all 10,000 public queries, the fraction of the 100 teachers voting +1.

42.4. How accurate is a noisy vote

42.4.1. Context

The cost of an answer does not depend on the teachers. Its accuracy depends on little else. How likely is the noisy vote to return the plurality label, and how should you choose the number of teachers k, given that more teachers means fewer records each?

42.4.2. Statement

On two labels, GNMax returns the plurality label with probability

$$\Pr[\text{plurality}] = \Phi\Big(\frac{g}{\sqrt{2}\,\sigma}\Big), \tag{42.5}$$

where g is the gap. On m labels, the probability that it returns anything other than the plurality i^* is at most

$$\tilde{\beta} = \sum_{i \neq i^*} \frac{1}{2} \operatorname{erfc}\left(\frac{N_{i^*} - N_i}{2\sigma}\right) \tag{42.6}$$

(Papernot et al. 2018, Proposition 7). If a fraction $a(x)$ of the k teachers vote for the correct label on a two-label query x, the gap measured toward the correct label is $k(2a(x) - 1)$, and the expected accuracy of the private answers is the average of $\Phi(k(2a(x) - 1)/(\sqrt{2}\sigma))$ over queries.

42.4.3. Derivation

1. **Two labels.** GNMax returns label 1 when $N_1 + Z_1 > N_2 + Z_2$, that is when $Z_2 - Z_1 < N_1 - N_2$. By Fact 4, $Z_2 - Z_1$ is $\mathcal{N}(0, 2\sigma^2)$, so this has probability $\Phi((N_1 - N_2)/(\sqrt{2}\sigma))$. With label 1 the plurality, $N_1 - N_2 = g$: Equation 42.5.

2. **Many labels.** GNMax returns some $i \neq i^*$ only if $N_i + Z_i > N_{i^*} + Z_{i^*}$ for at least one i. The probability that at least one of several events happens is at most the sum of their probabilities (the union bound), and each has probability $\frac{1}{2}\operatorname{erfc}((N_{i^*} - N_i)/(2\sigma))$ by Fact 4: Equation 42.6.
3. **Accuracy toward the truth.** Measure the gap toward the correct label instead of the plurality: it is the number of teachers that are right minus the number that are wrong, $ka - k(1-a) = k(2a-1)$, negative when most teachers are wrong. Step 1 with this signed gap gives the probability of a correct answer, and averaging over queries gives the expected accuracy.

42.4.4. Interpretation

The trade-off in k. For a fixed number of answers and budget, σ is fixed (Equation 42.4), and the signal is $k(2a-1)$. More teachers multiply the signal by k; but each teacher sees n/k records, is less accurate, and agrees less with the others, so $2a-1$ shrinks. Whether to add teachers depends on which effect wins. When the teachers' accuracy falls slowly with shard size, as it does for a model that learns from few examples, more teachers win; when a teacher needs many records to be any good, fewer teachers are better.

The ceiling. Without noise, the plurality vote is an ensemble, and its accuracy is the best any private answer can reach. Noise can only pull answers toward a coin flip. On queries the teachers find hard, where $a(x)$ is near $\frac{1}{2}$, any noise at all makes the answer close to random; this is the part of the accuracy that noise destroys first.

How tight is Equation 42.6? For two labels it is exact, since there is only one competitor. For many labels it adds the probabilities of beating the plurality one competitor at a time, which double-counts the outcomes where several competitors beat it. It is close when one competitor dominates the error and loose when many are nearly tied with the plurality.

42.4.5. Example: teachers on the running example

Table 42.3 splits the 10,000 private records among 25 to 500 teachers.

Table 42.3.: Teachers on the running example, measured on the evaluation set: each teacher's accuracy, the accuracy of the noiseless plurality vote, and the median gap as a fraction of the number of teachers.

Teachers k	Records each	Mean teacher accuracy	Plurality vote accuracy	Median $\lvert g\rvert/k$
25	400	0.8954	0.9403	1.000
50	200	0.8518	0.9389	0.880
100	100	0.7896	0.9384	0.660
250	40	0.7031	0.9336	0.408
500	20	0.6459	0.9339	0.276

The teachers get much worse as their shards shrink, from 0.8954 with 400 records to 0.6459 with 20, but the plurality vote hardly moves, between 0.9336 and 0.9403. Averaging many weak linear

classifiers recovers most of what one classifier on all the data would learn. The relative gap falls from 1.000 to 0.276, but the absolute median gap grows, from 25 to $0.276 \times 500 = 138$. Since the noise does not depend on k, more teachers win here. Table 42.4 puts numbers on it.

Table 42.4.: Expected accuracy of Q GNMax answers on the evaluation set, computed exactly from Equation 42.5 and each query's vote gap.

Budget	Answers Q	σ	$k = 25$	$k = 50$	$k = 100$	$k = 250$	$k = 500$
$\varepsilon = 1$	100	57.2	0.5961	0.6651	0.7461	0.8250	0.8588
	1,000	180.9	0.5308	0.5546	0.5889	0.6489	0.6987
	10,000	572.1	0.5097	0.5173	0.5285	0.5498	0.5709
$\varepsilon = 4$	100	16.4	0.7899	0.8803	0.9064	0.9185	0.9237
	1,000	51.8	0.6059	0.6805	0.7641	0.8378	0.8682
	10,000	163.7	0.5340	0.5602	0.5979	0.6625	0.7140

With 100 answers at $\varepsilon = 4$, 500 teachers answer with accuracy 0.9237, about 1 point below their noiseless vote, 0.9339. With 1,000 answers at $\varepsilon = 1$, even 500 teachers fall to 0.6987, and 25 teachers, whose gaps never exceed 25, to 0.5308, a coin flip with a slight bias.

42.4.6. Check yourself

- A query has 250 teachers split 175 to 75. With $\sigma = 40$, what is the probability that GNMax returns the plurality? *(The gap is 100, so* $\Phi(100/(\sqrt{2} \times 40)) = \Phi(1.77) \approx 0.96$*.)*
- Why does the plurality accuracy in Table 42.3 barely depend on k, when the teachers' own accuracy drops by 25 points? *(Each teacher's error is mostly its own sampling noise on a small shard, and these errors are close to independent across shards; a majority of many weak but independent voters is right much more often than any one of them.)*

42.5. Private answers against a private model

42.5.1. Context

Here is the question of the title in its sharpest form. You have a budget (ε, δ). You can spend it on training one model with DP-SGD, whose answers are then free, or on answering queries one at a time with a teacher ensemble. Which gives more accurate answers, and how does the answer depend on how many queries you expect?

42.5.2. Statement

Let $A_{\text{model}}(\varepsilon)$ be the accuracy of a privately trained model at budget ε; it does not depend on how many queries the model answers. Let $A_{\text{vote}}(Q, \varepsilon)$ be the expected accuracy of Q private answers at

the same budget, with σ from Equation 42.4. Then $A_{\text{vote}}(Q, \varepsilon)$ decreases in Q, from the noiseless vote's accuracy toward $\frac{1}{2}$ (on two labels), and private answers are better exactly for

$$Q < Q^*(\varepsilon) = \max\{Q : A_{\text{vote}}(Q, \varepsilon) \geq A_{\text{model}}(\varepsilon)\}, \tag{42.7}$$

with $Q^* = 0$ when even one answer is worse than the model.

42.5.3. Derivation

1. **The model's accuracy is constant in Q.** Every query to a released model is post-processing of its weights (Fact 2), so its answers cost nothing and are exactly as accurate as the model.
2. **The vote's accuracy falls with Q.** By Equation 42.4, σ grows like $\sqrt{Q}$. Each query's probability of a correct answer, $\Phi(g/(\sqrt{2}\sigma))$ with its signed gap g, decreases in σ when $g > 0$ and increases toward $\frac{1}{2}$ when $g < 0$; as $\sigma \to \infty$ every term tends to $\frac{1}{2}$. On this task the plurality is correct on most queries, and the average decreases in Q throughout the range shown here.
3. **Break-even.** A decreasing function crosses a constant at most once, at Q^*.

42.5.4. Interpretation

Private prediction wins when the budget is small and the queries are few. DP-SGD pays a fixed price whatever the number of queries, and at small ε that price is a model much worse than the non-private one. The vote pays per query; its first answers are almost as good as the noiseless ensemble. So at small ε there is a range of Q where the vote wins, and at large ε, where DP-SGD loses little, there may be none.

The ensemble's ceiling sets the large-ε limit. Even one noiseless answer is only as good as the plurality vote. If the teachers, each trained on a small shard, cannot match one model trained on all the data, no amount of budget closes the gap. On the running example the ensemble of linear teachers reaches 0.9403 at best, below what DP-SGD reaches at $\varepsilon = 2$.

What the comparison leaves out. It assumes you *can* run DP-SGD. When the teachers are LLMs behind an interface, models without gradients, or models trained by different parties who will not pool their data, the comparison is not with DP-SGD but with nothing, and private prediction is the only private option. It also ignores cost: DP-SGD trains once, while private prediction runs k models on every query.

42.5.5. Example: the running example

The DP-SGD baseline is the configuration of DP-SGD: $q = 0.01$, $C = 0.5$, learning rate 0.5, 10,000 steps, with the noise multiplier for each budget, retrained here and evaluated on this chapter's evaluation set (two runs each). Table 42.5 gives its accuracy and the break-even number of queries, taking for each budget the number of teachers that answers the most queries.

Table 42.5.: DP-SGD on the running example against private answers by GNMax: the largest number of queries for which the answers' expected accuracy is at least the private model's.

ε	DP-SGD accuracy (2 runs)	Break-even Q^*	Best k
0.5	0.8164 ± 0.0060	58	500
1	0.9128 ± 0.0207	18	500
2	0.9438 ± 0.0039	0	—
4	0.9573 ± 0.0024	0	—
8	0.9605 ± 0.0004	0	—

At $\varepsilon = 0.5$, where DP-SGD reaches only 0.8164, 500 teachers answer up to 58 queries more accurately than the private model. At $\varepsilon = 1$ the range shrinks to 18 queries. From $\varepsilon = 2$ on, DP-SGD beats even a single noiseless vote, because the ensemble's ceiling, 0.9336 to 0.9403, is below its 0.9438. Figure 42.2 shows the whole curve.

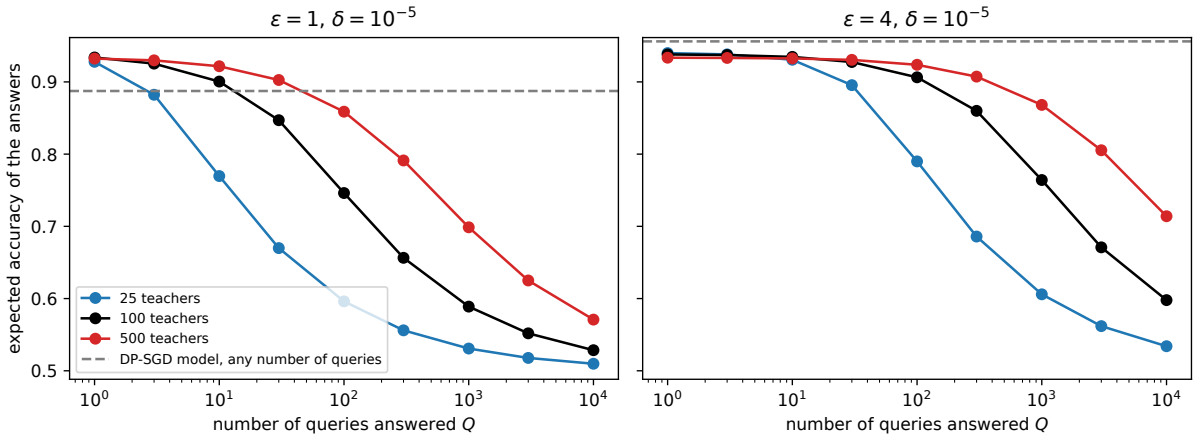

Figure 42.2.: Expected accuracy of Q private answers by GNMax against Q, for 25, 100 and 500 teachers, at $\varepsilon = 1$ (left) and $\varepsilon = 4$ (right), $\delta = 10^{-5}$. The dashed line is a DP-SGD model trained at the same budget, whose accuracy does not depend on the number of queries.

42.5.6. Check yourself

- If DP-SGD at $\varepsilon = 1$ were much worse on your task, say because you had only 1,000 records, would Q^* grow or shrink? *(It would grow, because the model's accuracy, the constant in Equation 42.7, falls. The teachers would also be weaker, though, so the vote's curve falls too; which effect wins has to be measured.)*
- A product team expects a model to answer a million queries. Should it use private prediction? *(Not query by query: a million answers need σ a hundred times that of 100 answers. It should either train privately or turn a few hundred private answers into a model, which is the next section.)*

42.6. PATE: from private answers to a private model

42.6.1. Context

Private answers cost budget forever; a private model costs it once. PATE combines them. Spend the budget on labelling a fixed number of *public, unlabelled* inputs with private answers, then train a new model, the **student**, on those inputs and labels. The student is released; the teachers never are. How private is the student, and how good can it be?

42.6.2. Statement

Let a student be trained, by any algorithm, on Q public inputs $x_1, \dots, x_Q$ and their GNMax labels with noise σ, and on any other public data, possibly unlabelled. Then the student, and every prediction it ever makes, is $(\alpha, Q\alpha/\sigma^2)$-RDP with respect to the private data, and so (ε, δ)-DP with ε from Equation 42.2. The privacy cost depends on the number of labelled queries Q and on σ, and on nothing about the student: not its size, its training algorithm or how many predictions it makes.

42.6.3. Derivation

1. **The only private output is the labels.** The student's training algorithm sees the public inputs, which do not depend on the private data, and the Q labels. It never touches the teachers or the private records.
2. **The labels are Q GNMax answers.** The inputs to be labelled may be chosen adaptively, for example by the student asking about inputs it is unsure of, because RDP composition holds for adaptively chosen mechanisms. Their total cost is $Q\alpha/\sigma^2$ (Section 42.3).
3. **Post-processing.** The student's weights are a function of the labels and of public data, so they are as private as the labels (Fact 2), and so is every prediction computed from the weights.

42.6.4. Interpretation

Three things limit the student. It is trained on Q examples rather than n, so it learns less than a model trained on all the private data. Its labels are noisy versions of the plurality vote, wrong on some fraction of the queries. And the plurality vote itself has the ensemble's ceiling. Budget pulls these in opposite directions: more labels mean more noise per label by Equation 42.4, so for each ε there is a best Q.

What PATE needs from you. Public, unlabelled inputs from the same distribution as the private data. In some domains this is easy (unlabelled images or text are plentiful; the labels are what is sensitive), in others impossible (there is no public pool of medical records). PATE also needs the public pool to be really public: an input that is itself a private record of someone else is protected by nothing in this analysis.

Semi-supervised students. The student may use every unlabelled public input, not only the Q it paid to label. Papernot et al. (2017) train the student as a semi-supervised generative

adversarial network (GAN) on the labelled and unlabelled inputs, and Papernot et al. (2018) use semi-supervised methods for their image tasks. This chapter's student uses only its Q labelled inputs, which is the simplest choice and the least favourable to PATE.

What PATE protects, and against whom. The guarantee covers the released student and its predictions. The teachers are non-private models of the data and must stay secret: an attacker who steals one can run any attack of Part 2 on its shard. PATE moves the trust from the training algorithm to the server that holds the teachers.

42.6.5. Example: students on the running example

Take $k = 250$ teachers. Their plurality vote labels the public pool with accuracy 0.9322. The student is the part's network (64 hidden units, 3,329 weights), trained non-privately on the first Q public inputs and their GNMax labels for 2,000 steps. Table 42.6 gives the results; the first two rows are references without privacy.

Table 42.6.: Test accuracy of a PATE student with 250 teachers, against the number of labelled public queries Q, one run each; in parentheses, the fraction of the student's GNMax labels that are correct.

Labels	$Q = 250$	$Q = 500$	$Q = 1{,}000$	$Q = 2{,}000$
True labels (not private)	0.8726	0.8990	0.9188	0.9410
Noiseless plurality (not private)	0.8913	0.9106	0.9229	0.9297
GNMax, $\varepsilon = 1$	0.8238 (0.7760)	0.7595 (0.6880)	0.6995 (0.6350)	0.6749 (0.6260)
GNMax, $\varepsilon = 2$	0.7980 (0.8040)	0.8393 (0.8140)	0.8141 (0.7490)	0.7318 (0.6885)
GNMax, $\varepsilon = 4$	0.8633 (0.8720)	0.8754 (0.8740)	0.8898 (0.8360)	0.8259 (0.7840)
GNMax, $\varepsilon = 8$	0.8950 (0.9160)	0.9037 (0.9040)	0.9049 (0.8870)	0.8884 (0.8525)

The best student reaches 0.8238 at $\varepsilon = 1$ ($Q = 250$), 0.8393 at $\varepsilon = 2$ ($Q = 500$), 0.8898 at $\varepsilon = 4$ ($Q = 1{,}000$) and 0.9049 at $\varepsilon = 8$ ($Q = 1{,}000$). DP-SGD, at 0.9128, 0.9438, 0.9573 and 0.9605, is better at every budget (Figure 42.3). The table shows why. With true labels, the student needs 2,000 examples to reach 0.9410; at $\varepsilon = 4$, 2,000 labels need $\sigma = 73.2$, and only 0.7840 of them are right. With fewer labels the noise is lower, but the student has too few examples. (The best Q for each budget is chosen here by looking at test accuracy, which is itself a leak; Hyperparameter tuning shows how to pay for it.)

On this task PATE loses, and it is worth saying why, because the reasons are the conditions under which it wins elsewhere. The task is binary, so a wrong label is the other label and label noise is as damaging as it can be. The teachers are weak (0.7031 each with 40 records) and disagree on many queries, so many gaps are small against the noise. The student needs thousands of labels to learn the decision boundary. And DP-SGD does well on this task even at $\varepsilon = 1$. PATE's published successes are on tasks where teachers agree on most inputs and a student learns from few labels plus many unlabelled inputs: on a handwritten-digit benchmark (MNIST), Papernot et

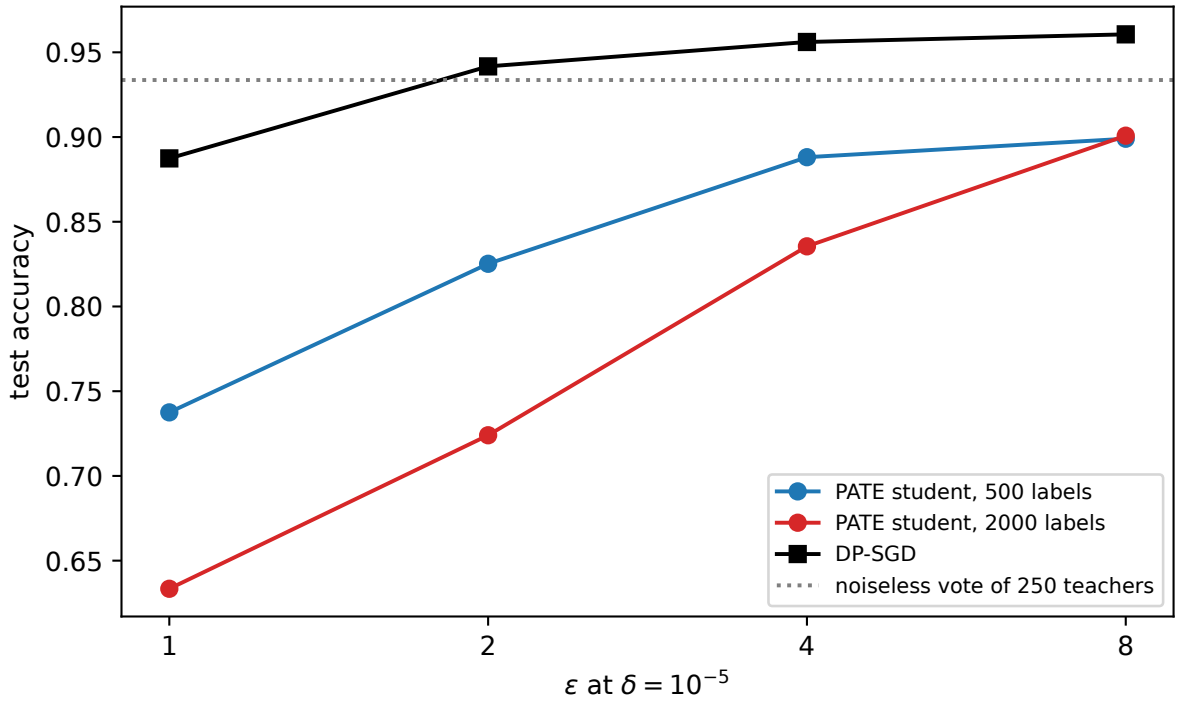

Figure 42.3.: Test accuracy of the PATE student with 250 teachers and 500 or 2,000 labelled public queries, and of DP-SGD, against ε at $\delta = 10^{-5}$, one run each. The dotted line is the accuracy of the teachers' noiseless plurality vote.

al. (2018, Table 1) report a student with 98.5% accuracy against a non-private 99.2%, at $\varepsilon = 1.97$ with 286 answered queries. The next section explains the analysis behind such small ε.

42.6.6. Check yourself

- The student is trained with 2,000 steps of non-private SGD and has 3,329 weights. Does either number change its ε? *(No. The student's training is post-processing of the labels; only Q and σ enter.)*
- Could the student query the teachers about inputs it is uncertain about, after a first round of training? *(Yes. The queries are public inputs chosen from earlier private answers, which adaptive composition allows; each answer still costs α/σ^2.)*

42.7. Data-dependent analysis and Confident-GNMax

42.7.1. Context

The cost α/σ^2 of a GNMax answer is a worst case over all vote histograms, including those where the vote is tied and one teacher decides it. But when 249 of 250 teachers agree, one record, which changes one teacher, can hardly change the answer: the noisy vote returns the plurality with overwhelming probability, with or without that record. Can a query on which the teachers agree be charged less? And can a mechanism be designed to answer only such queries?

42.7.2. Statement

The pure-DP form (Papernot et al. 2017, Theorem 3, written in RDP). Let M be ε_0-DP and suppose that on the actual dataset D there is an output i^* with $\Pr[M(D) \neq i^*] = \beta < e^{-\varepsilon_0}$. Then for every neighbour D',

$$D_\alpha(M(D)\|M(D')) \le \frac{1}{\alpha-1}\ln\Big[(1-\beta)^\alpha(1-e^{\varepsilon_0}\beta)^{1-\alpha} + \beta\, e^{(\alpha-1)\varepsilon_0}\Big]. \tag{42.8}$$

When only an upper bound $\tilde\beta \ge \beta$ is known, the bound holds with the largest value of the right side over $\beta \in (0, \tilde\beta]$. For LNMax, $\varepsilon_0 = 2/b$.

The Gaussian form (Papernot et al. 2018, Theorem 6, with their orders from Proposition 10). For GNMax with noise σ and $\tilde\beta$ from Equation 42.6, let $\alpha_2 = \sigma\sqrt{\ln(1/\tilde\beta)}$, $\alpha_1 = \alpha_2 + 1$, $\varepsilon_1 = \alpha_1/\sigma^2$ and $\varepsilon_2 = \alpha_2/\sigma^2$. If $\alpha \le \alpha_1$, $\alpha_2 > 1$ and $\tilde\beta \le e^{(\alpha_2-1)\varepsilon_2}\big/\big(\frac{\alpha_1}{\alpha_1-1}\cdot\frac{\alpha_2}{\alpha_2-1}\big)^{\alpha_2}$, then for every neighbour D'

$$D_\alpha(M(D)\|M(D')) \le \frac{1}{\alpha-1}\ln\Big[(1-\tilde\beta)A^{\alpha-1} + \tilde\beta B^{\alpha-1}\Big], \quad A = \frac{1-\tilde\beta}{1-(\tilde\beta e^{\varepsilon_2})^{(\alpha_2-1)/\alpha_2}}, \quad B = \frac{e^{\varepsilon_1}}{\tilde\beta^{1/(\alpha_1-1)}}. \tag{42.9}$$

Each answer is charged the smaller of this and α/σ^2, and the charges add up over answers.

Confident-GNMax (Papernot et al. 2018, Algorithm 1). For each query, release $\perp$ (no answer) unless $\max_i N_i + \mathcal{N}(0, \sigma_1^2) \geq \tau_1$; if the check passes, release a GNMax answer with noise σ_2. With data-independent accounting, Q_{pool} checks and Q_{ans} answers cost

$$\varepsilon(\alpha) = \Big(\frac{Q_{\text{pool}}}{2\sigma_1^2} + \frac{Q_{\text{ans}}}{\sigma_2^2}\Big)\alpha, \tag{42.10}$$

provided the total is kept below a budget fixed in advance.

42.7.3. Derivation

The pure-DP form shows where all data-dependent bounds come from; the Gaussian form follows the same plan with Rényi bounds at higher orders in place of the pure-DP ratio, and its proof is in Papernot et al. (2018, Appendix A). Section M.2 in the appendices derives it step by step.

1. **Write the divergence as a sum over outputs.** By Equation 42.1, $e^{(\alpha-1)D_\alpha} = \sum_y P(y)^\alpha P'(y)^{1-\alpha}$, with $P = M(D)$ and $P' = M(D')$. Split the sum into the likely output i^* and the rest. Write $\beta = P(\text{not } i^*)$ and $\beta' = P'(\text{not } i^*)$.
2. **The unlikely outputs.** For $y \neq i^*$, $P(y)^\alpha P'(y)^{1-\alpha} = P(y)(P(y)/P'(y))^{\alpha-1} \leq P(y)e^{(\alpha-1)\varepsilon_0}$, because ε_0-DP bounds the ratio by e^{ε_0}. Summed over $y \neq i^*$, this is at most $\beta\, e^{(\alpha-1)\varepsilon_0}$.
3. **The likely output.** Its term is $(1-\beta)^\alpha(1-\beta')^{1-\alpha}$. Pure DP, applied to the event "not i^*", gives $\beta' \leq e^{\varepsilon_0}\beta$, so $1-\beta' \geq 1-e^{\varepsilon_0}\beta > 0$. The exponent $1-\alpha$ is negative, so a larger base gives a smaller power: $(1-\beta')^{1-\alpha} \leq (1-e^{\varepsilon_0}\beta)^{1-\alpha}$.
4. **Collect.** Adding the two parts and taking $\frac{1}{\alpha-1}\ln$ gives Equation 42.8 with the true β. Since only a bound $\tilde{\beta}$ is computable, take the largest value over all β the bound allows; the right side increases in β for every $\beta < e^{-\varepsilon_0}$, because it is convex in β with a non-negative slope at 0 (Section M.2 in the appendices proves both), so the largest value is at $\beta = \tilde{\beta}$.
5. **Small β.** At $\beta = 0$ the bracket is 1 and the bound is 0. Its derivative there is $e^{(\alpha-1)\varepsilon_0} + (\alpha-1)e^{\varepsilon_0} - \alpha$, so for small β the bound is about β times a constant: the cost of an answer is proportional to the probability that the noise overturns the plurality.
6. **Confident-GNMax.** The check releases a noisy version of $\max_i N_i$, which one record changes by at most 1 (one count up or down by 1 moves the maximum by at most 1), so it is a Gaussian mechanism with sensitivity 1: $(\alpha, \alpha/(2\sigma_1^2))$-RDP for every query, answered or not. The second step is GNMax, $(\alpha, \alpha/\sigma_2^2)$-RDP, run only when the check passes. Whether it runs is decided by a released output, so its cost is chosen adaptively. Both costs are lines in α, and the Rényi filter of Adaptive composition says that adaptively chosen RDP costs that stay below a fixed budget on every path compose as if fixed. Summing gives Equation 42.10.

42.7.4. Interpretation

Agreement is cheap, disagreement costs full price. Figure 42.4 draws the cost of one GNMax answer with $\sigma = 40$ at order 8 against the gap. At gaps up to 100 the data-dependent bound is no better than the data-independent $\alpha/\sigma^2 = 0.005$; then it falls steeply, to 1.23×10^{-3} at a gap of 150 and 8.37×10^{-5} at 200. The dashed curve is the exact data-dependent cost on two labels, which the script computes directly: the output is then a coin with probability $\Phi(g/(\sqrt{2}\sigma))$,

one record moves g by 2, and Equation 42.1 applies to two outcomes. It lies below the bound everywhere: at a gap of 150, 2.42×10^{-4}, five times below. Theorem 6 is valid but not tight, and it is far from tight for small gaps, where on two labels even the data-independent cost overstates the truth.

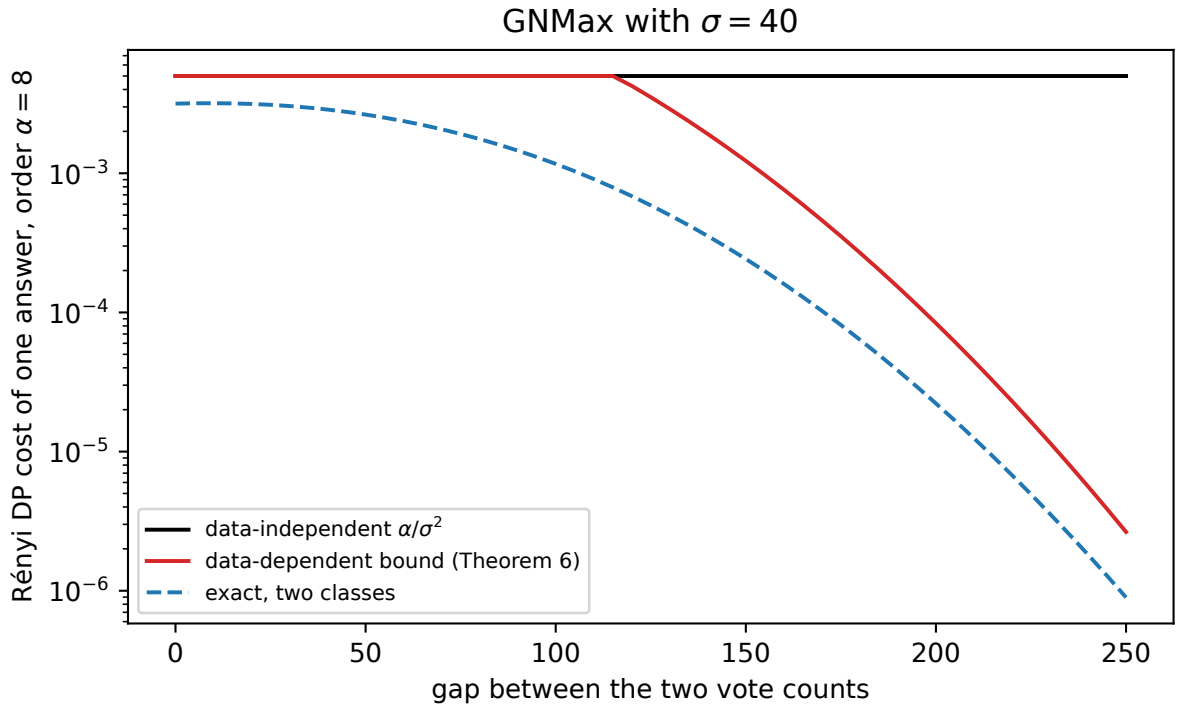

Figure 42.4.: The RDP cost at order 8 of one GNMax answer with $\sigma = 40$, against the gap between the two vote counts, on a log scale: the data-independent α/σ^2, the data-dependent bound of Equation 42.9, and the exact data-dependent cost on two labels.

Why it helps little here and a lot elsewhere. The total is a sum over queries, so the saving depends on how many queries have large gaps. With 250 teachers on the running example, only 0.2879 of the public queries have a gap of at least 150, so most answers pay close to full price. On a task where nearly all teachers agree on nearly all inputs, as on handwritten digits, almost every answer is nearly free, and ε falls by a large factor.

The data-dependent ε is itself private information. It is computed from the votes, so publishing it reveals something about the teachers and so about the data. Worse, its sensitivity is large: one record changes one teacher, and that teacher's votes can change on *every* query, moving every term of the sum. Papernot et al. (2018, Appendix B) therefore release the data-dependent ε with Gaussian noise scaled to its **smooth sensitivity**, the device of Beyond global sensitivity for functions whose worst-case sensitivity is far above their typical one, and pay for that release too. On MNIST, with 250 teachers of 200 examples, 640 queries, $\tau_1 = 200$, $\sigma_1 = 150$ and $\sigma_2 = 40$, they report an expected 283 answered queries and a data-dependent $\varepsilon = 2.00$ at $\delta = 10^{-5}$, which becomes 2.52 ± 0.385 once sanitized (their Table 2). Without that step, a data-dependent ε is a measurement, not a guarantee.

A one-directional bound. Equation 42.8 and Equation 42.9 bound $D_\alpha(M(D)\|M(D'))$ for the

actual dataset D against every neighbour, the direction the accounting of Papernot et al. uses. The exact two-label computation above takes the worse of both directions, and is still below the bound.

Confident-GNMax answers what is cheap and correct. Queries with a strong consensus are cheap under the data-dependent analysis, and their plurality label is more likely to be right. The noisy check selects them. It costs something on every query, but with σ_1 much larger than σ_2 that cost is small per query, and the expensive, likely-wrong queries are mostly skipped. The price is that the student never sees labels for the hard inputs near the decision boundary.

42.7.5. Example: data-dependent costs on the running example

The pure-DP form. For an LNMax answer with $\varepsilon_0 = 0.1$, at order 8 the data-independent cost is 0.0367. If the plurality fails with probability $\tilde{\beta} = 0.1$, Equation 42.8 gives 0.0235; at $\tilde{\beta} = 0.01$, 0.00248; at $\tilde{\beta} = 0.001$, 0.00025. Below $\tilde{\beta} = 0.1$ the cost falls in proportion to $\tilde{\beta}$, as step 5 predicts.

GNMax on 250 teachers. Table 42.7 compares the costs of answering the first Q public queries with $\sigma = 40$.

Table 42.7.: ε at $\delta = 10^{-5}$ for Q GNMax answers with 250 teachers and $\sigma = 40$ on the running example's public pool.

Answers Q	Data-independent ε	Data-dependent ε (not sanitized)
250	2.45	1.93
1,000	5.38	4.37
4,000	12.30	10.23

The saving is about 20% at every Q, the fraction of queries with large gaps. Figure 42.5 shows the same over Q, with LNMax at the same noise standard deviation for comparison: Laplace answers cost more at every Q shown, and the ratio grows with Q. The data-dependent ε also has the instability described above: if one teacher among the 250 switched every one of its votes on the first 1,000 queries, the data-dependent ε would move from 4.375 to 4.389.

Confident-GNMax. With the parameters Papernot et al. use on MNIST, $\tau_1 = 200$, $\sigma_1 = 150$ and $\sigma_2 = 40$, Table 42.8 runs the 250 teachers on pools of 1,000 and 4,000 public queries.

Table 42.8.: Confident-GNMax with 250 teachers, $\tau_1 = 200$, $\sigma_1 = 150$, $\sigma_2 = 40$, on the running example; the student is trained on the answered queries only.

Pool Q_{pool}	Answered Q_{ans}	Label accuracy	Data-independent ε	Data-dependent ε	Student accuracy
1,000	459	0.8693	3.59	2.82	0.8894
4,000	1,773	0.8917	7.87	6.28	0.9043

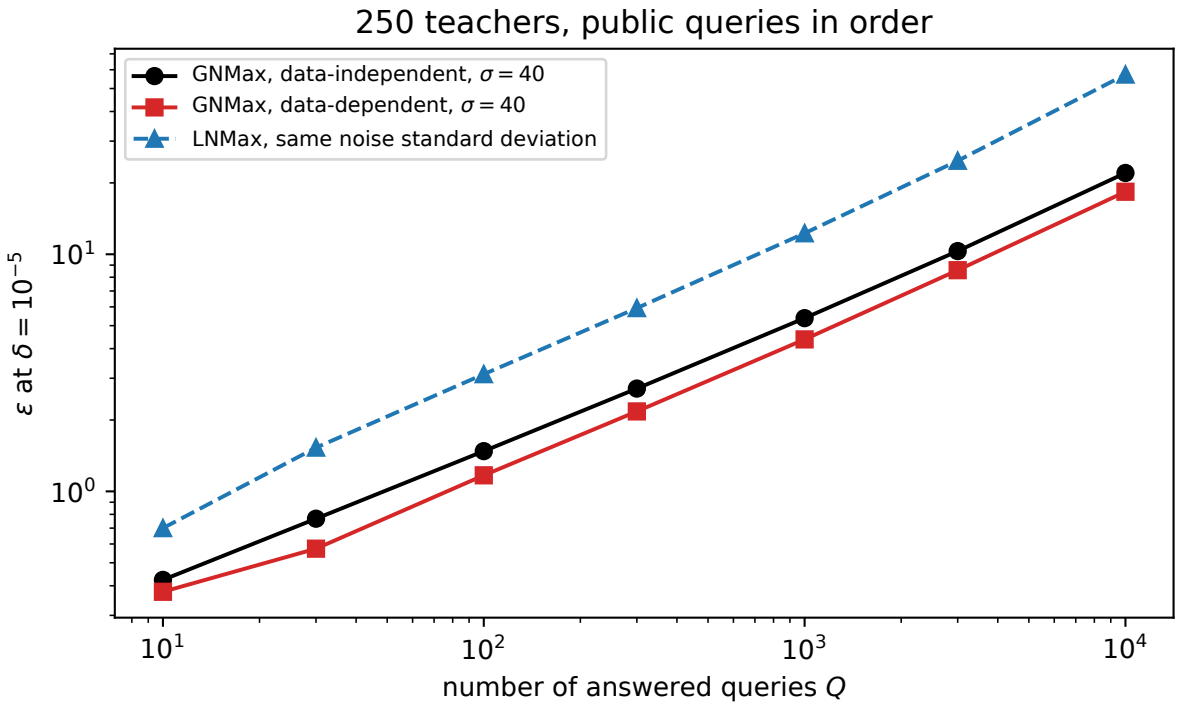

Figure 42.5.: ε at $\delta = 10^{-5}$ for Q answers with 250 teachers on the running example's public queries, on log–log axes: GNMax with $\sigma = 40$ under the data-independent and data-dependent analyses, and LNMax with the same noise standard deviation.

At a data-independent $\varepsilon = 3.59$, Confident-GNMax trains a student to 0.8894, about what plain GNMax reached at $\varepsilon = 4$ (0.8898 in Table 42.6). It improves on GNMax a little, not enough to catch DP-SGD at 0.9573. The check costs little: $1{,}000/(2 \times 150^2) = 0.022$ in slope, against $459/40^2 = 0.287$ for the answers.

42.7.6. Check yourself

- Why can't the data-dependent ε simply be released with noise calibrated to its global sensitivity? *(Its global sensitivity is huge. One record changes one teacher, whose votes may change on every query; on a histogram near a tie, each such change moves that query's cost from almost 0 to the full α/σ^2, so the worst-case change of the sum is close to the data-independent total.)*
- In Confident-GNMax, why is σ_1 chosen much larger than σ_2? *(The check is paid on every query and the answer only on answered ones. A large σ_1 makes the frequent cost small; the check only needs to separate strong consensus from weak, which a noisy maximum can do even with a lot of noise when τ_1 is set well.)*

42.8. Paying only for disagreement, with a worst-case guarantee

42.8.1. Context

The data-dependent analysis of Section 42.7 charges agreed answers less, but the ε it computes is itself a function of the votes, and publishing it needs a separate private release with smooth sensitivity. There is another way to make agreement cheap. Instead of measuring after the fact how much each answer cost, test privately, before answering, whether the vote is so lopsided that one record cannot overturn it. Release the plurality label exactly when the test passes, and nothing when it fails. Then let only the failures cost budget, by running the tests through the sparse vector technique of Selection. This is the stability-based aggregation of Thakurta & Smith (2013), which Bassily, Thakkar & Thakurta (2018) apply to PATE. Its guarantee is an ordinary (ε, δ) fixed before any vote is seen. What does it cost, and when does it pay?

42.8.2. Statement

For a query x, the **distance to instability** is the largest number j such that changing the votes of *any* j teachers leaves the same label strictly on top. With g the gap between the top two counts,

$$\operatorname{dist}(x) = \left\lceil \frac{g}{2} \right\rceil - 1, \quad \text{and } 0 \text{ when } g = 0. \tag{42.11}$$

Stable aggregation goes through the public queries in order, and asks of each one whether its distance is clearly above a threshold τ. AboveThreshold halts at the first query whose value is high, and here the procedure should halt at the first query whose distance is low. So it runs AboveThreshold at a budget ε_0 on the negated distances $-\operatorname{dist}(x_i)$ with threshold $-\tau$. The threshold gets noise $\xi \sim \operatorname{Lap}(2/\varepsilon_0)$ and each query fresh noise $\nu_i \sim \operatorname{Lap}(4/\varepsilon_0)$.

A query with $-\operatorname{dist}(x_i) + \nu_i \geq -\tau + \xi$ is **unstable**. It gets no label, and the run restarts with fresh threshold noise. Every other query is **stable**, and it gets the exact plurality label, with no noise. The procedure stops after c unstable answers or at the end of the pool of Q_{pool} queries.

The total slack δ is split in two. One part, δ_{bad}, bounds the chance that a query with no margin slips through the test, and the other, δ', goes to the conversion from RDP. Choose the threshold τ so that

$$Q_{\text{pool}} \cdot \Pr[\nu - \xi > \tau] \leq \delta_{\text{bad}}, \qquad \Pr[\nu - \xi > \tau] = \frac{b_1^2 e^{-\tau/b_1} - b_2^2 e^{-\tau/b_2}}{2(b_1^2 - b_2^2)}, \tag{42.12}$$

with $b_1 = 4/\varepsilon_0$ and $b_2 = 2/\varepsilon_0$ the two Laplace scales. Then all the released labels together are $(\varepsilon, \delta' + \delta_{\text{bad}})$-DP, where ε is the better of basic composition, $c\varepsilon_0$, and the conversion at δ' of c composed ε_0-DP steps,

$$\varepsilon = \min\Big\{ c\varepsilon_0,\ \min_{\alpha}\Big[c\,\varepsilon_{\text{RR}}(\alpha) + \ln\frac{\alpha - 1}{\alpha} - \frac{\ln\delta' + \ln\alpha}{\alpha - 1}\Big]\Big\}, \tag{42.13}$$

with ε_{RR} the randomized-response curve of Fact 3 at ε_0, the Rényi curve that bounds every ε_0-DP mechanism. The budget does not depend on how many stable labels are released.

42.8.3. Derivation

1. **The distance.** One changed teacher moves one vote from one label to another, so it lowers the gap by at most 2. After j changes the gap is at least $g - 2j$, and the label stays strictly on top while $g - 2j \geq 1$, that is for $j \leq (g-1)/2$. The largest such whole number is $\lceil g/2 \rceil - 1$, which is Equation 42.11.
2. **One record moves every distance by at most 1.** Adding or removing a record changes one teacher (Fact 1), which changes each query's distance by at most 1: if any j changes from D' keep the label on top, then any $j - 1$ changes from D do, because D is one change away from D'. This is the distance-to-a-set argument of Beyond global sensitivity. So the query values $-\operatorname{dist}(x_i)$ have sensitivity 1, for every query at the same time.
3. **The stable/unstable answers cost c runs.** Each run of AboveThreshold on sensitivity-1 queries is ε_0-DP, however many queries it reads (Selection). There are at most c runs, each started after the previous one's output. Basic composition gives $c\varepsilon_0$ with no slack. Alternatively, Fact 3 gives each run the randomized-response RDP curve, the curves add, and the conversion of Fact 2 at δ' gives the second term of Equation 42.13. Either bound is valid, so the smaller one is.
4. **Exact labels are safe where the distance is at least 1.** If $\operatorname{dist}(x_i) \geq 1$ on D, one change of teacher leaves the same label strictly on top, so the plurality of x_i is the same on D and on its neighbour D'. So on such queries the released label is the same on D and D'. Whenever every labelled query has distance at least 1 on D, the whole output is therefore determined by which queries were declared stable, in the same way for both datasets.
5. **The only danger is a passed test at distance 0.** Call it the bad event. A query with distance 0 is declared stable when $\nu_i < -\tau + \xi$, that is $\nu_i - \xi < -\tau$. The difference of two independent symmetric variables is symmetric, so this has probability $\Pr[\nu - \xi > \tau]$. A union bound over at most Q_{pool} queries bounds the probability of the bad event by $Q_{\text{pool}} \cdot \Pr[\nu - \xi > \tau] \leq \delta_{\text{bad}}$. The tail formula in Equation 42.12 comes from integrating the density of a sum of two Laplace variables (Section E.5 in the appendices does the integral), and the script checks it by simulation.

6. **Put the two together.** For any set S of outputs, the probability that the output lands in S on D is at most the probability that it lands in S without the bad event, plus δ_{bad}. Without the bad event, every labelled query has distance at least 1 on D. So the output lands in S only if the stable/unstable answers land in a set S' of answer sequences, defined from D, whose stable queries all have distance at least 1 on D and whose labels, the same on D and D' by step 4, put the output in S. Step 3 bounds the probability of S' on D by e^{ε} times its probability on D', plus δ'. On D', answers in S' produce an output in S, because their labels are the same. That gives $(\varepsilon, \delta' + \delta_{\text{bad}})$-DP.

42.8.4. Interpretation

Nothing needs sanitizing. The budget is fixed by c, ε_0 and the two δs before any vote is seen, so it can be published as it is. What depends on the data is how many labels you get for that budget, which is the reverse of the data-dependent analysis, where the labels are fixed and the cost depends on the data. The cutoff c must be fixed in advance for this to hold.

The labels are exact. A stable query gets the noiseless plurality, so the student's labels are as good as the ensemble's on every query it receives. Label noise, which hurt the students of Section 42.6, is gone. The hard queries near the boundary are skipped, as in Confident-GNMax.

The threshold is the obstacle. The test must almost never pass a query at distance 0, over the whole pool, so τ grows like $4\ln(Q_{\text{pool}}/\delta_{\text{bad}})/\varepsilon_0$. At $\varepsilon_0 = 1$ and a pool of 10,000 queries, that is $\tau = 84.0$. So a query passes reliably only when the plurality leads by about $2\tau \approx 170$ votes. On top of that, every unstable answer costs a whole ε_0, and c runs compose almost linearly unless c is in the hundreds. So the method pays only when there are many teachers and they are nearly unanimous on almost every query. Bassily, Thakkar & Thakurta (2018) use it to prove accuracy guarantees for the student under such conditions. Deployed PATE systems use Confident-GNMax with data-dependent accounting instead, and pay for the sanitizing.

42.8.5. Example: the running example

Take $\varepsilon_0 = 1$, and split the slack equally, $\delta_{\text{bad}} = \delta' = 5 \times 10^{-6}$, so that the total δ is 10^{-5}. For a pool of 1,000 queries Equation 42.12 gives the threshold $\tau = 74.8$, and for 10,000 queries it gives 84.0. The tail formula is easy to check, since at $\tau = 8$ it gives 0.0872 and a million simulated pairs give 0.0866. The budget of Equation 42.13 is $\varepsilon = 5.00$ for $c = 5$ unstable answers, and 20.00 for $c = 20$, both from basic composition. The composition saves almost nothing at this scale: even 100 unstable answers cost 83.45 rather than 100.

The teachers rarely clear the bar. The running example's pool has 10,000 queries, so the threshold is 84.0. With 250 teachers the largest distance on the pool is 124, and only 0.1996 of the queries have a distance of at least 84.0. With 500 teachers that share is 0.3923. Table 42.9 runs the procedure on the pool.

Table 42.9.: Stable aggregation on the running example's public pool, $\delta_{\text{bad}} = \delta' = 5 \times 10^{-6}$: queries read before the c-th unstable answer, labels released, their accuracy against the true labels, and the budget.

Teachers	ε_0	Cutoff c	Queries read	Labels released	Label accuracy	ε
250	1	20	23	3	1.0000	20.00
250	2	20	41	21	0.9524	40.00
500	1	20	34	14	1.0000	20.00
500	2	20	54	34	0.9412	40.00

The labels it releases are accurate, but there are only between 3 and 34 of them at a budget of 20 or more, against hundreds of noisy GNMax labels at $\varepsilon = 4$ in Table 42.6. On this task, where most queries fall short of the threshold, the worst-case-safe route is far more expensive than paying for the sanitizing.

42.8.6. Check yourself

- Why is it safe to release the plurality with no noise at all when the test says "stable"? *(If the query's distance is at least 1, the neighbouring dataset has the same plurality, so the label carries no information that the stable/unstable answer did not. The only risk is a query at distance 0 that passes, which the threshold makes unlikely, at probability δ_{bad} over the whole pool.)*
- Why must the cutoff c be fixed before the run? *(The budget is set by c. Choosing c after seeing how many queries turned out unstable would make the budget depend on the votes, the problem this construction avoids.)*

42.9. Private in-context learning

42.9.1. Context

An LLM can learn a task from examples placed in its prompt, without any training: show it four labelled movie reviews and it will label the fifth. This **in-context learning** has its own privacy problem. If the examples, the **exemplars**, are private records, every answer is computed from them, and an attacker who can query the prompted model can learn about them. Duan, Dziedzic, Papernot and Boenisch (NeurIPS 2023) demonstrate this with a membership inference attack (MIA): querying GPT-3 prompted with one private example, the model's probability for the correct label is markedly higher on the example that was in the prompt than on other records. Training the LLM with DP-SGD is not an option when it is only reachable through an interface. How do you answer privately from a prompt?

42.9.2. Statement

Private in-context learning (Wu, Panda, Wang & Mittal, ICLR 2024; Duan et al. 2023): split the private exemplars into disjoint groups by a fixed rule, prompt the model once per group with that group's exemplars and the query, and release the GNMax label of the k answers. Each answer is $(\alpha, \alpha/\sigma^2)$-RDP, exactly as in Section 42.3. If, as in Wu et al., each query first draws a fresh Poisson sample of the exemplars, each record included independently with probability q, and the sample is split into groups by the fixed rule, then each answer's RDP curve is that of the Poisson-subsampled Gaussian with sampling rate q and noise multiplier $\sigma/\sqrt{2}$, and Q answers add up:

$$\varepsilon(\alpha) = Q\,\varepsilon_{q,\,\sigma/\sqrt{2}}(\alpha), \tag{42.14}$$

with $\varepsilon_{q,s}$ the subsampled-Gaussian curve of Amplification by subsampling, the same accountant DP-SGD uses. **PromptPATE** (Duan et al.) turns the answers into a public prompt instead: label a few public inputs with Confident-GNMax over an ensemble of prompted models, and use the labelled public inputs as the exemplars of a single prompt that is then deployed with no further cost, the student of PATE in prompt form.

42.9.3. Derivation

1. **One exemplar, one prompt.** With the groups fixed by a rule that does not depend on the data (a hash, as in Fact 1), adding or removing an exemplar changes the content of one group's prompt and so at most one answer: one vote moves. The histogram has ℓ_2 sensitivity $\sqrt{2}$.
2. **Without subsampling.** GNMax on this histogram is $(\alpha, \alpha/\sigma^2)$-RDP (Section 42.3), whatever the language model computes from its prompt.
3. **With Poisson subsampling.** The record is in the query's sample with probability q, independently of the others. If it is not, the output is distributed as without it; if it is, the histogram shifts by a vector of length at most $\sqrt{2}$ against noise of standard deviation σ on each coordinate. Rotating the shift onto one axis and rescaling by $\sqrt{2}$, this is the subsampled Gaussian of DP-SGD with sensitivity 1 and noise multiplier $\sigma/\sqrt{2}$.
4. **Compose.** The Q answers use independent samples and add up in RDP: Equation 42.14.
5. **PromptPATE.** The deployed prompt contains public inputs and their private labels. It is post-processing of the labels, so its cost is that of the labels alone, however often it is used.

42.9.4. Interpretation

Answering from a prompt is private prediction. Everything in the previous sections carries over: the cost grows with the number of answered queries, the accuracy depends on how much the prompted models agree, and the data-dependent analysis applies. The difference is the teacher. A prompted LLM is a strong learner from very few examples, because most of what it knows comes from pretraining; its errors with different exemplars are correlated, so its votes agree far more than independently trained small models do. Duan et al. observe this high consensus and suggest that it may come from all teachers sharing the same underlying model. High consensus is exactly what makes data-dependent costs small.

Subsampling amplifies; disjointness is still needed. Subsampling lets a large exemplar set serve many queries cheaply, since each record takes part in a fraction q of them. But within one query the groups must be disjoint, or a record in two groups moves two votes.

Text generation needs another aggregator. Votes work for labels. For free text, Wu et al. map each group's answer into a space where averaging makes sense, either sentence embeddings, which they privatize with the Gaussian mechanism, or keyword counts, from which they select keywords privately with propose-test-release or a joint exponential mechanism, and then ask the model to produce an answer from the private aggregate.

What the papers report. These numbers are from the papers, not from this chapter's script. Duan et al. report, with GPT-3 as the base model, 92.7% accuracy on a movie-review sentiment task at $(\varepsilon, \delta) = (0.147, 10^{-6})$ with PromptPATE, against 95.2% without privacy. Wu et al. (arXiv version) report on the same sentiment task, with 10,000 queries each answered by a vote of ten 4-shot prompts, 91.97% at $\varepsilon = 1$ and 92.83% at $\varepsilon = 3$ with GPT-3 Babbage, against 91.89% for a single non-private 4-shot prompt and 86.58% with no examples at all.

42.9.5. Example: a simulated in-context learner

No language model is available here, so the script simulates the mechanics with a **stand-in**: an "in-context learner" that, given exemplars (x_j, y_j), labels a query by the sign of $\langle \sum_j y_j x_j, x \rangle$. It has no pretraining at all, which makes it far weaker than an LLM; what carries over is the accounting and the dependence on agreement, not the accuracy.

The leak. An attacker who knows a candidate record (x, y) scores it by $y\langle \theta, x \rangle$, with $\theta = \sum_j y_j x_j$ the learner's parameter vector, its confidence in the right label. The area under the curve (AUC) of this attack, the probability that a random member scores above a random non-member, is 1.000 against a 1-shot learner, 0.996 against a 4-shot learner and 0.889 against a 16-shot learner (400 trials each). A prompt with few exemplars reveals them almost perfectly, as Duan et al. found for GPT-3.

Private answers. Each query draws a Poisson sample of the 10,000 private records at rate $q = 0.04$, about 400 records, and splits it by record index into 25 groups of about 16. One 16-shot learner is right on 0.6232 of the evaluation set (50 draws); the 25-vote without noise, on 0.8090 of 2,000 queries. Table 42.10 adds the noise for a budget spread over Q queries, from Equation 42.14.

Table 42.10.: Private in-context learning with the stand-in learner: 25 groups of about 16 exemplars per query, Poisson sampling rate 0.04, GNMax noise for Q answers at $(\varepsilon, 10^{-5})$, accuracy on 2,000 evaluation queries.

Budget	Answers Q	σ	Accuracy
$\varepsilon = 1$	100	2.75	0.7780
	1,000	7.39	0.6800
	10,000	22.93	0.5615
$\varepsilon = 4$	100	1.30	0.8080
	1,000	2.36	0.7910
	10,000	6.65	0.7025

Subsampling makes the noise small: 1,000 answers at $\varepsilon = 1$ need $\sigma = 7.39$ here, against 181 without subsampling (Table 42.2). But the vote has only 25 voters, so even $\sigma = 7.39$ is large against its gaps, and accuracy falls from 0.8090 to 0.6800. Figure 42.6 shows the decline over Q.

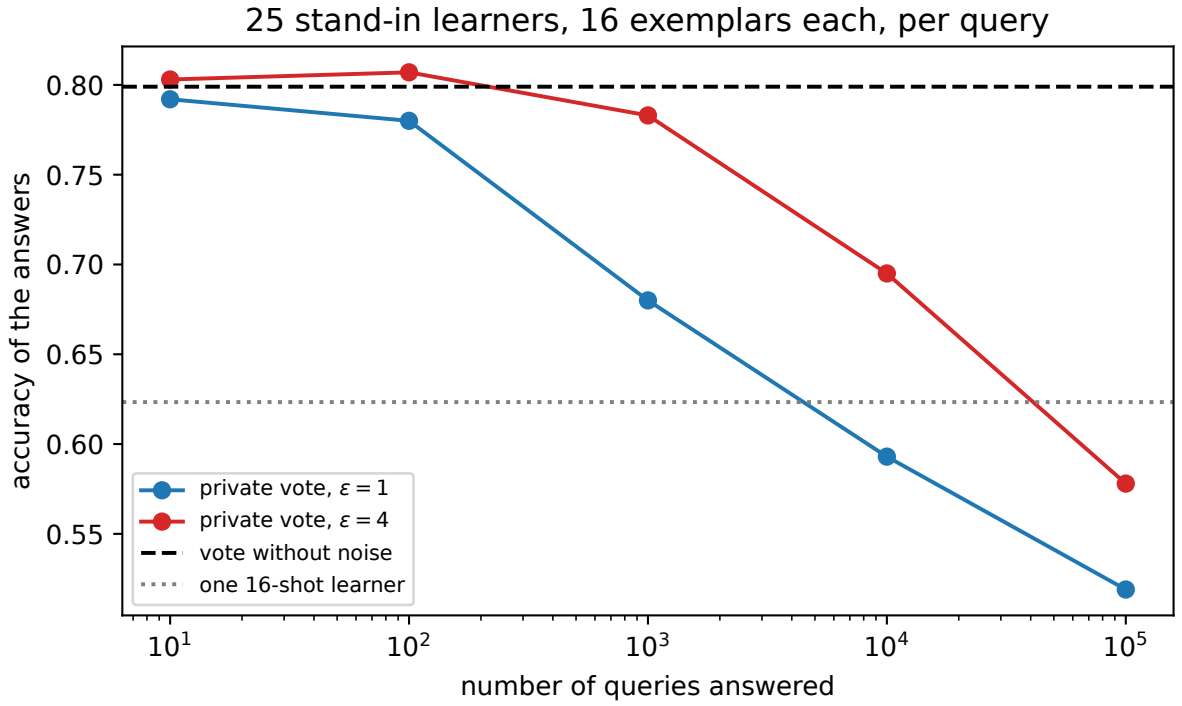

Figure 42.6.: Accuracy of private answers from the stand-in in-context learner against the number of queries answered at $\varepsilon = 1$ and $\varepsilon = 4$ ($\delta = 10^{-5}$), with 25 groups of about 16 exemplars drawn per query at rate 0.04. The dashed line is the vote without noise and the dotted line a single 16-shot learner.

A student prompt. Split all 10,000 records into 625 disjoint 16-shot learners; their noiseless vote is right on 0.9366 of the evaluation set. Label the first Q public inputs with GNMax at $\varepsilon = 1$ and use them as the exemplars of one public learner. With 16 labelled inputs ($\sigma = 22.9$) the student prompt reaches 0.6315; with 64 ($\sigma = 45.8$), 0.7237; with 256 ($\sigma = 91.5$, labels 0.8086 correct), 0.7954, about the accuracy of 100 private answers at the same budget, but for any number of queries. The stand-in needs hundreds of exemplars because it has no prior knowledge; an LLM needs a handful, which is why PromptPATE can stop at very few labelled public inputs and a very small ε.

42.9.6. Check yourself

- A developer puts 200 private exemplars into one long prompt and answers 1,000 user queries with it. Is anything private? *(No. Every answer is a deterministic or sampled function of all 200 exemplars, with no noise and no bound on any one exemplar's influence; the membership attack above works against it.)*
- Why does Equation 42.14 use noise multiplier $\sigma/\sqrt{2}$ rather than σ? *(The vote histogram moves by $\sqrt{2}$ in ℓ_2 norm when one exemplar's group changes its vote. The subsampled-*

Gaussian curve is stated for a shift of 1, and a shift of $\sqrt{2}$ against noise σ is the same as a shift of 1 against noise $\sigma/\sqrt{2}$.)

42.10. Code: check every number by computation

The script code/private_prediction.py trains the teachers, implements LNMax, GNMax, Confident-GNMax, stable aggregation and their accountants (data-independent, the data-dependent bounds of Equation 42.8 and Equation 42.9, and the exact two-label cost), trains the PATE students and the DP-SGD baselines, and simulates private in-context learning. It imports the running example, the network, DP-SGD and the subsampled-Gaussian accountant from code/dp_sgd.py, and the logistic regression from code/dp_erm.py. From the repository root:

```
uv run python code/part05-dp-ml/private_prediction.py
```

Output (seed 0), summarized in Table 42.11:

Table 42.11.: The script's output with the default seed.

Experiment	Result
Noise for Q answers	$\sigma \propto \sqrt{Q}$: 57.2 for 100 answers at $\varepsilon = 1$, 572 for 10,000
Teachers	Plurality accuracy 0.9336 to 0.9403 for 25 to 500 teachers
Answers against DP-SGD	Answers win for up to 58 queries at $\varepsilon = 0.5$, 18 at $\varepsilon = 1$, none from $\varepsilon = 2$
PATE student, 250 teachers	Best 0.8238 at $\varepsilon = 1$ to 0.9049 at $\varepsilon = 8$; DP-SGD 0.9128 to 0.9605
Data-dependent analysis	About 20% lower ε on this task; Theorem 6 above the exact two-label cost
Confident-GNMax	459 of 1,000 queries answered, student 0.8894 at $\varepsilon = 3.59$
Stable aggregation	Threshold 84.0 at $\varepsilon_0 = 1$; 14 exact labels for $\varepsilon = 20$ with 500 teachers
In-context learning, stand-in	Membership AUC 0.889 for a 16-shot learner; 0.7780 accuracy for 100 private answers at $\varepsilon = 1$

tests/test_private_prediction.py checks that the output still matches.

What to take from it. The privacy of private prediction is easy: one record, one vote, a Gaussian histogram, an accountant. Its accuracy is the hard part, and it is decided by the teachers' agreement against noise that grows like $\sqrt{Q}$. On a binary task where DP-SGD works well, private prediction wins only at small budgets and for a few dozen queries, and PATE's student loses to DP-SGD at every budget. That is not a verdict on the method but a description of when to use it: when you cannot train privately, when the queries are few, and when the teachers agree, which is what pretrained models in in-context learning provide.

42.12. Cheat sheet

k teachers on disjoint shards fixed by a hash, m labels, vote counts N_i, gap g, Q answered queries, add/remove neighbours. Table 42.12 collects the results.

Table 42.12.: Every result of the chapter.

Result	Formula	Conditions
Histogram sensitivity	ℓ_1: 2, ℓ_2: $\sqrt{2}$	One record in one shard
LNMax	$(2/b)$-DP per answer	Release the label only
GNMax	$(\alpha, \alpha/\sigma^2)$-RDP per answer	Release the label only

Result	Formula	Conditions
Noise for Q answers	$\sigma = \sqrt{Q/\rho(\varepsilon,\delta)}$; $\rho = 0.0306$ for $\varepsilon = 1$, 0.3731 for $\varepsilon = 4$ at $\delta = 10^{-5}$	Adaptive queries allowed
Accuracy, two labels	$\Phi(g/(\sqrt{2}\sigma))$	Exact
Failure, m labels	$\tilde{\beta} = \sum_{i \neq i^*} \frac{1}{2}\operatorname{erfc}((N_{i^*} - N_i)/(2\sigma))$	Union bound
Break-even	Answers beat a private model for $Q < Q^*(\varepsilon)$	Compare at the same budget
PATE student	Cost of its Q labels; predictions free	Public unlabelled inputs
Data-dependent, pure DP	$\frac{1}{\alpha-1}\ln[(1-\beta)^\alpha(1 - e^{\varepsilon_0}\beta)^{1-\alpha} + \beta e^{(\alpha-1)\varepsilon_0}]$	$\beta < e^{-\varepsilon_0}$; must be sanitized to publish
Data-dependent, GNMax	Equation 42.9	Conditions of Theorem 6; must be sanitized
Confident-GNMax	$(Q_{\text{pool}}/(2\sigma_1^2) + Q_{\text{ans}}/\sigma_2^2)\alpha$	Budget fixed in advance
Stable aggregation	Exact plurality where dist $= \lceil g/2 \rceil - 1$ passes a sparse-vector test at threshold τ; c runs of ε_0-DP	$Q_{\text{pool}} \Pr[\nu - \xi > \tau] \leq \delta_{\text{bad}}$; c fixed in advance
Private in-context learning	$Q\,\varepsilon_{q,\sigma/\sqrt{2}}(\alpha)$	Poisson rate q, disjoint groups per query

Rules of thumb

- Private prediction costs per answer; private training costs once. Count your queries before choosing.
- The noise grows like $\sqrt{Q}$ and does not depend on the number of teachers; add teachers as long as their vote gaps grow.
- Use Gaussian noise for more than a handful of answers, Laplace only for one or two.
- A teacher ensemble is only as good as its noiseless vote; measure that ceiling first.
- Data-dependent ε is not a guarantee until it is released privately; report the data-independent one, or pay for the release.
- Stable aggregation avoids the sanitizing, but only pays with many, nearly unanimous teachers: check what share of your queries clears its threshold first.
- Never put private exemplars in a prompt that answers users directly; vote over disjoint groups with noise, or distil into a public prompt.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

43. Public data and private fine-tuning

43.1. Why this matters

The previous chapters trained models with differential privacy (DP) from random weights, by stochastic gradient descent (SGD) with per-example clipping and Gaussian noise, called DP-SGD, as in DP-SGD: every step adds Gaussian noise to a sum of clipped per-example gradients, and an accountant turns the steps into one (ε, δ). On the part's running example it costs little at $\varepsilon = 8$ and a great deal at $\varepsilon = 1$ and below. The most accurate private models in the literature are not trained that way. They start from a model **pretrained** non-privately on a large **public** dataset, such as text or images collected from the web, and only **fine-tune** it privately on the sensitive data. Private image classifiers and private language models fine-tuned this way are far more accurate, at the same ε, than the same models trained privately from scratch (Tramèr & Boneh 2021; Yu et al. 2022; Li et al. 2022; De et al. 2022).

This chapter asks why that helps so much, and why a second practice helps on top of it: fine-tuning only a small part of the model, such as the last layer or a low-rank update to each weight matrix, often beats fine-tuning all of it under DP, although without privacy it would usually be the other way round.

43.1.1. The one idea: the noise is paid per trainable direction, the signal is not

DP-SGD adds noise of the same size to every coordinate it updates: with noise multiplier σ, clipping norm C and expected batch size B, the noise on the averaged gradient has standard deviation $\sigma C/B$ in each of the d trainable coordinates, so its length is about $\sigma C\sqrt{d}/B$. The useful part of the gradient, the average over the records, does not grow with d: it has length at most C whatever the number of coordinates, and it is usually concentrated in a few directions. Every trainable coordinate that the task does not need is a coordinate that only collects noise.

Public data helps in two ways that both follow from this. First, it moves the starting point close to a good model, so that what remains to be learned privately is small and lies in few directions. Second, it tells you which directions those are, before you touch the private data and at no privacy cost: the last layer on top of good features, a low-rank update, or the top principal directions of public gradients. Restricting training to those directions cuts the noise without cutting the signal. Whether it is worth restricting depends on how much of the signal the restriction throws away, and that is what decides between fine-tuning all weights and fine-tuning a few.

Table 43.1 lists the results and where each is used.

Table 43.1.: The results of this chapter and where each is used.

Result	Where it is used
The noise's length grows like $\sqrt{d}$; its cost grows with the number of directions it has time to fill, d_{eff}	Deciding how many weights to train; why full fine-tuning can still work
A linear model on fixed features is private convex empirical risk minimization (ERM)	Linear probing; when features from public data suffice
A low-rank adapter has $r(d_{\text{in}} + d_{\text{out}})$ weights and outer-product gradients	Parameter-efficient private fine-tuning; ghost clipping of adapters
Private gradients lie near a public low-dimensional subspace	Projected DP-SGD and gradient embedding; why fine-tuning is low-dimensional
Pretraining and fine-tuning on the running example	What each strategy buys at each ε
The guarantee covers the private data only	What to check about "public" data before relying on it

Notation. As in DP-SGD: n private records, C the clipping norm, σ the noise multiplier, q the sampling rate, $B = qn$ the expected batch size, T the number of steps and η the learning rate (also called the step size). The model has p weights, of which d **are trainable** during private fine-tuning; the others are frozen at their pretrained values. $s = \sigma C/B$ is the noise standard deviation per coordinate on the averaged gradient. D_{pub} is the public dataset, used freely, and D the private one. H is the curvature (Hessian) of the training loss at the starting point, with eigenvalues $h_1 \geq h_2 \geq \ldots$. Neighbouring private datasets differ by adding or removing one record.

The running example. The private task is the part's running example: 50-dimensional standard normal inputs labelled by a fixed random teacher network with 8 hidden tanh units, $n = 10{,}000$ training records, and a student with 64 hidden tanh units and $p = 3{,}329$ weights. The public task, built for this chapter, has 50,000 inputs from the same distribution labelled by a **related teacher**, which shares most of the private teacher's structure but not all of it; Section 43.7 gives the details. Pretraining on it helps on the private task without solving it. Fine-tuning runs DP-SGD with $q = 0.01$, $C = 0.5$ and $T = 10{,}000$ steps, the part's configuration, at $\delta = 10^{-5}$.

How to read this chapter. Read the toolkit and Section 43.3, which explains the rest. Section 43.4 and Section 43.5 are the two standard ways to train few weights; Section 43.6 explains why training all of them can still work. Section 43.7 runs everything on the running example, and Section 43.8 says what the guarantee does and does not cover. Read the last one even if you skip the others.

43.2. Toolkit: four facts every derivation uses

43.2.1. Fact 1 — DP-SGD's guarantee depends on the clipped sum, not on which weights it updates

Each step of DP-SGD releases $\sum_{i\in S_t}\bar{g}_i+\mathcal{N}(0,\sigma^2C^2I)$, where $\bar{g}_i$ is record i's gradient clipped to length at most C and S_t is a Poisson-sampled batch. Adding or removing one record changes the sum by one clipped gradient, of length at most C, so the noise is σ times the sensitivity, and the accountant composes the steps into (ε,δ) from q, σ and T alone (DP-SGD). Nothing in this argument depends on what the gradient is a gradient *of*: all weights, the last layer, the factors of a low-rank update, or a projection of the gradient onto a fixed subspace. The clipping simply applies to the vector of trainable coordinates, whatever it is. With $q=0.01$ and $T=10{,}000$, the accountant gives $\sigma=7.72$, 4.13, 2.28 and 0.917 for $\varepsilon=0.5$, 1, 2 and 8 at $\delta=10^{-5}$.

43.2.2. Fact 2 — A Gaussian vector's length grows like the square root of its dimension, and a projection keeps it Gaussian

If $\xi\sim\mathcal{N}(0,s^2I_k)$, then $\mathbb{E}\|\xi\|^2=ks^2$, a sum of d squared coordinates each with mean s^2, and $\|\xi\|$ concentrates near $s\sqrt{d}$ (Concentration inequalities). If P is the orthogonal projection onto a fixed m-dimensional subspace, then $P\xi$ is again Gaussian, with standard deviation s along each of m orthonormal directions of the subspace and nothing outside it. The reason is rotation invariance: the density of ξ depends only on $\|\xi\|$, so in any orthonormal basis its coordinates are independent $\mathcal{N}(0,s^2)$, and the projection keeps m of them. So noise restricted to a subspace has length about $s\sqrt{m}$.

43.2.3. Fact 3 — Public data is free, and so is anything computed from it

DP bounds how the output's distribution changes when one *private* record changes. A computation that reads only public data, such as pretraining, choosing a subspace from public gradients or tuning on a public validation set, produces a fixed object as far as the private data are concerned, and using it as the starting point or a hyperparameter of a private algorithm costs nothing. In the DP-SGD proof this enters as the condition that the initial weights θ_0 are chosen independently of the private data (DP-SGD). Anything computed afterwards from the private algorithm's output is post-processing (Post-processing, group privacy and composition).

43.2.4. Fact 4 — A dense layer's per-example gradient is an outer product

For a layer that maps an input $a\in\mathbb{R}^{d_{\text{in}}}$ to Wa, the gradient of record i's loss with respect to W is $\nu_i a_i^\top$, where ν_i is the gradient with respect to the layer's output, and its length is $\|\nu_i\|\,\|a_i\|$, because the squared entries $\nu_{ij}^2a_{il}^2$ sum to $(\sum_j\nu_{ij}^2)(\sum_l a_{il}^2)$. Clipping can therefore compute each record's gradient norm without forming the gradient, **ghost clipping** (DP-SGD).

43.3. Why dimension costs, and when it does not

43.3.1. Context

Every bound on private learning in this part grows with the dimension. Private empirical risk minimization shows that the best excess risk achievable under (ε, δ)-DP grows like $\sqrt{d}$ for convex Lipschitz losses and like d for strongly convex ones. Matching lower bounds hold up to logarithmic factors. The noise in DP-SGD has length $\sigma C\sqrt{d}/B$, growing with the number of trainable weights. Yet large pretrained language models with hundreds of millions of weights are fine-tuned privately with good results. How much does each trainable direction really cost, and what decides it?

43.3.2. Statement

The noise on the averaged gradient, restricted to the d trainable coordinates, has length

$$\|\xi_t\|/B \approx s\sqrt{d} = \frac{\sigma C\sqrt{d}}{B}. \tag{43.1}$$

Near the starting point, model the loss as a quadratic with curvature H. Then T steps of noisy gradient descent with learning rate η and noise of standard deviation s per coordinate raise the expected loss, compared with the same steps without noise, by $\mathcal{E}$, the noise cost:

$$\mathcal{E} = \sum_{j=1}^{d} \frac{\eta s^2}{2(2-\eta h_j)}\Big(1-(1-\eta h_j)^{2T}\Big) \approx \frac{\eta s^2}{4}\, d_{\text{eff}}, \qquad d_{\text{eff}} = \sum_{j=1}^{d}\Big(1-(1-\eta h_j)^{2T}\Big), \tag{43.2}$$

where h_j are the eigenvalues of H restricted to the trainable coordinates, $0 \le h_j < 2/\eta$, and the approximation assumes $\eta h_j \ll 1$. The **effective dimension** d_{eff} satisfies

$$d_{\text{eff}} \le \min\Big(d,\ 2\eta T \operatorname{tr} H\Big). \tag{43.3}$$

43.3.3. Derivation

The idea is to follow the noise separately from the signal. On a quadratic, the dynamics are linear, so the noise's contribution to the weights is a sum of independent Gaussian kicks, each shrunk by the curvature. Directions with high curvature forget old kicks quickly and reach a steady state; directions with almost no curvature keep accumulating kicks but charge very little for them.

1. **Separate the noise.** Write $\mathcal{L}(\theta)$ for the training loss, the empirical risk on the fixed private dataset. On the quadratic $\mathcal{L}(\theta) = \mathcal{L}(\theta^*) + \frac{1}{2}(\theta-\theta^*)^\top H(\theta-\theta^*)$ the gradient is $H(\theta-\theta^*)$. Let θ_t follow the noisy steps $\theta_{t+1} = \theta_t - \eta(H(\theta_t-\theta^*) + \xi_t)$ and $\bar\theta_t$ the same steps without noise, from the same start. Their difference $e_t = \theta_t - \bar\theta_t$ obeys $e_{t+1} = (I-\eta H)e_t - \eta\xi_t$ with $e_0 = 0$, because the terms with θ^* are the same for both and cancel. So e_t is a linear function of the noise alone, a Gaussian with mean zero.
2. **The loss increase.** Expanding the quadratic around $\bar\theta_T$, $\mathcal{L}(\theta_T) = \mathcal{L}(\bar\theta_T) + \nabla\mathcal{L}(\bar\theta_T)^\top e_T + \frac{1}{2}e_T^\top H e_T$. The middle term has mean zero, because e_T has mean zero and is independent of the deterministic $\bar\theta_T$. So $\mathcal{E} = \frac{1}{2}\mathbb{E}[e_T^\top H e_T]$.

3. **One direction at a time.** In the eigenbasis of H the coordinates decouple, and by Fact 2 each coordinate of the noise is still $\mathcal{N}(0, s^2)$, independently. Along an eigenvector with curvature h, the coordinate e of the error obeys $e_{t+1} = (1-\eta h)e_t - \eta\xi$, so after T steps it is $-\eta\sum_{t<T}(1-\eta h)^{T-1-t}\xi_t$, with variance

$$v_T = \eta^2 s^2 \sum_{t=0}^{T-1}(1-\eta h)^{2t} = \eta^2 s^2\,\frac{1-(1-\eta h)^{2T}}{1-(1-\eta h)^2}, \tag{43.4}$$

   a geometric sum.
4. **Its cost.** The direction contributes $\frac{1}{2}hv_T$ to $\mathcal{E}$. Since $1-(1-\eta h)^2 = \eta h(2-\eta h)$, this is $\frac{\eta s^2}{2(2-\eta h)}(1-(1-\eta h)^{2T})$, and summing over the directions gives Equation 43.2. With $\eta h \ll 1$ the first factor is $\eta s^2/4$.
5. **Two limits.** For $2\eta hT \gg 1$ the bracket is 1: the direction is at its steady state, the case Private empirical risk minimization analyses, and it costs $\eta s^2/4$ whatever its curvature (stiffer directions wander less but charge more per unit of wandering). For $2\eta hT \ll 1$ the bracket is about $2\eta hT$, by $(1-x)^{2T} \approx 1-2Tx$, and the direction costs about $\frac{\eta s^2}{4}\cdot 2\eta hT$: the noise has random-walked a distance of variance $T\eta^2 s^2$, charged at rate $h/2$, which is small when the direction is flat.
6. **The bound.** Each bracket is at most 1, which gives $d_{\text{eff}} \le d$. And $1-(1-x)^{2T} \le 2Tx$ for $0 \le x \le 1$ (Bernoulli's inequality, $(1-x)^{2T} \ge 1-2Tx$), so $d_{\text{eff}} \le 2\eta T\sum_j h_j = 2\eta T\,\operatorname{tr} H$.

43.3.4. Interpretation

The count of trainable weights is an upper bound, not the price. Equation 43.2 says that noise in a direction the loss does not care about, $h_j \approx 0$, costs nothing, however long it is. What you pay for is roughly the number of directions whose curvature exceeds $1/(2\eta T)$, the directions the noise has time to fill. A large pretrained model whose loss is curved in only a few directions near the pretrained weights can be fine-tuned in all its weights at a cost set by those few. This is the explanation Li, Liu, Hashimoto, Inan, Kulkarni, Lee & Thakurta (2022) give for why private fine-tuning of large language models does not suffer from their size: the optimal rates of Private empirical risk minimization are worst cases over all losses with a given Lipschitz constant, and they replace the dimension d by a quantity that measures how the gradients spread over directions.

Fewer trainable weights still help, for two reasons. Freezing weights removes their directions from the sum, so d_{eff} can only fall. And clipping happens to the trainable gradient: with fewer coordinates, per-example gradients are shorter, fewer are clipped, and the average clipped gradient, the signal, can be longer. Both effects appear in the example below. Against them stands the **bias** of freezing: if the task needs a direction that is frozen, no amount of private data can move it.

The learning rate and the number of steps are part of the dimension. d_{eff} grows with ηT: a longer or more aggressive run fills more flat directions with noise. This is one reason private fine-tuning works best with smaller learning rates than private training from scratch, as Section 43.7 finds.

How good is the model? The quadratic is a local model, accurate while fine-tuning stays near its starting point; the loss of a network is not quadratic far from it. And the loss increase is

not an accuracy loss: accuracy changes only when noise flips predictions. Use Equation 43.2 to compare strategies, not to predict accuracy.

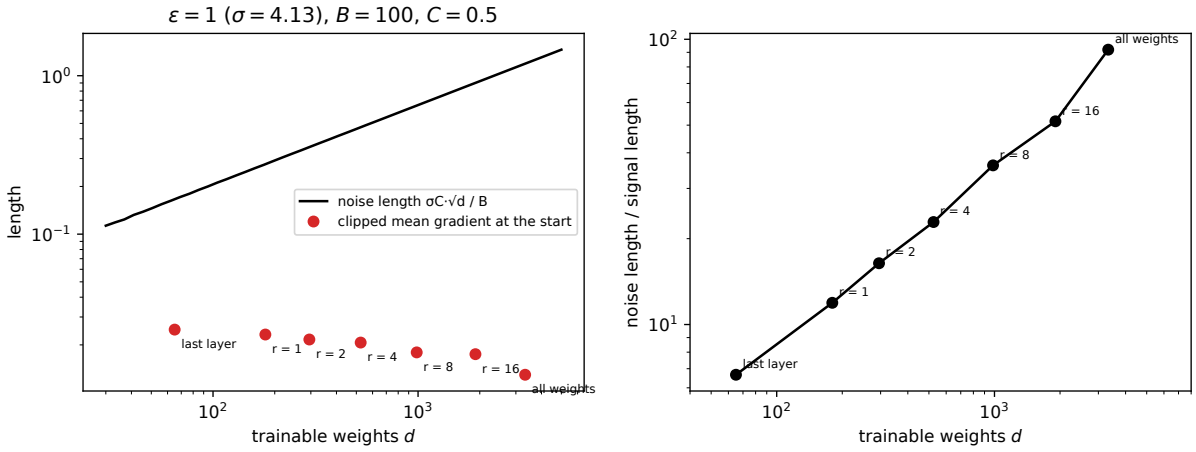

Figure 43.1.: Left: at $\varepsilon = 1$ ($\sigma = 4.13$, $B = 100$, $C = 0.5$), the noise length $\sigma C\sqrt{d}/B$ (line) against the number of trainable weights d, and the length of the average clipped gradient at the pretrained model (points) for the last layer, low-rank adapters of ranks 1 to 16, and all weights. Right: their ratio. The noise grows like $\sqrt{d}$ while the signal shrinks, because longer gradient vectors are clipped more.

43.3.5. Example: the running example after pretraining

Table 43.2 gives the noise length Equation 43.1 for the three trainable sets of Section 43.7, with $B = 100$ and $C = 0.5$.

Table 43.2.: Length of the noise on the averaged gradient, $\sigma C\sqrt{d}/B$, for three numbers of trainable weights.

ε	σ	All weights, $d = 3{,}329$	Rank-4 adapter and last layer, $d = 525$	Last layer, $d = 65$
0.5	7.72	2.227	0.884	0.311
1	4.13	1.191	0.473	0.166
2	2.28	0.658	0.261	0.092
8	0.917	0.265	0.105	0.037

The signal is the average clipped gradient over the private records at the start of fine-tuning. From the pretrained weights its length is 0.0130 when all weights are trained, 0.0207 for the adapter and 0.0250 for the last layer alone (Figure 43.1). The last layer's 65 coordinates carry a *longer* average clipped gradient than all 3,329 coordinates together, because each record's gradient restricted to 65 coordinates is shorter and less often clipped. At $\varepsilon = 1$ the noise is 92.0 times the signal for all weights, 22.9 times for the adapter and 6.7 times for the last layer. By the break-even argument of DP-SGD, a signal of constant direction outgrows a random walk of noise

after (noise/signal)^2 steps: 8,455, 523 and 44 steps. From a random initialization the signal is 0.0618, five times longer than from the pretrained weights, because a random network gets many records wrong and their gradients are long; but it shrinks quickly as training proceeds, to 0.026 after 1,000 steps in DP-SGD.

The curvature tells a less pessimistic story. Take the **Gauss–Newton curvature** of the private loss at the pretrained weights: the Hessian of the logistic loss with the network replaced by its linearization around the current weights, the average over records of $\pi_i(1-\pi_i)\nabla f_i \nabla f_i^\top$, with f_i the network's output on record i and π_i its predicted probability. It is positive semi-definite, and near a good fit it is close to the full Hessian, which is what the quadratic model needs. Estimated from 2,000 private records, it has largest eigenvalue 0.723 and trace 16.310 over all weights; for the last layer alone the largest eigenvalue is 0.142 and the trace 0.681. With $\eta = 0.1$ and $T = 10{,}000$, only 406 of the 3,329 directions have curvature above $1/(2\eta T) = 5 \times 10^{-4}$, and $d_{\text{eff}} = 451$; for the last layer, $d_{\text{eff}} = 60.2$ of 65. The full model's noise is $\sqrt{3{,}329/65} = 7.2$ times longer than the last layer's, but by Equation 43.2 it costs only $451/60.2 = 7.5$ times more, not $3{,}329/65 = 51$ times. At $\varepsilon = 1$, where $s = 0.0206$, Equation 43.2 predicts a loss increase of 0.0048 for all weights at $\eta = 0.1$, against 0.0355 if every direction had reached its steady state, and 0.00064 for the last layer alone.

43.3.6. Check yourself

- You double the number of steps at the same σ (ignoring that this would raise ε). Which directions' noise cost changes? *(Only the flat ones, $2\eta h T \lesssim 1$, whose cost doubles roughly; directions already at their steady state cost the same.)*
- Why does $d_{\text{eff}} \le 2\eta T \operatorname{tr} H$ not help much in the running example? *(Because $2\eta T \operatorname{tr} H = 2 \times 0.1 \times 10{,}000 \times 16.31 = 32{,}620$, far above $d = 3{,}329$. The trace is dominated by a few large eigenvalues; the bound is useful only when the total curvature is small compared with $1/(\eta T)$.)*

43.4. Good features: the last layer as private convex ERM

43.4.1. Context

The simplest way to use a pretrained model is to freeze everything except the last layer and train a linear classifier on the frozen features, **linear probing**. For the running example that is logistic regression on the 64 hidden activations plus a bias, 65 weights. It turns private deep learning back into the convex problem of Private empirical risk minimization, where the rates and the methods are known. Tramèr & Boneh (2021) showed that this simple recipe beats end-to-end private training of convolutional networks on standard image benchmarks at moderate budgets, even with handcrafted features (the ScatterNet wavelet transform), and that features learned on public data do better still. What does the private part of a linear probe cost, and what limits it?

43.4.2. Statement

Let $\phi(x) \in \mathbb{R}^d$ be the frozen features, computed from public data only, and $\ell(\theta; (x, y)) = \ln(1 + e^{-y\langle\theta, \phi(x)\rangle})$. Then:

1. The per-record gradient has length at most $\|\phi(x)\|$. For $d-1$ tanh features and a constant 1, $\|\phi(x)\| \le \sqrt{d}$, so the loss is $\sqrt{d}$-Lipschitz in θ and clipping is optional.
2. The excess risk of a private probe splits into a **feature gap** and a **privacy cost**:

$$\mathcal{L}_{\mathcal{D}}(\tilde{\theta}) - \mathcal{L}_{\text{best}} = \underbrace{\mathcal{L}_{\mathcal{D}}(\theta^{\phi}) - \mathcal{L}_{\text{best}}}_{\text{features}} + \underbrace{\mathcal{L}_{\mathcal{D}}(\tilde{\theta}) - \mathcal{L}_{\mathcal{D}}(\theta^{\phi})}_{\text{privacy}}, \tag{43.5}$$

   where $\mathcal{L}_{\mathcal{D}}$ is the population risk, $\mathcal{L}_{\text{best}}$ the best population risk of any model, $\tilde{\theta}$ the private probe and θ^{ϕ} the best linear model on the features ϕ. The first term does not depend on n or ε. The second is private convex ERM in d dimensions. Take losses that are L-Lipschitz over a ball of radius R. Noisy projected gradient descent keeps the privacy cost below a constant times $LR\sqrt{d\ln(1/\delta)}/(n\varepsilon)$. No private algorithm can do better than order $LR\sqrt{d}/(n\varepsilon)$ (Bassily, Smith & Thakurta 2014).

43.4.3. Derivation

1. **The gradient bound.** $\nabla_\theta \ell = \ell'(m)\, y\, \phi(x)$ with $m = y\langle\theta, \phi(x)\rangle$ the margin and $\ell'(m) = -1/(1 + e^m) \in (-1, 0)$. So $\|\nabla_\theta \ell\| \le \|\phi(x)\|$. Each tanh activation lies in $(-1, 1)$, so $\|\phi(x)\|^2 < (d-1) + 1 = d$.
2. **The split.** Add and subtract $\mathcal{L}_{\mathcal{D}}(\theta^{\phi})$. The first difference compares two non-private quantities and contains no noise.
3. **The privacy term.** By Fact 3, ϕ is a fixed function, so the probe is an ordinary convex ERM problem on the transformed records $(\phi(x_i), y_i)$, with dimension d and Lipschitz constant $\sqrt{d}$ or the clipping norm. The upper bound is the one Private empirical risk minimization derives for noisy projected gradient descent, and the lower bound is Bassily, Smith & Thakurta's (2014). The Lipschitz constant and the dimension enter through the noise $\propto L\sqrt{d}$ that every private method must add.

43.4.4. Interpretation

Features cap accuracy; privacy only decides how close you get to the cap. The feature gap is the price of freezing, paid even with infinite data and no privacy. The privacy cost falls like $\sqrt{d}/(n\varepsilon)$. With few features and good ones, both are small; with few features and poor ones, the probe is private, cheap and bad. This is the trade-off behind the title of Tramèr & Boneh's paper: private learning needs better features, or much more data. End-to-end training can eventually beat a probe, because it can learn better features, but it pays for every one of its weights to do so, and at small ε and small n it does not catch up.

Why linear probing is the safe first baseline. The problem is convex, so the optimizer cannot wander into a bad region, and the theory of Private empirical risk minimization applies: output perturbation, objective perturbation and noisy gradient descent all work, with known rates and no clipping bias if you use the Lipschitz bound. It has few hyperparameters, and with

very few weights it can even be run full-batch. If a probe on public features is already within your accuracy target, there is little reason to fine-tune more.

Clipping below the Lipschitz bound still pays. The bound $\sqrt{d}$ is a worst case: it is reached only by a record with every activation saturated and a large negative margin. Most records' gradients are much shorter, because a record classified with a wide margin has $|\ell'(m)|$ close to 0. Clipping at a smaller C biases the gradient of the few long ones and divides the noise by $\sqrt{d}/C$; Exercise 3 in the exercise book compares the two on the running example.

43.4.5. Example: the ceiling and the cost on the running example

The pretrained network's 64 hidden units plus a constant give $d = 65$ features; the largest feature norm on the private training records is 7.035, below the bound $\sqrt{65} = 8.062$. The pretrained network itself, with its public last layer, labels 0.9035 of the private test inputs correctly (the report half, Section 43.7). Fitting the last layer exactly and non-privately on the 10,000 private records, by Newton's method, raises this to 0.9536: that is the probe's ceiling, θ^{ϕ} in Equation 43.5. A network trained non-privately on the private data from scratch reaches 0.9606, so the feature gap is 0.007 in accuracy. The private probe reaches 0.9478 at $\varepsilon = 0.5$ and 0.9514 at $\varepsilon = 8$ (Table 43.5): at every budget it is within 0.006 of its ceiling, and at no budget can it pass it.

43.4.6. Check yourself

- The public features are replaced by 650 features of the same quality (same ceiling). What happens to the privacy cost of the probe? *(The noise length grows by $\sqrt{10} \approx 3.2$ at the same σ, so the privacy term of Equation 43.5 grows by about that factor at a fixed $n\varepsilon$; you need about 3.2 times more data for the same cost.)*
- Is the probe private if the features were computed by a network pretrained on data that included some of the private records? *(The probe is private with respect to the private dataset given the features; but the features themselves are a function of those records and were not trained privately, so the released model as a whole has no guarantee for them. See Section 43.8.)*

43.5. Low-rank adapters

43.5.1. Context

The last layer is often not enough: the features of a model pretrained on one task are not exactly right for another, and the probe stops at its ceiling. Training all weights fixes the features but pays for every weight. **Low-rank adaptation (LoRA)** sits in between: it freezes each pretrained weight matrix W_0 and learns a low-rank correction, $W = W_0 + UV^{\top}$ with $U \in \mathbb{R}^{d_{\text{out}} \times r}$ and $V \in \mathbb{R}^{d_{\text{in}} \times r}$ (Hu et al. 2022). Yu et al. (2022) showed that private fine-tuning of language models with LoRA and similar parameter-efficient methods matches or beats private full fine-tuning at a fraction of the cost. How many weights does it train, what are its per-example gradients, and in which directions can it move W?

43.5.2. Statement

A rank-r adapter on a $d_{\text{out}} \times d_{\text{in}}$ matrix has

$$d = r(d_{\text{in}} + d_{\text{out}}) \tag{43.6}$$

trainable weights, against $d_{\text{in}} d_{\text{out}}$ for the matrix. With ν_i the gradient of record i's loss with respect to the layer's output and a_i its input, the per-example gradients are outer products,

$$\nabla_U \ell_i = \nu_i \, (V^\top a_i)^\top, \qquad \nabla_V \ell_i = a_i \, (U^\top \nu_i)^\top, \tag{43.7}$$

with lengths $\|\nu_i\| \|V^\top a_i\|$ and $\|a_i\| \|U^\top \nu_i\|$, so ghost clipping applies. One step with noisy gradient sums $G_U = \sum_i \overline{\nabla_U \ell_i} + \xi_U$ and $G_V = \sum_i \overline{\nabla_V \ell_i} + \xi_V$ and step η/B changes W to W', with

$$W' - W = -\frac{\eta}{B}(G_U V^\top + U G_V^\top) + O\Big(\frac{\eta^2}{B^2}\Big). \tag{43.8}$$

In particular, from the usual start $U = 0$, the first step's change has rank at most r, and to first order its rows lie in the span of the columns of V. The privacy guarantee is that of DP-SGD with the same q, σ and T (Fact 1).

43.5.3. Derivation

1. **Counting.** U has $d_{\text{out}} r$ entries and V has $d_{\text{in}} r$.
2. **The chain rule through the product.** By Fact 4 the gradient with respect to W is $G_i = \nu_i a_i^\top$, and the loss depends on U and V only through W. A small change dU changes W by $dU\, V^\top$, which changes the loss by $\operatorname{tr}(G_i^\top dU\, V^\top) = \operatorname{tr}(V^\top G_i^\top dU) = \langle G_i V, dU \rangle$, using the cyclic property of the trace. So $\nabla_U \ell_i = G_i V = \nu_i (a_i^\top V) = \nu_i (V^\top a_i)^\top$. In the same way a change dV changes W by $U\, dV^\top$ and the loss by $\operatorname{tr}(G_i^\top U\, dV^\top) = \langle G_i^\top U, dV \rangle$, so $\nabla_V \ell_i = G_i^\top U = a_i (\nu_i^\top U) = a_i (U^\top \nu_i)^\top$. This is Equation 43.7.
3. **Norms.** Each is an outer product of two vectors, so its length is the product of their lengths, as in Fact 4. The norm of record i's whole gradient is the square root of the sum of the squared norms over U, V and the other trainable layers, computed from vectors of length d_{out}, d_{in} and r without forming any matrix.
4. **The step.** After the step, $W' = W_0 + (U - \frac{\eta}{B} G_U)(V - \frac{\eta}{B} G_V)^\top$. Expanding the product, $W' - W = -\frac{\eta}{B}(G_U V^\top + U G_V^\top) + \frac{\eta^2}{B^2} G_U G_V^\top$, which is Equation 43.8.
5. **From $U = 0$.** Then $\nabla_V \ell_i = 0$ for every record, so $G_V = \xi_V$ is pure noise, and $W' - W = -\frac{\eta}{B} G_U V^\top + \frac{\eta^2}{B^2} G_U \xi_V^\top$. The first term is a $d_{\text{out}} \times r$ matrix times $V^\top$, of rank at most r, with rows that are combinations of the columns of V. The second term is of order η^2/B^2 and tilts those rows slightly. The whole change $W' - W$ is a product of a $d_{\text{out}} \times r$ and an $r \times d_{\text{in}}$ matrix, so its rank is at most r exactly.

43.5.4. Interpretation

An adapter is DP-SGD in a smaller, moving space. The noise of DP-SGD on (U, V) lives in $d = r(d_{\text{in}} + d_{\text{out}})$ coordinates, so Equation 43.1 applies with that d. Seen from W, each step moves the matrix within a set of dimension about d: the directions $XV^\top + UY^\top$ for arbitrary X

and Y, which change as U and V change. The adapter restricts the update to that set; noise in the other $d_{\text{in}}d_{\text{out}} - d$ directions of W never arises.

What the restriction costs. At the start, with $U = 0$ and V random, the update is the true gradient G multiplied on the right by $VV^\top$, which for a random V with small r is close to a multiple of the projection onto the span of its columns: the gradient is projected onto a random r-dimensional subspace of the inputs. Random subspaces capture a fraction of about r/d_{in} of a fixed vector's energy, which for small r is little. As V moves (its gradient is no longer zero once $U \neq 0$) the subspace aligns with the useful directions. Low-rank adaptation works when the change from the pretrained weights that the new task needs is itself close to low rank, as Hu et al. (2022) observed for language models. The rank r trades bias against noise like the number of trainable weights does.

Full fine-tuning is not ruled out. Li, Tramèr, Liang & Hashimoto (2022) fine-tuned all the weights of pretrained language models with DP-SGD and matched or beat the parameter-efficient methods, once the hyperparameters were right: large batches, a learning rate tuned for private training, and a fine-tuning objective aligned with pretraining. Equation 43.2 explains why this can work: what full fine-tuning pays is d_{eff}, not p. Whether an adapter or full fine-tuning wins is an empirical question that depends on the model, the data and the tuning, and the published evidence goes both ways. The adapter's advantages that do not depend on accuracy are certain: it stores and communicates only d numbers per task, and it computes and clips much smaller gradients.

43.5.5. Example: counting, and checking the gradients

The running example's first layer maps 51 inputs (50 features and a constant) to 64 hidden units: 3,264 weights. A rank-4 adapter trains $4 \times (51 + 64) = 460$ of them, plus the 65 weights of the last layer, $d = 525$; rank 1 gives 180 and rank 16 gives 1,905. For a 768×768 projection of a transformer, rank 8 trains $8 \times 1{,}536 = 12{,}288$ weights instead of 589,824, a factor of 48 fewer, so the noise is $\sqrt{48} = 6.9$ times shorter. On 256 private records, the ghost norms of Equation 43.7 agree with explicitly formed per-example gradients of the adapter to a relative difference of 3.3×10^{-16}. Exercise 4 in the exercise book checks the rank of the first step.

43.5.6. Check yourself

- Why does LoRA start with $U = 0$ rather than both factors random? *(So that $W = W_0$ at the start: the fine-tuned model begins exactly at the pretrained one. With both random, the first forward pass would use a randomly perturbed matrix.)*
- An adapter of rank $r = \min(d_{\text{in}}, d_{\text{out}})$ can represent any change of W. Does it then have the same noise as training W directly? *(No, more: it has $r(d_{in} + d_{out})$ coordinates, more than $d_{in}d_{out}$ when r is this large. Adapters save noise only at small rank.)*

43.6. Gradients near a public subspace

43.6.1. Context

Section 43.3 says the noise costs little in directions the loss does not use. If you knew the directions the private gradients do use, you could add noise only there. Public data gives an estimate: compute per-example gradients on public records at the current or pretrained weights, find their top principal directions, and project the private gradients onto them. Zhou, Wu & Banerjee (2021) do this as **projected DP-SGD**, and Yu, Zhang, Chen & Liu (2021) as **gradient embedding perturbation**, which also releases the residual outside the subspace with separate noise. Li et al. (2022) measured that the gradients of private fine-tuning are dominated by a few principal components. How much does a projection save, and what does it lose?

43.6.2. Statement

Let P_m be the orthogonal projection onto an m-dimensional subspace computed from public data only. Releasing

$$P_m\Big(\sum_{i\in S_t}\bar{g}_i\Big)+\mathcal{N}(0,\sigma^2C^2P_m) \tag{43.9}$$

(noise of standard deviation σC along each of m orthonormal directions of the subspace) at every step has the same (ε,δ) as DP-SGD with the same q, σ and T. If $\bar{m}$ is the average clipped gradient and $f_m=\|P_m\bar{m}\|^2/\|\bar{m}\|^2$ the fraction of its energy that the subspace captures, the kept signal has length $\sqrt{f_m}\|\bar{m}\|$, the noise on the averaged gradient has length about $s\sqrt{m}$, and signal outgrows noise after about

$$T_{\text{even}}(m)=\Big(\frac{s\sqrt{m}}{\sqrt{f_m}\,\|\bar{m}\|}\Big)^2 \tag{43.10}$$

steps, against $(s\sqrt{p}/\|\bar{m}\|)^2$ without projection. The lost fraction $1-f_m$ of the signal is a bias that no number of steps recovers.

43.6.3. Derivation

1. **Sensitivity.** A projection never lengthens a vector: $\|P_mx\|\le\|x\|$, because $x=P_mx+(x-P_mx)$ with the two parts orthogonal, so $\|x\|^2=\|P_mx\|^2+\|x-P_mx\|^2$. Adding or removing one record changes the projected sum by $P_m\bar{g}$, of length at most C.
2. **The mechanism.** In an orthonormal basis of the subspace, Equation 43.9 is m coordinates of a vector of sensitivity at most C plus independent $\mathcal{N}(0,\sigma^2C^2)$ noise on each: a Gaussian mechanism with ratio $1/\sigma$, exactly as in DP-SGD, and Poisson sampling makes it the same subsampled Gaussian. The subspace is fixed before the private data are read (Fact 3), so it is a public parameter of the mechanism. Equivalently, Equation 43.9 is the projection of the ordinary DP-SGD release onto the subspace (Fact 2), and projection is post-processing.
3. **Signal and noise.** Dividing by B, the kept signal is $P_m\bar{m}$, of length $\sqrt{f_m}\|\bar{m}\|$ by the definition of f_m, and the noise has m coordinates of standard deviation s, length about $s\sqrt{m}$ (Fact 2).
4. **Break-even.** As in DP-SGD, over j steps a signal of constant direction adds up to j times its length and independent noise to $\sqrt{j}$ times; they are equal at Equation 43.10.

43.6.4. Interpretation

A projection trades bias for variance, and public data fix the exchange rate. The noise falls by $\sqrt{p/m}$, the signal by $\sqrt{f_m}$. If the private gradients lie near the public subspace, f_m is close to 1 for $m \ll p$ and the trade is excellent. If the public data are unrelated, the subspace is no better than a random one, $f_m \approx m/p$, and the projection removes as much signal as noise, gaining nothing. The quality of the public data appears here directly as f_m.

A fixed subspace is a cap; methods refresh it or add the residual. Since P_m removes the part $1 - f_m$ of the signal at every step, training with a fixed projection can only move the weights within the subspace. Projected DP-SGD recomputes the subspace from public gradients as training proceeds; gradient embedding perturbation releases the residual $\bar{g} - P_m\bar{g}$ too, with its own noise, so the bias disappears at the price of a little more noise. LoRA, in this light, chooses a subspace by structure (low-rank changes of each matrix) and lets training move it.

Why this explains full fine-tuning. The same concentration that makes a public subspace useful makes d_{eff} small in Equation 43.2: gradients near a low-dimensional subspace are gradients of a loss curved in few directions. Projection makes the saving explicit and certain; full fine-tuning gets part of it implicitly, if the learning rate and number of steps are small enough that flat directions do not fill up with noise.

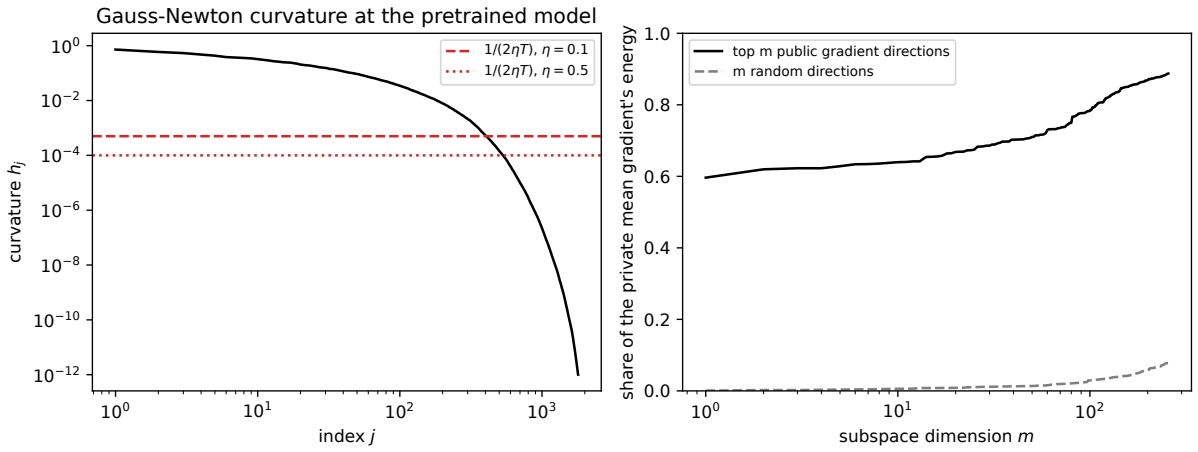

Figure 43.2.: Left: eigenvalues of the Gauss–Newton curvature of the private loss at the pretrained weights, estimated from 2,000 private records, on log scales, with the thresholds $1/(2\eta T)$ for $\eta = 0.1$ and 0.5 and $T = 10{,}000$; directions below a threshold contribute little noise cost. Right: the fraction of the energy of the private average clipped gradient that lies in the top m principal directions of 500 public per-example gradients (solid), and in m random directions (dashed).

43.6.5. Example: how concentrated the running example's gradients are

At the pretrained weights the average clipped private gradient has length 0.0130. The top principal directions of 500 clipped public per-example gradients capture Table 43.3's fractions of its energy; random subspaces of the same dimension capture about m/p.

Table 43.3.: How much of the private average clipped gradient lies in public subspaces, at the pretrained weights, and the steps after which the kept signal outgrows the noise at $\varepsilon = 1$ ($s = 0.0206$).

Dimension m	1	4	16	64	256	3,329 (all)
Public top-m directions, f_m	0.596	0.623	0.655	0.732	0.887	1
m random directions	0.001	0.001	0.004	0.022	0.080	1
Break-even steps at $\varepsilon = 1$, Equation 43.10	4	16	62	222	733	8,455

A single public direction holds 60% of the private gradient's energy, and 64 directions, 2% of the dimensions, hold 73%. At $\varepsilon = 1$ the kept signal outgrows the noise after 222 steps in the 64-dimensional subspace, against 8,455 steps for all weights. The cost is the 27% of the energy outside it, which a fixed projection never learns. The left panel of Figure 43.2 shows the curvature: its eigenvalues fall from 0.723 to below 5×10^{-4} within the first 406 directions and keep falling steeply after, so the noise of a run with $\eta = 0.1$ fills only the directions above the dashed line.

43.6.6. Check yourself

- The public subspace is computed from the private data instead, by a non-private principal component analysis. Is Equation 43.9 still (ε, δ)-DP? *(No. The subspace then depends on the private records, the projection is no longer a fixed public map, and the subspace itself leaks information about them; it must be computed privately, at a cost in budget, or from public data.)*
- When does projection onto m public directions not shorten the break-even time? *(When $f_m \leq m/p$ or close to it, so that the signal shrinks as much as the noise: for public data unrelated to the private task, or for a subspace computed at weights far from where training now is.)*

43.7. Pretraining and fine-tuning the running example

43.7.1. Context

How much does a related public dataset buy on the running example, at each budget, and which part of the model should be fine-tuned?

43.7.2. Statement

The public task. The private teacher has a first layer W_1^{priv} (8 hidden units, 51 inputs) and an output layer W_2^{priv}. The public teacher has first layer $W_1^{\text{priv}} + 0.15Z_1$ and output layer $\cos(0.3)\, W_2^{\text{priv}} + \sin(0.3)\, Z_2$, where Z_1 and Z_2 are fixed standard normal draws: the same hidden units, each slightly perturbed, read out with weights turned by 0.3 radians toward a random vector. It labels 50,000 inputs drawn from the private input distribution. The design makes pretraining useful but not sufficient: the public student must learn features close to the ones the private task needs, but cannot learn the private task itself. The public teacher agrees with the private one on 0.9004 of the private test inputs.

Pretraining. The 64-unit student is trained on the public data by non-private SGD, 10,000 steps with batches of 100 and learning rate 0.5, to 0.9861 training accuracy on the public task. On the private task it reaches 0.9035 without any private data.

Fine-tuning. From the pretrained weights, DP-SGD with $q = 0.01$, $C = 0.5$ and $T = 10{,}000$ trains: all 3,329 weights (*full*); the last layer, $d = 65$ (*last layer*); a rank-4 adapter $W_1 = W_1^{\text{pre}} + UV^\top$ and the last layer, $d = 525$ (*adapter*). The baseline trains all weights from a random initialization (*scratch*), the setting of DP-SGD. The private test set of 20,000 records is split in half: the learning rate of each method is chosen from three values on the first half at $\varepsilon = 1$ (Table 43.4) and used at every budget, and accuracy is reported on the second half.

Table 43.4.: Learning-rate selection at $\varepsilon = 1$, one run each, on the validation half of the private test set.

Method	Learning rates tried, accuracy on the validation half	Chosen
Scratch	0.25: 0.9318; 0.5: 0.9303; 1: 0.8582	0.25
Full	0.03: 0.9559; 0.1: 0.9567; 0.3: 0.9433	0.1
Last layer	0.1: 0.9479; 0.3: 0.9499; 1: 0.9460	0.3
Adapter, rank 4	0.03: 0.9556; 0.1: 0.9619; 0.3: 0.9472	0.1

Table 43.5 gives the results.

Table 43.5.: Test accuracy on the report half of the private test set, mean and standard deviation over two runs, $\delta = 10^{-5}$. The pretrained model without fine-tuning has 0.9035. Non-private: SGD for 1,000 steps from scratch and from the pretrained weights, and the exact logistic regression on the frozen features.

	Scratch	Full	Last layer	Adapter, rank 4
Trainable weights d	3,329	3,329	65	525
$\varepsilon = 0.5$	0.8589 ± 0.0075	0.9395 ± 0.0006	0.9478 ± 0.0010	0.9464 ± 0.0005

	Scratch	Full	Last layer	Adapter, rank 4
$\varepsilon = 1$	0.9246 ± 0.0050	0.9599 ± 0.0013	0.9497 ± 0.0000	0.9616 ± 0.0001
$\varepsilon = 2$	0.9518 ± 0.0010	0.9663 ± 0.0001	0.9519 ± 0.0005	0.9653 ± 0.0002
$\varepsilon = 8$	0.9611 ± 0.0012	0.9677 ± 0.0001	0.9514 ± 0.0005	0.9655 ± 0.0001
Non-private	0.9606	0.9704	0.9536	—

43.7.3. Derivation

Each entry is a measurement, and each method's privacy follows from Fact 1 and Fact 3: the pretrained weights and the adapter's random V are fixed before the private data are read, the clipped sum of each step has sensitivity C in the method's trainable coordinates, and the accountant gives $\sigma = 7.72$, 4.13, 2.28 and 0.917 for the four budgets, the same for every method because q and T are the same. The learning rates were chosen by looking at private data, the validation half, without paying for it; Hyperparameter tuning shows how to do that privately, and the comparison here is of methods at their best, as in DP-SGD.

43.7.4. Interpretation

Pretraining is worth about a factor of eight in ε. Every fine-tuning method at $\varepsilon = 0.5$ (0.9395 to 0.9478) beats training from scratch at $\varepsilon = 1$ (0.9246), and the best of them comes within 0.004 of training from scratch at $\varepsilon = 2$ (0.9518). The adapter at $\varepsilon = 1$ (0.9616) matches training from scratch at $\varepsilon = 8$ (0.9611) and the non-private model trained from scratch (0.9606), and full fine-tuning at $\varepsilon = 2$ (0.9663) beats both. The public data carry information about the private task that 10,000 private records do not, and that information is free.

Which weights to train depends on the budget. At $\varepsilon = 0.5$ the last layer is best: with 65 trainable weights its noise is $\sqrt{3{,}329/65} = 7.2$ times shorter than full fine-tuning's, and its ceiling, 0.9536, is not yet binding. From $\varepsilon = 1$ on, the last layer is stuck near its ceiling (0.9497 to 0.9519) while the adapter and full fine-tuning keep improving: they can correct the features, and the noise is now small enough to let them. The adapter, with 525 weights, is never more than 0.0022 below the best method at any budget: the middle choice is the robust one. Full fine-tuning is behind at $\varepsilon = 0.5$, by 0.0083, but not far behind elsewhere once its learning rate is right, as Li et al. (2022) found for language models; at $\varepsilon = 2$ and 8 it is the best, by 0.0010 and 0.0022. Figure 43.3, a separate set of single runs, shows the same overall picture, with the order of the three pretrained methods at $\varepsilon = 0.5$ and 1 changed: differences of a few thousandths between them are within run-to-run variation.

Learning rates matter as much as the method. In Table 43.4 full fine-tuning loses 1.3 points at a learning rate three times too large, and the adapter 1.5 points. The best learning rate for full fine-tuning and the adapter, 0.1, is 2.5 times smaller than for training from scratch. That is the effective-dimension argument of Section 43.3 at work: a larger η fills more flat directions with noise and undoes what pretraining provided.

What the run-to-run spread says. The standard deviations over two runs are small for the pretrained methods, 0.0013 or less, but two runs estimate a spread only roughly: the rank sweep below repeats the adapter at $\varepsilon = 1$ and finds a standard deviation of 0.0023, and a mean of 0.9624

against the table's 0.9616. Differences between the pretrained methods smaller than about 0.005 should not be read as rankings.

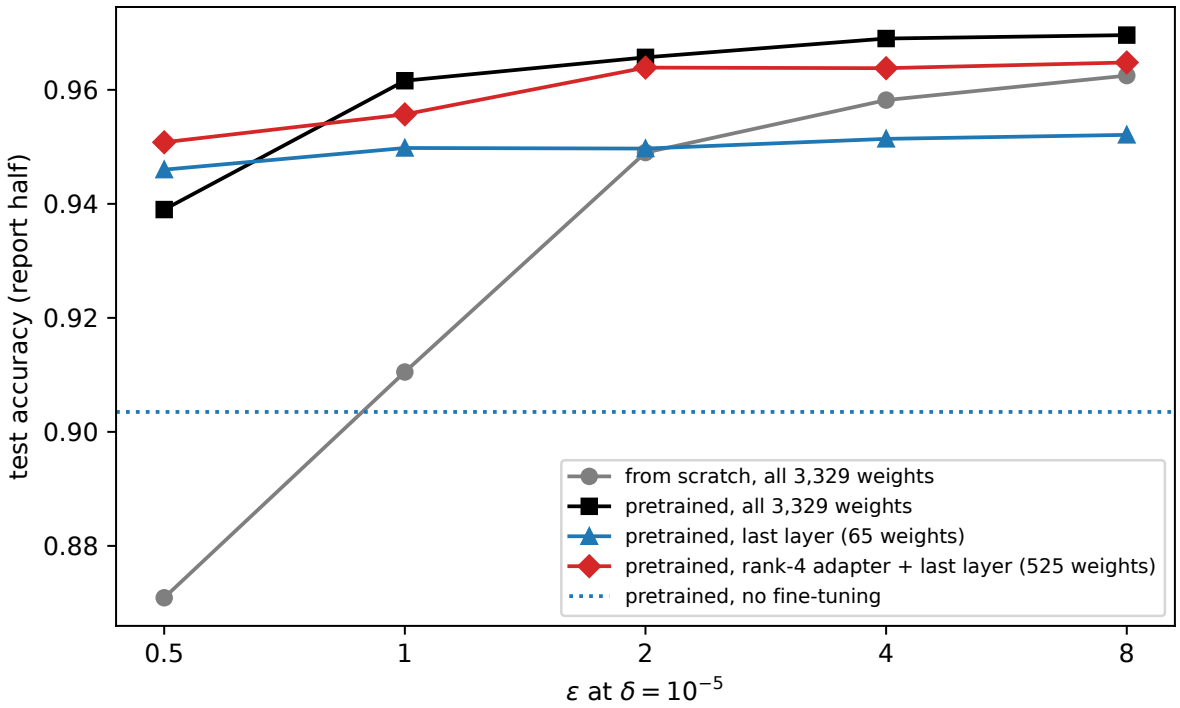

Figure 43.3.: Test accuracy of the four strategies against ε at $\delta = 10^{-5}$, one run each with the learning rates of Table 43.4 and a different seed from Table 43.5, with the pretrained model's accuracy before fine-tuning (dotted). The pretrained methods are far ahead of training from scratch at small budgets; the last layer stays near its ceiling from $\varepsilon = 1$ on, and training from scratch passes it at larger budgets.

43.7.5. Example: the adapter's rank

At $\varepsilon = 1$, with the adapter's learning rate 0.1, two runs each give 0.9590 ± 0.0038 at rank 1 ($d = 180$), 0.9624 ± 0.0023 at rank 4 ($d = 525$) and 0.9586 ± 0.0031 at rank 16 ($d = 1{,}905$). Rank 4 is best, but the differences are about the size of the run-to-run spread. Two forces pull in opposite directions: a higher rank lets the update follow more of the directions the task needs, and it adds noise, whose length grows like $\sqrt{d}$ (Figure 43.1). On this problem neither dominates over a sixteenfold range of ranks, so the rank is a cheap hyperparameter to get roughly right.

43.7.6. Check yourself

- Why is the last layer's accuracy at $\varepsilon = 8$ (0.9514) not higher than at $\varepsilon = 2$ (0.9519)? *(It is at its ceiling, the best linear model on the frozen features, 0.9536 non-privately. Less noise cannot help a model that cannot represent a better classifier.)*

- If the public teacher were identical to the private one, which strategy would you expect to win at $\varepsilon = 0.5$, and why? *(The last layer, or no fine-tuning at all: the pretrained model would already be close to perfect, so there would be nothing for the extra weights to learn and only noise for them to collect. Exercise 5 in the exercise book measures it.)*

43.8. What public data does not buy

43.8.1. Context

Everything so far treated the public data as free. Formally that is right: the guarantee of a private fine-tuning run does not depend on what the public data are. But "public" is a label someone chose, and the guarantee says nothing about the records under that label. Tramèr, Kamath & Carlini (2024) argue that the field's reliance on large web-scraped pretraining data needs scrutiny on several counts. What exactly is guaranteed, and what is not?

43.8.2. Statement

Let $M(D_{\text{pub}}, D)$ pretrain on D_{pub} without privacy and fine-tune on D with an (ε, δ)-DP algorithm. Then for every fixed D_{pub}, the map $D \mapsto M(D_{\text{pub}}, D)$ is (ε, δ)-DP. There is no guarantee of any kind with respect to D_{pub}. A person with a record x in both datasets is protected only for the copy in D: removing it from D changes the output's distribution by at most (ε, δ), while the copy in D_{pub} can be revealed completely.

43.8.3. Derivation

1. **Fixed public data.** With D_{pub} fixed, pretraining produces fixed weights θ_0 (or a fixed distribution over them, if pretraining is randomized, independent of D). The DP-SGD proof of DP-SGD holds for any θ_0 chosen independently of the private data (Fact 3), so it holds conditionally on θ_0, and therefore for the mixture over θ_0.
2. **Nothing for the public data.** Changing one record of D_{pub} can change θ_0 arbitrarily, and the fine-tuned model inherits whatever θ_0 encodes; non-private training can memorize individual records (Memorization and extraction). No noise was calibrated to that change.
3. **A record in both.** The neighbouring datasets that DP compares are D and D without x, with D_{pub} the same in both. A test of whether x was in D has true positive rate at most e^{ε} times its false positive rate plus δ (The definition). A test of whether x is in the training data at all can use the copy in D_{pub}, which nothing bounds.

43.8.4. Interpretation

Overlap and contamination. Web-scale "public" datasets contain personal data: posts, profiles, documents put online by others, data that leaked. A private fine-tuning set of medical notes or emails may overlap with them, and the people whose records appear in both are protected only as well as the pretraining protects them, that is, not at all. Calling the resulting model "differentially private" is accurate about D and misleading about those people. Tramèr, Kamath & Carlini

(2024) argue for this reason that the label should be used with care, and that the privacy of pretraining data deserves its own consideration.

Distribution shift. Public data help as much as they resemble the private task. Benchmarks in which the "private" set is a standard dataset whose distribution is close to well-curated public data, for example two collections of natural images, can overstate what the method will do on genuinely sensitive data, which is often unlike anything public: medical images, rare languages, internal logs. Table 43.5 used a public task close to the private one by design; Exercise 5 in the exercise book shows the gain shrinking, and for the last layer turning into a loss against training from scratch, as the public teacher drifts away.

Public is not the same as non-sensitive. Even when every pretraining record is public, a model trained on them can reproduce them, link them, or make inferences about people that the original publication did not allow. And large pretrained models are often too large to fine-tune locally, so the private data are sent to whoever has the compute, which is a trust question DP does not address (Trust models).

What to report. State what the public data are, how they were obtained, whether overlap with the private data was checked (deduplication against the private set is the minimum), and that the (ε, δ) covers the private dataset given the pretrained model. Any choice made by looking at private data, such as which public model to start from or the learning rate, is part of the private computation and must be accounted for.

43.8.5. Example: one record, two copies

At $\varepsilon = 1$ and $\delta = 10^{-5}$, any test of whether a record was in the private fine-tuning set that has false positive rate 0.01 has true positive rate at most $e \times 0.01 + 10^{-5} = 0.0272$. If the same record is also in the public set, a membership test against the pretrained model, such as the likelihood-ratio attack of Membership inference, is bounded by nothing; it may still fail in practice, but no theorem says it will. If the record appears twice in the private set, group privacy gives $(2\varepsilon, 2e^{\varepsilon}\delta) = (2, 5.44 \times 10^{-5})$ for the pair (Post-processing, group privacy and composition), a weaker but real guarantee. A copy in the public set is worse than a duplicate in the private set.

43.8.6. Check yourself

- You choose between three public pretrained models by fine-tuning each privately and keeping the one with the best private validation accuracy. What have you spent? *(Three private training runs plus a selection on private data: the budget of all three, composed, or a private selection procedure from Hyperparameter tuning. Choosing by public validation data would have been free.)*
- A company deduplicates its private dataset against the public pretraining corpus by exact string matching. What can still go wrong? *(Near-duplicates and paraphrases of the same personal information survive exact matching, and records about the same person need not be duplicates at all; the deduplication protects copies, not people.)*

43.9. Code: check every number by computation

The script code/public_data.py builds the public task, pretrains the student, implements the last-layer and low-rank-adapter versions of DP-SGD with their per-example gradients (ghost norms included), estimates the curvature and the public gradient subspace, and runs the comparison. It imports the model, DP-SGD and the accountant from code/dp_sgd.py. From the repository root:

```
uv run python code/part05-dp-ml/public_data.py
```

It takes about four minutes on a laptop, most of it in about 70 training runs of 10,000 steps.

Output (seed 0), summarized in Table 43.6:

Table 43.6.: The script's output with the default seed.

Experiment	Result
Public task	Teacher agreement 0.9004; pretrained student 0.9035 on the private task
Noise length at $\varepsilon = 1$	1.191, 0.473 and 0.166 for $d = 3{,}329$, 525 and 65
Signal at the pretrained weights	0.0130, 0.0207 and 0.0250; break-even 8,455, 523 and 44 steps
Curvature	Largest eigenvalue 0.723, trace 16.310; $d_{\text{eff}} = 451$ against 60.2 for the last layer at $\eta = 0.1$
Public subspace	60% of the private gradient's energy in one direction, 73% in 64
Adapter ghost norms	Agree with explicit gradients to 3.3×10^{-16}
Fine-tuning, $\varepsilon = 0.5$	Last layer 0.9478, adapter 0.9464, full 0.9395, scratch 0.8589
Fine-tuning, $\varepsilon = 1$	Adapter 0.9616, full 0.9599, last layer 0.9497, scratch 0.9246

tests/test_public_data.py checks that the output still matches.

What to take from it. A related public dataset is worth more than any choice made afterwards: it moves accuracy at $\varepsilon = 1$ from 0.9246 to about 0.96. After that, the right number of trainable weights depends on the budget: few at very small ε, more as the noise allows. The noise length predicts the ranking at small budgets; the feature ceiling and the effective dimension explain the rest.

43.11. Cheat sheet

p weights, d trainable; noise standard deviation $s = \sigma C/B$ per coordinate on the averaged gradient; curvature eigenvalues h_j; learning rate η, T steps. Table 43.7 collects the results.

Table 43.7.: Every result of the chapter.

Result	Formula	Conditions
Noise length	$\sigma C\sqrt{d}/B$	d trainable coordinates
Noise cost of T steps	$\approx \frac{\eta s^2}{4} d_{\text{eff}}$, $d_{\text{eff}} = \sum_j (1-(1-\eta h_j)^{2T})$	Quadratic loss near the start, $\eta h_j \ll 1$
Effective dimension	$d_{\text{eff}} \le \min(d, 2\eta T \operatorname{tr} H)$	—

Result	Formula	Conditions
Linear probe	Private convex ERM in d dimensions, $L \le \sqrt{d}$ for bounded features	Features computed from public data
Probe error	Feature gap (fixed) + privacy cost of order $\sqrt{d}/(n\varepsilon)$, up to $\sqrt{\ln(1/\delta)}$ and logarithms	Convex, Lipschitz
LoRA weights	$r(d_{\text{in}} + d_{\text{out}})$ per matrix	Rank r
LoRA gradients	$\nabla_U = \nu(V^\top a)^\top$, $\nabla_V = a(U^\top \nu)^\top$	Ghost norms apply
Projection	Same (ε, δ); break-even $(s\sqrt{m}/(\sqrt{f_m}\|\bar{m}\|))^2$; bias $1 - f_m$	Subspace from public data only
Guarantee	(ε, δ)-DP in D for every fixed D_{pub}; nothing for D_{pub}	—

Rules of thumb

- Start from a model pretrained on public data that resembles the private task. On the running example this is worth about a factor of eight in ε.
- At very small budgets, train the last layer: few weights, a convex problem, a known ceiling. Measure that ceiling non-privately on public data to know what is at stake.
- At moderate budgets, train a low-rank adapter or all weights; the adapter is the robust middle choice. Tune the learning rate, smaller than from scratch, on public data.
- Count the trainable weights, but think in effective dimension: noise in directions the loss does not use is cheap; noise in directions it does use is what you pay for.
- The guarantee covers the private data given the public model. Check the public data for overlap with the private data, and say what they are when you report ε.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

44. User-level differential privacy

44.1. Why this matters

Every differential privacy (DP) guarantee in this part so far protects one record. Stochastic gradient descent (SGD) with per-example clipping and Gaussian noise, DP-SGD, clips each record's gradient, adds noise scaled to that clip, and reports $\varepsilon = 6.71$ at $\delta = 10^{-5}$ for the part's running example: an adversary who sees the trained model learns little about whether any single training example was used. But the people behind the data do not contribute one record each. A user of a messaging app contributes hundreds of messages, a patient dozens of visits, a photographer thousands of photos. Each of those records is protected by DP, and the person is not, because what the adversary learns about all of a person's records together can be much larger than what they learn about one.

This chapter asks two questions. What does a record-level ε say about a person who contributed k records? And how do you train a model with a guarantee for the person instead?

44.1.1. The one idea: the neighbouring relation is the privacy unit

A DP guarantee compares the outputs on two **neighbouring** datasets, and whatever differs between neighbours is what is protected. If neighbours differ in one record, records are protected; if they differ in all of one person's records, people are. Nothing else in the definition changes. The work is to bound how much the *unit*, now a person, can move the computation, and to account for that bound.

There are two ways to get a guarantee for a person. The first keeps the record as the unit and pays for the person afterwards, by group privacy or by an accountant that knows the person has k records. It is cheap to implement and expensive in privacy, because the noise was calibrated to one record while the person moves the output by up to k. The second makes the person the unit from the start: sample people instead of records, bound each person's total contribution by clipping it, and run the usual accountant with people in place of records. On the running example the first route gives a useless model at any reasonable budget, and the second gives one within a few points of the non-private model.

Table 44.1 lists the results and where each is used.

Table 44.1.: The results of this chapter and where each is used.

Result	Where it is used
The privacy unit and group privacy	Reading a record-level guarantee as a statement about people

Result	Where it is used
The accountant for a user with k records under example-level sampling	Auditing what an existing DP-SGD model guarantees to heavy users
User-level DP-SGD	Training with a guarantee per person; federated learning
Contribution bounding and its bias–variance trade-off	Keeping an example-level pipeline while protecting people
Heterogeneous users	Deciding how to weight heavy and light users
The strategies compared on the running example	Choosing among the three in practice

Notation. The training set has n records belonging to U users; user u owns n_u records. Two datasets are **example-level neighbours** if they differ by adding or removing one record, and **user-level neighbours** if they differ by adding or removing all the records of one user. k is the number of records a user contributes, or the cap on it. In a batch drawn by Poisson sampling at rate q, H is the number of a given user's records that are drawn. As in DP-SGD, C is the clipping norm, σ the noise multiplier, T the number of steps and B the expected batch size, now counted in whichever unit is sampled.

The running example. The part's network (one hidden layer of 64 tanh units, 3,329 weights) learns labels produced by a fixed teacher network from 10,000 training records of 50 features, and is tested on 20,000 more. This chapter assigns the 10,000 records to $U = 1{,}000$ users. Each user gets one record, and the other 9,000 are spread over users with probabilities proportional to log-normal weights, so user sizes are very uneven: the mean is 10 records, the median 4, and the largest user holds 348 (Figure 44.1). A user's records are a nearest-neighbour cluster around a random record, so they resemble each other the way one person's messages do: the label balance $|\bar{y}|$ is 0.21 on average in the ten largest users, against 0.06 in the whole set. The population is fixed, like the dataset.

How to read this chapter. The toolkit restates three facts from earlier parts. Section 44.3 and Section 44.4 say what a record-level guarantee gives a person; the second has the chapter's main derivation, the accountant for a user with k records. Section 44.5 and Section 44.6 are the two ways to train with a user-level guarantee, Section 44.7 asks what they do to heavy users, and Section 44.8 compares everything on the running example.

44.2. Toolkit: three facts every derivation uses

44.2.1. Fact 1 — Group privacy

If a mechanism is (ε, δ)-DP for neighbours that differ in one record, then for two datasets that differ in k records it satisfies, for every event S,

$$\Pr[M(D) \in S] \le e^{k\varepsilon} \Pr[M(D'') \in S] + \delta_k, \qquad \delta_k = \delta \sum_{j=0}^{k-1} e^{j\varepsilon} = \delta \, \frac{e^{k\varepsilon} - 1}{e^{\varepsilon} - 1}. \tag{44.1}$$

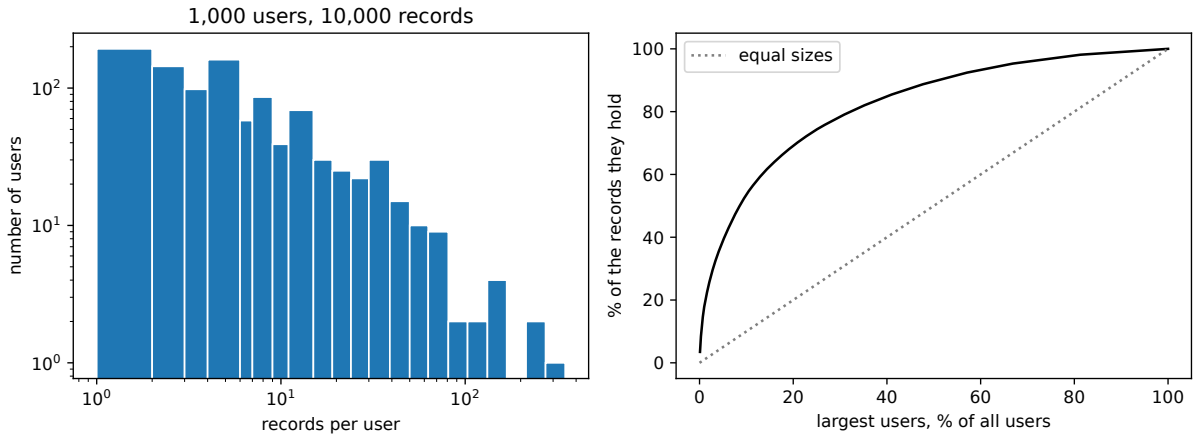

Figure 44.1.: Left: the number of records per user in the running example's population of 1,000 users, on log–log axes; 193 users have one record and the largest has 348. Right: the share of all records held by the largest users. The largest 10 users hold 17.9% of the records and the smallest half of the users 10.3%.

The reason is a chain: D and D'' are joined by a path of k steps, each between neighbouring datasets. Applying the one-record guarantee once per link multiplies the probability bound by e^{ε} each time, and each link's slack δ is then multiplied by the e^{ε} of every later link, which is where the geometric sum comes from. The bound is attained by some mechanisms, so no better one holds for every (ε, δ)-DP mechanism (Post-processing, group privacy and composition). For Rényi differential privacy (RDP) the chain is weaker still, because the Rényi divergence has no triangle inequality: an (α, ε)-RDP mechanism is $(\alpha/2^c, 3^c\varepsilon)$-RDP for groups of 2^c records, when $\alpha \geq 2^{c+1}$ (Mironov 2017; Rényi DP). Each doubling of the group halves the order and triples ε.

44.2.2. Fact 2 — The accountant of DP-SGD

One step of DP-SGD adds Gaussian noise of standard deviation σC to a sum of clipped per-example gradients computed on a Poisson batch: each record enters independently with probability q. In units of C, the worst case for one record is the pair $P_0 = \mathcal{N}(0, \sigma^2)$, the output without the record, and the mixture $(1-q)P_0 + q\mathcal{N}(1, \sigma^2)$, the output with it. Its RDP curve at order α, the Rényi divergence of order α between the two, is $\varepsilon_{q,\sigma}(\alpha) = \frac{1}{\alpha - 1} \ln A_\alpha$, and for integer α

$$A_\alpha = \sum_{j=0}^{\alpha} \binom{\alpha}{j} (1-q)^{\alpha-j} q^j \exp\left(\frac{j^2 - j}{2\sigma^2}\right). \tag{44.2}$$

The sum comes from expanding $\left((1-q) + q\,r\right)^{\alpha}$, with r the Gaussian likelihood ratio, by the binomial theorem and averaging each power r^j under P_0 (Amplification by subsampling). RDP curves add over the T steps, even when each step depends on earlier outputs, and the total converts to (ε, δ) at the best order:

$$\varepsilon = \min_{\alpha} \left[T\varepsilon_{q,\sigma}(\alpha) + \ln \frac{\alpha - 1}{\alpha} - \frac{\ln \delta + \ln \alpha}{\alpha - 1} \right]. \tag{44.3}$$

The terms $j = 0$ and 1 carry no privacy cost, since their exponential factor is 1. For small q and moderate orders only the $j = 2$ term matters beyond them, so $A_\alpha \approx 1 + \binom{\alpha}{2} q^2 (e^{1/\sigma^2} - 1)$ and $\varepsilon_{q,\sigma}(\alpha) \approx \frac{\alpha}{2} q^2 (e^{1/\sigma^2} - 1)$.

44.2.3. Fact 3 — The Gaussian moment generating function

If $Y \sim \mathcal{N}(0, \sigma^2)$, then $\mathbb{E}[e^{sY}] = e^{s^2\sigma^2/2}$ for every real s (Distributions). Every Rényi divergence between Gaussians with the same variance reduces to it, because their likelihood ratio is the exponential of a linear function of the output: for $P_m = \mathcal{N}(m, \sigma^2)$,

$$\frac{P_m(y)}{P_0(y)} = \exp\Big(\frac{-(y-m)^2 + y^2}{2\sigma^2}\Big) = \exp\Big(\frac{2my - m^2}{2\sigma^2}\Big). \tag{44.4}$$

44.3. The privacy unit

44.3.1. Context

A model trained with record-level DP-SGD at $\varepsilon = 6.71$ is released. One of the people in the training set contributed k of its records. What, exactly, does the guarantee promise that person? The question has to be answered before a deployment can say "your data are protected", because the promise is about whatever the neighbouring relation changes, and that relation was chosen by the engineer, not by the person.

44.3.2. Statement

A mechanism is **user-level** (ε, δ)-DP if for every pair of datasets D, D' that differ by adding or removing all the records of one user, and every event S,

$$\Pr[M(D) \in S] \le e^{\varepsilon} \Pr[M(D') \in S] + \delta. \tag{44.5}$$

It is **example-level** DP if the same holds for datasets that differ in one record. A mechanism that is example-level (ε, δ)-DP is user-level $(k\varepsilon, \delta_k)$-DP for users with at most k records, with δ_k from Equation 44.1. Without more information about the mechanism, nothing better can be said.

44.3.3. Derivation

1. **User-level neighbours are k example-level steps apart.** If D' is D plus the k records of one user, add them one at a time. The datasets $D, D \cup \{x_1\}, D \cup \{x_1, x_2\}, \dots, D'$ form a chain in which each is an example-level neighbour of the next.
2. **Apply group privacy.** Fact 1 along this chain gives Equation 44.1 with $D'' = D'$, in both directions, since the chain can be walked either way.
3. **Nothing better holds in general.** The bound is attained by a mechanism built for the purpose, which outputs an alarm with probabilities chosen so that every link's inequality is an equality (Post-processing, group privacy and composition). A guarantee that is only known as "(ε, δ)-DP" could come from that mechanism.

44.3.4. Interpretation

The definition is the same; the unit is not. User-level DP is not a new privacy notion. It is DP with a coarser neighbouring relation, so every property proved for DP holds for it: post-processing, composition and the accountants of Part 4. The only thing that changes is the sensitivity: how far one unit can move the computation. Records, users, households, devices and organizations are all possible units, and the choice should follow the question "whose participation do I want to hide?" A deployment that says "DP" without naming the unit leaves that question open, and Choosing an accountant lists the unit among the things a guarantee must report.

Group privacy is linear in ε and exponential in δ. For pure DP a user with k records gets $k\varepsilon$, already weak: at $\varepsilon = 1$ per record, a user with 10 records gets $\varepsilon = 10$, a likelihood ratio of $e^{10} \approx 22{,}000$. With $\delta > 0$ it is worse. In Equation 44.1 each δ is multiplied by up to $e^{(k-1)\varepsilon}$, so to keep the user's δ_k at 10^{-5} the per-record δ must be tiny, and a smaller δ means a larger per-record ε. For DP-SGD this trade can be made at any δ, because the accountant's RDP curve converts to (ε, δ) at every δ: choose the per-record δ so that $\delta_k = 10^{-5}$ exactly.

For DP-SGD it can fail altogether. The per-record ε grows as the per-record δ shrinks, so $\delta_k = \delta\frac{e^{k\varepsilon}-1}{e^{\varepsilon}-1}$ is a race between a falling δ and a rising $e^{(k-1)\varepsilon}$. For small k the falling δ wins. For larger k the rising ε wins at every δ, and no choice brings δ_k down to 10^{-5}. Group privacy then gives no $(\varepsilon, 10^{-5})$ guarantee at all (Exercise 2 in the exercise book traces the race).

44.3.5. Example: the running example's users

The running example's model is example-level $(6.71, 10^{-5})$-DP. Read naively as a user-level statement, a user with two records gets $\varepsilon = 2 \times 6.71 = 13.42$ with $\delta_2 = 10^{-5}(1 + e^{6.71}) = 0.0082$: a probability of almost one in a hundred that the guarantee fails outright, which is no guarantee. Re-converting the accountant's RDP curve at a smaller per-record δ does better. The per-record δ that makes $\delta_2 = 10^{-5}$ gives a per-record ε of 9.30, so the user gets $(18.61, 10^{-5})$. For five records the same procedure gives a per-record ε of 23.62 and a user-level ε of 118.12. For ten records it gives nothing: no per-record δ makes δ_{10} as small as 10^{-5}. In the running example's population, 244 of the 1,000 users have at least ten records (the median is 4), and 30 have at least 50.

44.3.6. Check yourself

- A dataset has one row per hospital visit, and a mechanism is 0.2-DP (pure) at the visit level. What does a patient with 7 visits get? *(1.4-DP, by group privacy with $k = 7$; for pure DP the bound is just $k\varepsilon$.)*
- Why does a user-level guarantee still compose and survive post-processing? *(Because it is DP with a different neighbouring relation, and those proofs hold for any fixed relation: they never use what a neighbour is.)*

44.4. A user with k records in example-level DP-SGD

44.4.1. Context

Group privacy treats DP-SGD as a black box. It is not one: we know exactly how a user with k records enters each step. Each of the user's records is drawn into the batch independently with probability q, so in each step a random number of them, between 0 and k, contributes to the noisy sum. An accountant that knows this can compute the user's guarantee directly, as Amplification by subsampling did for one record. How large is that guarantee, and how does it grow with k?

44.4.2. Statement

Let $H \sim \mathrm{Bin}(k, q)$ be the number of the user's records in a Poisson batch, and $b_m = \binom{k}{m} q^m (1-q)^{k-m}$ its probabilities. In units of C, one step of example-level DP-SGD compares

$$P_0 = \mathcal{N}(0, \sigma^2) \qquad \text{and} \qquad P_{(k)} = \sum_{m=0}^{k} b_m \, \mathcal{N}(m, \sigma^2), \tag{44.6}$$

the output without the user and with the user, whose drawn records all push the sum by the full C in the same direction. Charles et al. (2024, Theorem 3) prove that this pair, composed over the T steps, bounds the user's privacy loss, and that the bound is attained by a loss for which the user's gradients are aligned. The user's RDP curve is therefore $\varepsilon_k(\alpha) = \max\{D_\alpha(P_{(k)} \| P_0), D_\alpha(P_0 \| P_{(k)})\}$. The first divergence is $\frac{1}{\alpha-1} \ln A_\alpha$ with

$$A_\alpha = \mathbb{E}\Big[\exp\Big(\frac{1}{\sigma^2} \sum_{1 \le i < j \le \alpha} H_i H_j \Big) \Big], \qquad H_1, \dots, H_\alpha \text{ independent copies of } H, \tag{44.7}$$

for integer α. For small kq the curve is close to that of a single record sampled at rate kq:

$$\varepsilon_k(\alpha) \approx \frac{\alpha}{2} (kq)^2 (e^{1/\sigma^2} - 1). \tag{44.8}$$

The user's (ε, δ) after T steps is Equation 44.3 applied to $T\varepsilon_k(\alpha)$.

44.4.3. Derivation

The derivation follows the one for a single record: find the distribution of one step's output with and without the user, write the Rényi divergence as an average of a power of the likelihood ratio, and evaluate the average. The new ingredient is that the power of a mixture over m becomes a product of independent copies of H, which makes the average computable by Fact 3.

1. **How many of the user's records are drawn.** Poisson sampling draws each record independently with probability q, so the number of the user's k records in the batch is a sum of k independent coins: $H \sim \mathrm{Bin}(k, q)$, independent of which other records are drawn.

2. **What they do to the sum.** Fix the other records' contribution, which is the same with and without the user. Given $H = m$, the user adds m clipped gradients, each of length at most C, so their sum has length at most mC, with equality when they all point the same way. In units of C and along that direction, the output is $\mathcal{N}(m, \sigma^2)$ with probability b_m: the mixture of Equation 44.6. That the aligned case is the worst over all configurations of the user's gradients, and that the reduction to one dimension is valid, is the content of Charles et al.'s Theorem 3, which Section M.4 in the appendices proves for $D_\alpha(P_{(k)}\|P_0)$ at integer orders; the intuition is that gradients pointing in different directions add in squares rather than in length, and spread the user's influence over several coordinates where it is harder to detect.
3. **The divergence as an average.** By the definition of the Rényi divergence, $e^{(\alpha-1)D_\alpha(P_{(k)}\|P_0)} = \mathbb{E}_{y\sim P_0}\big[(P_{(k)}(y)/P_0(y))^\alpha\big]$. Dividing the mixture by P_0 term by term with Equation 44.4,

$$\frac{P_{(k)}(y)}{P_0(y)} = \sum_m b_m \exp\Big(\frac{2my - m^2}{2\sigma^2}\Big) = \mathbb{E}_H\Big[\exp\Big(\frac{2Hy - H^2}{2\sigma^2}\Big)\Big], \tag{44.9}$$

   an average over the number of drawn records.
4. **The power of an average is an average over independent copies.** For integer α, $(\mathbb{E}_H[f(H)])^\alpha = \mathbb{E}[f(H_1)f(H_2)\cdots f(H_\alpha)]$ with $H_1, \dots, H_\alpha$ independent copies of H: multiplying out α copies of the sum $\sum_m b_m f(m)$ gives one term for every choice $(m_1, \dots, m_\alpha)$, with weight $b_{m_1}\cdots b_{m_\alpha}$, which is the joint distribution of independent copies. The product of exponentials is the exponential of the sum, so with $V = H_1 + \cdots + H_\alpha$, the total over the copies,

$$\Big(\frac{P_{(k)}(y)}{P_0(y)}\Big)^\alpha = \mathbb{E}\Big[\exp\Big(\frac{2Vy - \sum_i H_i^2}{2\sigma^2}\Big)\Big]. \tag{44.10}$$

5. **Average over y.** Exchange the two averages, which is allowed because everything is positive. For fixed copies, Fact 3 with $s = V/\sigma^2$ gives $\mathbb{E}_{y\sim P_0}[e^{Vy/\sigma^2}] = e^{V^2/(2\sigma^2)}$, so

$$A_\alpha = \mathbb{E}\Big[\exp\Big(\frac{V^2 - \sum_i H_i^2}{2\sigma^2}\Big)\Big]. \tag{44.11}$$

   Expanding the square, $V^2 = \sum_i H_i^2 + 2\sum_{i<j} H_iH_j$, and the squares cancel: this is Equation 44.7. Only products of *different* copies remain.
6. **Check against one record.** For $k = 1$, each H_i is a coin, 0 or 1. If J of the α coins are 1, the sum $\sum_{i<j} H_iH_j$ counts the pairs among them, $\binom{J}{2} = (J^2 - J)/2$, and $J \sim \mathrm{Bin}(\alpha, q)$. The average of $e^{(J^2-J)/(2\sigma^2)}$ over J is Equation 44.2.
7. **Small kq.** When kq is small, most copies are 0. The terms of Equation 44.7 with at most one non-zero copy have $\sum_{i<j} H_iH_j = 0$ and contribute their probability times 1. The first term that costs privacy has exactly two copies equal to 1, the most likely way for a product to be non-zero: there are $\binom{\alpha}{2}$ pairs of copies, each copy is 1 with probability about kq, and the factor is e^{1/σ^2}. So $A_\alpha \approx 1 + \binom{\alpha}{2}(kq)^2(e^{1/\sigma^2} - 1)$, the same as Equation 44.2's first three terms with q replaced by kq. Taking $\ln(1+x) \approx x$ and dividing by $\alpha - 1$ gives Equation 44.8.
8. **Other orders and the other direction.** For non-integer α, and for $D_\alpha(P_0\|P_{(k)})$, there is no finite expansion. Compute both as one-dimensional integrals of $P_0(y)$ times a power of the mixture ratio of step 3, on a grid of step $\sigma/10$ wide enough to contain the bump near $y = \alpha k$ that large orders create, with log-sum-exp to avoid overflow, exactly as for one record.

44.4.4. Interpretation

A user with k records looks like one record sampled k times as often. Equation 44.8 says that, in the regime where amplification works well, the only thing that matters is the probability that some record of the user is in the batch, about kq. Halving the sampling rate exactly compensates doubling the user's records. Since the per-step RDP grows like $(kq)^2$, and ε after conversion grows roughly like the square root of the RDP slope, the user's ε grows roughly linearly in k while kq is small.

Beyond that regime it grows faster. Two things break the approximation. First, kq is no longer small: for $k = 50$ and $q = 0.01$, half of all steps include one of the user's records, and subsampling, which helps only because the unit is usually absent, stops helping. Second, the higher terms of Equation 44.7 grow like $e^{H_i H_j/\sigma^2}$, and $H_i H_j$ can be as large as k^2. A step that draws all k records shifts the sum by kC, a mechanism with noise multiplier σ/k, whose privacy loss has a tail that no amount of rarity can hide at high orders. The accountant then uses orders close to 1, where the conversion is expensive.

Group privacy is the wrong tool for DP-SGD. It ignores both the structure of the mechanism and the fact that the RDP curve is known. The direct accountant gives a smaller ε for every k and a finite one for every k.

The accountant is a worst case over gradients, not over users. It assumes the user's drawn records push the sum in the same direction by the full C. Real users' gradients are partly aligned, which is precisely why their records are correlated, and the theorem says some loss attains the bound. An auditor should therefore treat it as the guarantee, not as a pessimistic estimate.

44.4.5. Example: the running example's guarantee for its users

Table 44.2 applies the accountant to the running example's DP-SGD run, $q = 0.01$, $\sigma = 1$, $T = 10{,}000$, $\delta = 10^{-5}$.

Table 44.2.: The user-level ε at $\delta = 10^{-5}$ of the running example's example-level DP-SGD, for a user with k records. "None" means that group privacy gives no $(\varepsilon, 10^{-5})$ guarantee.

Records of the user k	1	2	5	10	50
User accountant, Equation 44.6	6.72	15.54	52.36	146.20	2161.43
Best order α	4	2.5	1.65	1.3	1.05
Group privacy, Equation 44.1	6.71	18.61	118.12	none	none
One record at rate kq	6.71	15.32	50.11	134.50	1673.08

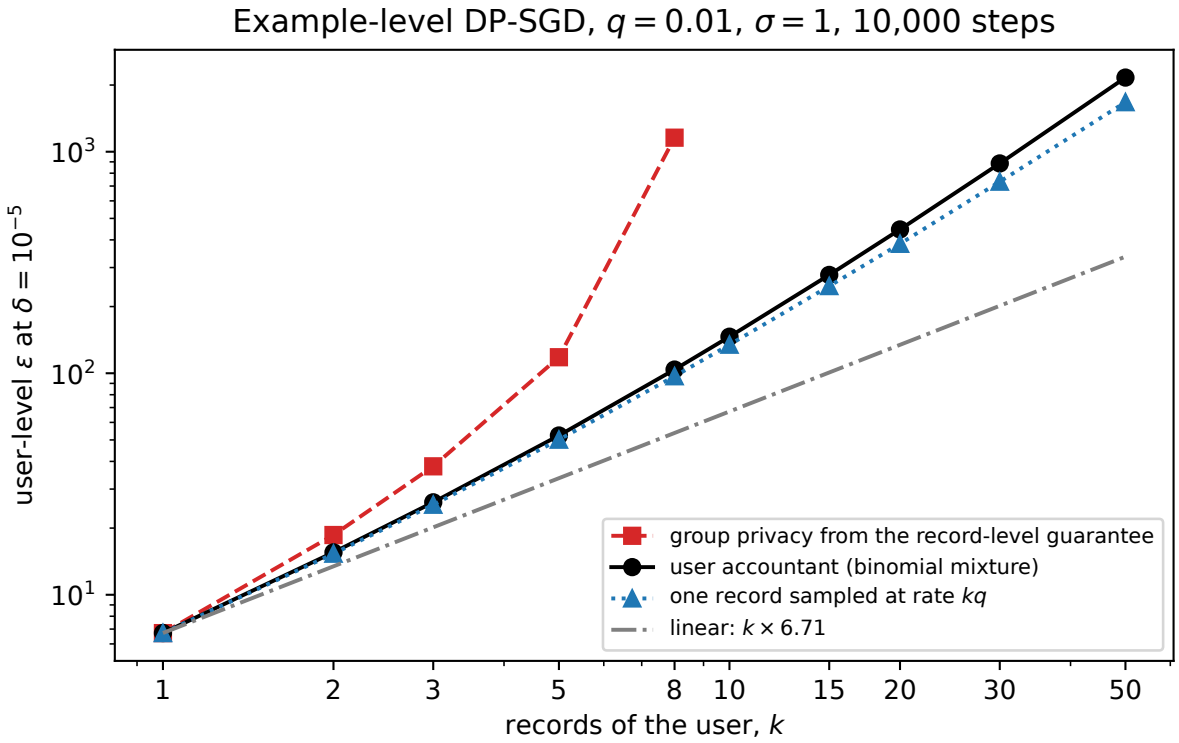

Figure 44.2.: The user-level ε at $\delta = 10^{-5}$ of the running example's DP-SGD ($q = 0.01$, $\sigma = 1$, 10,000 steps; $\varepsilon = 6.71$ per record) for a user with k records. The direct accountant of Equation 44.6 (black) is close to a single record sampled at rate kq (blue, dotted) and grows faster than linearly (grey). Group privacy from the record-level guarantee (red, dashed) is larger, and gives no guarantee at all for $k = 10$ and above.

The first column checks the accountant: with one record it is the DP-SGD accountant, 6.72 against 6.71, the difference coming from the coarser grid of orders this chapter's script uses (its best order is 4, against 4.1 on the finer grid). At $\alpha = 4.1$ the two curves agree to all printed digits, 3.733633×10^{-4}. For $k = 2$ and 5 at $\alpha = 2$, the numerical integral and the exact formula Equation 44.7, $A_2 = \mathbb{E}[e^{H_1 H_2/\sigma^2}]$, agree to seven digits (6.992273×10^{-4} and 4.626224×10^{-3}), and the reverse direction is smaller (6.119238×10^{-4} and 3.412123×10^{-3}).

Already at two records, the person behind them is protected at $\varepsilon = 15.54$, more than twice the record's 6.71. At ten, $\varepsilon = 146.20$ means no protection at all. The rate-kq approximation is within 1.5% at $k = 2$ (15.32 against 15.54) and 8% at $k = 10$ (134.50 against 146.20), so it is a quick estimate of the user's exposure: rerun the record-level accountant with q replaced by kq. In every row it errs on the low side, because it drops the terms in which several of the user's records are drawn together.

44.4.6. Check yourself

- Your model was trained with example-level DP-SGD at $q = 0.001$, and its heaviest user has 20 records. Which single-record accountant run gives a quick estimate of that user's ε, and in which direction is it off? *(The run with $q = 0.02$ and the same σ and T. It underestimates slightly, because it ignores steps that draw several of the user's records at once.)*
- In Equation 44.7, why do only products of different copies appear? *(Because the $\sum_i H_i^2$ in the exponent of the likelihood ratio cancels the squares in V^2 after the Gaussian average. Each copy alone averages to a ratio whose expectation under P_0 is 1, as for one record.)*

44.5. User-level DP-SGD

44.5.1. Context

Accounting for users after the fact charges a heavy user for every one of their records. The alternative changes the algorithm, so that the unit DP-SGD samples, clips and accounts for is the user. The idea is due to McMahan, Ramage, Talwar & Zhang (2018), who used it to train a language model with federated learning, where each user's device computes an update on its own data and the server only sees the updates. What does the algorithm compute, and what does it guarantee?

44.5.2. Statement

Start from weights θ_0 chosen independently of the data. For $t = 0, \dots, T-1$:

1. **Sample users.** Put each user in the set S_t independently with probability q.
2. **Per-user update.** For each $u \in S_t$, compute one vector from user u's records alone, for example the average gradient $\bar{g}_u = \frac{1}{n_u} \sum_{i \in u} \nabla_\theta \ell(\theta_t; z_i)$, or the change in weights after a few local steps of SGD on those records.
3. **Clip per user.** $\tilde{g}_u = \bar{g}_u \min(1, C/\|\bar{g}_u\|)$.
4. **Noisy sum.** $G_t = \sum_{u \in S_t} \tilde{g}_u + \xi_t$ with $\xi_t \sim \mathcal{N}(0, \sigma^2 C^2 I)$.

5. **Step.** $\theta_{t+1} = \theta_t - \eta\, G_t/(qU)$.

Releasing $\theta_1, \dots, \theta_T$ is user-level (ε, δ)-DP with ε given by Equation 44.3 for the curve $T\varepsilon_{q,\sigma}(\alpha)$ of Fact 2: exactly the accountant of example-level DP-SGD, with users in place of records and q the user sampling rate.

A common variant replaces steps 2 and 3 by **per-record clipping and a cap**: keep at most k records per user, clip each record's gradient to C, and sum them. One user then moves the sum by at most kC, and the guarantee is that of noise multiplier σ/k:

$$A_\alpha = \sum_{j=0}^{\alpha} \binom{\alpha}{j} (1-q)^{\alpha-j} q^j \exp\Big(\frac{k^2(j^2-j)}{2\sigma^2}\Big), \tag{44.12}$$

Equation 44.2 with σ replaced by σ/k.

44.5.3. Derivation

The proof of DP-SGD used four properties of the clipped sum. Each holds with users in place of records.

1. **One user moves the clipped sum by at most C.** Fix the weights θ_t and the other sampled users. Each $\tilde{g}_v$ is computed from user v's records alone, so adding user u to the dataset leaves every other term unchanged and adds $\tilde{g}_u$, of length at most C by step 3. However many records u has, they enter only through $\tilde{g}_u$.
2. **One step is a subsampled Gaussian mechanism over users.** User u enters S_t with probability q, independently of the other users. So the step's output with u is a mixture: with probability $1-q$ the same as without u, with probability q shifted by $\tilde{g}_u$. After rescaling by C and rotating the shift onto one axis, the worst case is the pair of Fact 2, and the step's RDP curve is $\varepsilon_{q,\sigma}(\alpha)$.
3. **Dividing by qU is post-processing**, since the number of users U is treated as public, as n is in example-level DP-SGD.
4. **Compose and convert.** RDP composition over the T adaptive steps and Equation 44.3 finish the proof, as before.
5. **The capped-sum variant.** With per-record clipping, user u's contribution is a sum of at most k vectors of length at most C, so its length is at most kC, and the user is still sampled as a whole with probability q. In units of C the pair is $\mathcal{N}(0, \sigma^2)$ against $(1-q)\mathcal{N}(0, \sigma^2) + q\mathcal{N}(k, \sigma^2)$. Dividing the output by k, an invertible map that changes no divergence, gives the pair with shift 1 and noise σ/k, whose curve is Equation 44.2 with σ/k: that is Equation 44.12. The script checks it at $k = 2$, $\alpha = 3$: both give 8.219438×10^{-2}.

44.5.4. Interpretation

The count that matters is the number of units. User-level DP-SGD has the privacy of example-level DP-SGD on a dataset of U records. To keep the same expected batch of B units, the sampling rate must be B/U, larger than B/n by the average number of records per user, and amplification is correspondingly weaker. On the running example, with 1,000 steps and an expected batch of 100 units, a record-level $\varepsilon = 4$ needs $\sigma = 0.778$ at $q = 0.01$, and a user-level

$\varepsilon = 4$ needs $\sigma = 3.78$ at $q = 0.1$. The noise on the averaged update, $\sigma C/B$, is 0.0189 against 0.00389, about five times larger. This is the honest price of protecting people: there are ten times fewer of them than records, and DP's cost per unit is fixed.

Records inside a user are free. The guarantee does not depend on n_u. A user's records can be averaged, used for several local steps, or subsampled, all without changing ε, as long as the result is one clipped vector computed from that user's data alone. More records per user make each $\bar{g}_u$ a better estimate of the user's gradient, so the signal improves while the noise stays fixed. Levy et al. (2021) show that, when each user's records come from the same distribution, user-level private learning gains from having more records per user.

Average, or sum then clip? Averaging before clipping gives every user a vector of the same kind regardless of size, which keeps the clipping norm meaningful across users. Clipping each record and summing at most k of them uses per-example gradient code that already exists, but pays a factor k in noise multiplier (Equation 44.12). Summing all of a user's records and then clipping the sum is also valid (sensitivity C), and gives heavy users more weight than averaging does, as Section 44.7 shows.

What the proof assumes. Step 1 needs every user's contribution to be computed from that user alone, which rules out cross-user normalization and requires that one user's records are not spread across several "users" in the data. If one person has several accounts, the unit is the account, and the person is again a group. Step 2 needs users to be Poisson-sampled; an implementation that iterates over users in a fixed shuffled order is a different mechanism, as for records.

44.5.5. Example: the noise each strategy needs

Table 44.3 fixes 1,000 steps with an expected batch of 100 sampled units and gives the noise multiplier for four user-level budgets. The column "record-level" is not a user-level guarantee; it shows the noise the same schedule would need to protect only records. Column (a) is example-level DP-SGD on all 10,000 records ($q = 0.01$), accounted for the largest user with $k = 348$ by Equation 44.6; (b) is user-level DP-SGD ($q = 0.1$); (c) keeps at most 2 records per user, 1,807 records in all, and runs example-level DP-SGD on them with $q = 100/1{,}807 = 0.0553$, accounted for $k = 2$ (Section 44.6).

Table 44.3.: Noise multipliers for 1,000 steps with an expected batch of 100 units, at $\delta = 10^{-5}$.

User-level ε	Record-level (not user-level)	(a) All records, $k = 348$	(b) User-level DP-SGD	(c) At most 2 records per user
1	1.52	449	12.9	14.4
2	1.03	237	6.89	7.62
4	0.778	128	3.78	4.18
8	0.616	70.3	2.18	2.4

Column (a) is the cost of keeping the record as the unit when one user has 348 records: in each step this user has on average $348 \times 0.01 = 3.48$ records in the batch, so subsampling hardly hides them, and the noise must cover a shift of several clipping norms in nearly every step. At $\varepsilon = 4$ the noise on the averaged gradient has standard deviation $128 \times 0.5/100 = 0.64$ per coordinate, so length about $0.64 \times \sqrt{3{,}329} = 36.9$, against a clipped average of length at most 0.5.

44.5.6. Check yourself

- In user-level DP-SGD, a user with 300 records runs five local steps of SGD on them and sends the clipped change in weights. Does that change ε? *(No. The user's contribution is still one vector computed from their records alone, clipped to C; the local computation is invisible to the accountant.)*
- Why does user-level DP-SGD on 1,000 users need more noise than example-level DP-SGD on 10,000 records, at the same expected batch, steps and ε? *(To keep the batch at 100 units it must sample at rate 0.1 instead of 0.01. Amplification by subsampling is weaker at a higher rate, so the same ε needs a larger σ.)*

44.6. Contribution bounding

44.6.1. Context

User-level DP-SGD needs a data pipeline that groups records by user and computes one vector per user. Many training pipelines are built around records: shuffled files of examples, per-example gradient code, fixed-length batches. Can you keep that pipeline and still protect users? You can, if you limit how many records each user contributes. The question is what limit to choose, because the limit trades the noise the accountant requires against the data you throw away.

44.6.2. Statement

Contribution bounding keeps at most k records of each user, chosen without looking at other users' data, for example at random, and discards the rest. Run example-level DP-SGD on the $n_k = \sum_u \min(n_u, k)$ remaining records with sampling rate q. The result is user-level (ε, δ)-DP with ε given by the accountant of Equation 44.6 for a user with k records. The trade-off:

- the **noise** grows with k: in the small-kq regime the user's RDP is that of a record sampled at rate kq (Equation 44.8), so the noise multiplier must grow roughly in proportion to k at a fixed q;
- the **bias** shrinks with k: the training set loses $n - n_k$ records, all of them from users with more than k records, so the data are both smaller and reweighted toward light users.

44.6.3. Derivation

1. **Bounding is applied per user.** Write the bounded dataset as $\Pi(D) = \bigcup_u \pi(D_u)$, where D_u is user u's records and π keeps at most k of them using randomness that is independent of everything else. Adding user u to D adds $\pi(D_u)$ to $\Pi(D)$ and changes nothing else, so user-level neighbours map to datasets that differ in at most k records, all of one user.
2. **Account for those records.** Example-level DP-SGD on $\Pi(D)$ sees the user's at most k records, each drawn independently with probability q. By Section 44.4, the pair for one step is Equation 44.6 with k. A user with fewer records is covered too: they are a k-record user some of whose clipped gradients happen to be 0, and the worst case of Section 44.4 is over all gradients of length at most C, including 0. Composition and conversion are as before.

3. **The noise grows with k.** At fixed q, Equation 44.8 depends on k and q through kq only. Keeping the user's RDP fixed while k doubles therefore requires either halving q, which halves the batch, or raising σ. In the regime where the per-step RDP is about $\frac{\alpha}{2}(kq)^2/\sigma^2$, holding it fixed means $\sigma \propto kq$.
4. **The bias.** Before bounding, the expected update of DP-SGD averages over all n records; after it, over n_k records in which each user has weight $\min(n_u, k)/n_k$ instead of n_u/n. A user with $n_u > k$ loses weight, and their records beyond k are not used at all.

44.6.4. Interpretation

Choosing k is a bias–variance trade-off. Amin, Kulesza, Muñoz Medina & Vassilvitskii (2019) studied exactly this choice for private empirical risk minimization, and showed that the best cap depends on the distribution of user sizes: a cap above most users' sizes buys little data at a large noise cost, and a cap below them throws away most of the data. Their framing is the same as that of choosing the clipping norm in Beyond global sensitivity: a smaller bound means less noise and more distortion of what is computed. Because the cap depends on the data, it should be chosen from public knowledge of the population or privately; choosing it by trying several caps and looking at test accuracy, as the example below does to show the trade-off, spends privacy that the accountant does not see (Hyperparameter tuning).

Which records to keep matters. Random selection keeps the proof simple. Chua et al. (2024) compare selection rules for fine-tuning language models under contribution bounding and report that keeping each user's longest records worked best on one of their datasets. Any rule that looks only at the user's own records is allowed, by step 1.

Bounding plus user-level DP-SGD. The two techniques combine: cap each user at k records to bound compute, then compute one clipped vector per user. With user sampling, the cap no longer costs noise, only data, and users can contribute their full records again by subsampling them inside each step.

44.6.5. Example: the cap on the running example

Table 44.4 fixes the user-level budget at $\varepsilon = 4$, $\delta = 10^{-5}$ and 1,000 steps with an expected batch of 100 records. For each cap, the sampling rate is $q = 100/n_k$, so kq is the probability scale at which a full user enters a batch.

Table 44.4.: Contribution bounding at user-level $\varepsilon = 4$: example-level DP-SGD on at most k records per user, accounted for k records, one run each.

Cap k	Records kept	Sampling rate q	kq	Noise multiplier σ	Test accuracy
1	1,000 (10.0%)	0.1	0.100	3.78	0.8917
2	1,807 (18.1%)	0.0553	0.111	4.18	0.8920
5	3,506 (35.1%)	0.0285	0.143	5.34	0.8790
10	5,063 (50.6%)	0.0198	0.198	7.34	0.8276
20	6,631 (66.3%)	0.0151	0.302	11.2	0.7562
50	8,437 (84.4%)	0.0119	0.593	21.8	0.6401

Raising the cap from 1 to 50 multiplies the data by 8.4 and the noise multiplier by 5.8, and accuracy falls from 0.8917 to 0.6401. On this task the noise dominates: a 1,000-record dataset, one record per user, already contains most of what the network can learn privately at this budget, and every extra record per user costs more in noise than it adds in signal. The caps 1 and 2 are tied. The cap $k = 1$ row is user-level DP-SGD on one record per user in disguise: with one record per user, sampling records at rate 0.1 is sampling users at rate 0.1, and the accountant is the same, $\sigma = 3.78$.

44.6.6. Check yourself

- Why must the cap be applied with randomness independent of other users' data? *(The derivation needs adding one user to change only that user's kept records. If, say, the cap kept the k records most similar to the rest of the dataset, adding a user could change which records other users keep, and neighbours would differ in more than k records.)*
- In Table 44.4, kq rises from 0.100 to 0.593 as the cap goes from 1 to 50. What does Equation 44.8 predict for the noise multiplier, and why is the actual one smaller? *(Proportionality to kq predicts about* $3.78 \times 5.93 = 22.4$. *The rule is only approximate: it holds where* σ *is large and kq small, and at* $kq = 0.593$ *neither the rate-kq approximation nor the large-*σ *law is accurate, so the accountant's 21.8 differs from it.)*

44.7. Heterogeneous users

44.7.1. Context

User sizes are rarely equal. In the running example's population, 30 users with at least 50 records each hold 30.6% of the records, while the smallest half of the users hold 10.3% (Figure 44.1). Example-level training weights each user by their number of records; user-level training does not. What objective does user-level DP-SGD optimize, and what does that mean for heavy users?

44.7.2. Statement

Averaged over the user sampling and the noise, the update direction of user-level DP-SGD is

$$\mathbb{E}\Big[\frac{G_t}{qU}\Big] = \frac{1}{U}\sum_{u=1}^{U} \min\Big(1, \frac{C}{\|\bar{g}_u\|}\Big)\bar{g}_u, \tag{44.13}$$

a sum in which each user has weight at most $1/U$ whatever their number of records. Example-level DP-SGD gives user u weight n_u/n in its expected update, $\frac{1}{n}\sum_u \sum_{i\in u} \min(1, C/\|g_i\|)g_i$.

44.7.3. Derivation

1. **Average over the sampling.** User u is in S_t with probability q, so $\mathbb{E}\sum_{u\in S_t} \tilde{g}_u = q\sum_u \tilde{g}_u$. The noise has mean zero.
2. **Divide by qU.** The q cancels, leaving $\frac{1}{U}\sum_u \tilde{g}_u$, which is Equation 44.13 by the definition of $\tilde{g}_u$.

3. **The weight of one user.** $\|\tilde{g}_u\| \leq C$ for every user, so each term has length at most C/U, and the share of any group of users in the update is at most their share of the users.
4. **Example-level.** The same computation for DP-SGD over records (DP-SGD) gives each record weight $1/n$, so user u's records together have weight n_u/n.

44.7.4. Interpretation

User-level training changes the objective, not only the noise. With averaged per-user gradients, the model minimizes (a clipped version of) the average over users of each user's average loss, $\frac{1}{U}\sum_u \frac{1}{n_u}\sum_{i\in u}\ell(\theta; z_i)$, rather than the average over records. Whether that is what you want depends on the application. For a keyboard model, weighting people equally keeps a few very active users from defining everyone's suggestions. For a model meant to fit the overall distribution of records, it under-weights heavy users' content, and the bias can matter when heavy users differ from light ones, for example by language, topic or device.

Clipping caps heavy users twice. A heavy user's average gradient is a good estimate, typically short when the model already fits their data, and is rarely clipped. But if the user's data are unusual, their gradient is long and is clipped to C, so their influence is capped at that of any other user. This is the user-level analogue of what clipping does to records with large gradients (Disparate impact).

Sum-then-clip sits in between. Summing a user's gradients before clipping makes a heavy user's vector up to n_u times longer than one record's, so heavy users are clipped first, and their influence rises with n_u until it reaches C. It interpolates between record weighting, for users whose sum stays below C, and user weighting, for those above it (Exercise 5 in the exercise book).

44.7.5. Example: heavy users in the running example

The 30 users with at least 50 records hold 30.6% of the records, and so 30.6% of the weight in the expected example-level update. Under user-level DP-SGD their weight is at most 30/1,000 = 3.0%. Does that hurt the model where heavy users' data are? The script splits the test set by the owner of each test point's nearest training record. Because a heavy user's records were chosen as the nearest neighbours of one seed in 50 dimensions, they spread widely, and 68.3% of test points have a heavy user's record as their nearest neighbour. At user-level $\varepsilon = 4$, user-level DP-SGD reaches 0.9361 on those points and 0.9319 on the others; the non-private model, 0.9607 and 0.9622. On this task, down-weighting heavy users costs nothing measurable, because one teacher network labels every record, so the light users' records teach the same function. On data where heavy users' records follow their own patterns, the same reweighting would cost accuracy on those patterns.

44.7.6. Check yourself

- A user-level model will be used to predict for each record equally, and you know that heavy users' records differ from light users'. What can you change without changing ε? *(How each user's vector is computed: summing instead of averaging before clipping, or a larger C relative to typical averaged gradients. Both are inside the per-user computation and leave the sensitivity at C.)*

- Why is each user's share of the user-level update at most $1/U$ rather than exactly $1/U$? *(Because a user's clipped vector has length at most C; users whose average gradient is shorter than C, typically those the model already fits, contribute less.)*

44.8. Comparing the strategies on the running example

44.8.1. Context

Three ways to train the running example with a user-level guarantee are now on the table: (a) example-level DP-SGD on all records, with the user accountant for the heaviest user; (b) user-level DP-SGD; (c) contribution bounding to two records per user, then example-level DP-SGD. At the same user-level (ε, δ), which model is best?

44.8.2. Statement

Table 44.5 trains each strategy for 1,000 steps with an expected batch of 100 units, $C = 0.5$ and $\eta = 0.5$, at the noise multipliers of Table 44.3, one run each.

Table 44.5.: Test accuracy at the same user-level budget, $\delta = 10^{-5}$, one run each.

User-level ε	(a) Example-level, all records	(b) User-level DP-SGD	(c) At most 2 records per user
1	0.5318	0.8065	0.7084
2	0.5582	0.9028	0.8374
4	0.5713	0.9347	0.8810
8	0.5478	0.9442	0.9333
Non-private, 1,000 steps	0.9612		

44.8.3. Derivation

Each strategy's guarantee was derived above: (a) and (c) by the accountant of Section 44.4 with $k = 348$ and $k = 2$, and (b) by Section 44.5. The cap $k = 2$ is the best cap at $\varepsilon = 4$ in Table 44.4, tied with $k = 1$; choosing it from test accuracy is a leak that a real deployment would have to pay for. Run-to-run variation is of the order of a point at these budgets: the cap $k = 1$ and user-level DP-SGD restricted to one random record per user are the same algorithm with the same σ, and two runs of it gave 0.8917 and 0.9070.

44.8.4. Interpretation

Keeping the record as the unit fails. Strategy (a) is at chance, between 0.53 and 0.57, at every budget up to $\varepsilon = 8$. The heaviest user dictates the noise for everyone: σ between 70.3 and 449 drowns every gradient. That is the practical meaning of Figure 44.2: an example-level pipeline on data with heavy users needs either an enormous ε or a cap.

Changing the unit wins. User-level DP-SGD is the best strategy at every budget, 0.9347 at $\varepsilon = 4$ against 0.9612 for the non-private model. It needs a little less noise than the cap of 2 (Table 44.3) and, unlike the cap, it uses every record, through the per-user average. Its advantage is largest at small budgets: 9.8 points at $\varepsilon = 1$, 1.1 points at $\varepsilon = 8$. Its cost is compute: each step processes all the records of about 100 users, about 1,000 records, ten times what the example-level strategies process.

Bounding is the fallback. Strategy (c) keeps the example-level pipeline and loses 5 to 10 points against (b) below $\varepsilon = 8$. It comes close at $\varepsilon = 8$, where the noise is small enough that the discarded data, not the noise, limits accuracy.

These findings agree with published comparisons on language models, which use different data, models and accountants. Chua et al. (2024) compare contribution bounding with group-privacy accounting ("Group Privacy") against user-level DP-SGD with per-user averaging ("User-wise DP-SGD") for fine-tuning, and report that user-wise DP-SGD generally does better, especially at small budgets. Charles et al. (2024), who call the two sampling schemes example-level and user-level sampling, report that user-level sampling usually does better when each user's data are varied and when strong privacy is required, and that example-level sampling sometimes wins. Note that Chua et al. account for the cap with the generic group privacy of Equation 44.1; the direct accountant of Section 44.4 would give them less noise.

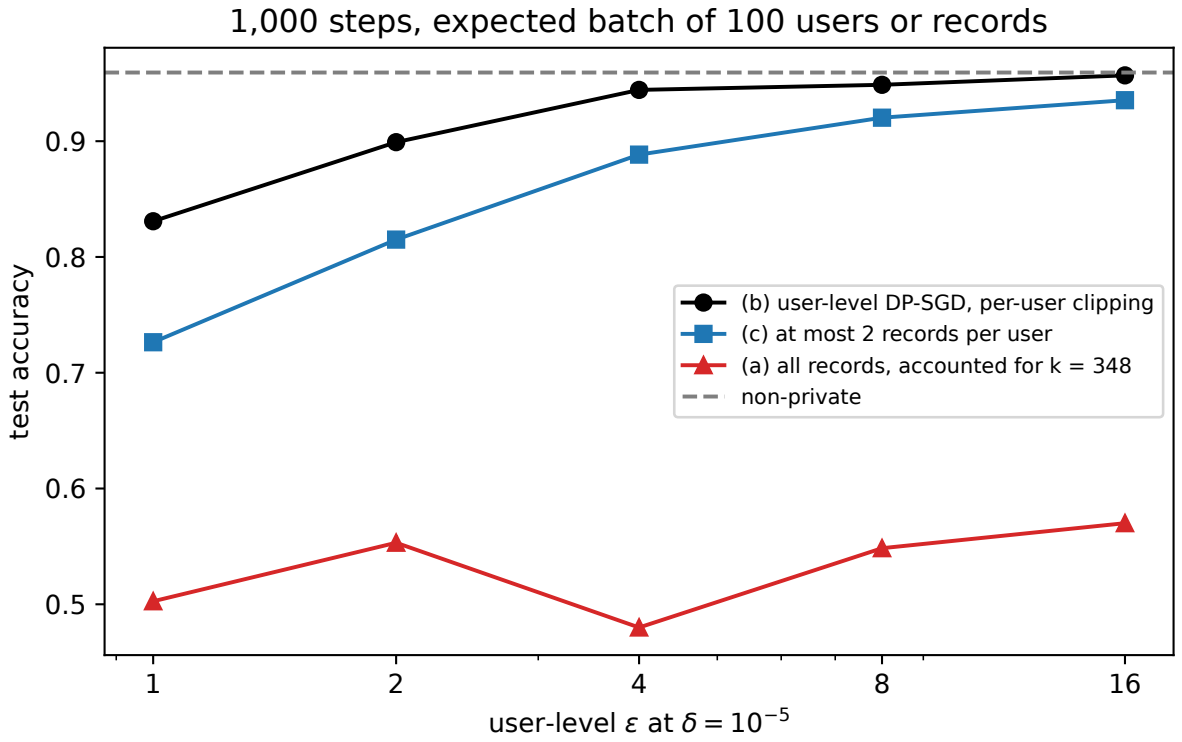

Figure 44.3.: Test accuracy of the running example against the user-level ε at $\delta = 10^{-5}$, for the three strategies (1,000 steps, expected batch 100, one run each; the runs differ from Table 44.5 in their random seeds). User-level DP-SGD is best at every budget; example-level DP-SGD on all records, accounted for its heaviest user, stays near chance.

44.8.5. Example: what the user-level guarantee costs

At $\varepsilon = 4$ the running example loses 2.7 points to protect users (0.9347 against 0.9612). The record-level model of DP-SGD at the same ε, trained for 10,000 steps, reached 0.9548, and this chapter's 1,000-step schedule would need only $\sigma = 0.778$ for a record-level guarantee (Table 44.3). The difference is the price of the unit: 1,000 people instead of 10,000 records, and a guarantee that now covers the person with 348 records as well as the one with a single record.

44.8.6. Check yourself

- Strategy (a) uses every record and the tightest available accountant. Why does it do worst? *(Because the guarantee must hold for the heaviest user, whose 348 records put about 3.5 of them into every batch; the noise has to hide a shift of several clipping norms in almost every step, which takes σ in the hundreds.)*
- Would strategy (a) look better if the heaviest user were removed from the data? *(Only a little: the accountant would be for the next-largest user, who has 258 records, so about 2.6 of them would still be in every batch. Removing a user because of their size is itself a data-dependent choice that must be made with public information or paid for, and it is a crude form of contribution bounding.)*

44.9. Code: check every number by computation

The script code/user_level.py builds the user population, implements the user accountant of Equation 44.6 by numerical integration and checks it against Equation 44.7 and Equation 44.2, compares it with group privacy, and trains the three strategies with the part's network. It imports the model, DP-SGD and the record-level accountant from code/dp_sgd.py. From the repository root:

```
uv run python code/part05-dp-ml/user_level.py
```

It takes about a minute and a half, most of it spent in user-level DP-SGD, which processes about 1,000 records per step, and in finding the noise multiplier for the user with 348 records.

Output (seed 0), summarized in Table 44.6:

Table 44.6.: The script's output with the default seed.

Experiment	Result
Population	1,000 users; mean 10, median 4, largest 348 records; 193 users with one record
Accountant checks	$k = 1$ matches the subsampled Gaussian; integral matches Equation 44.7 to seven digits
Running example, user with k records	$\varepsilon = 15.54$ at $k = 2$, 146.20 at $k = 10$; group privacy 18.61 and none

Experiment	Result
Noise at user-level $\varepsilon = 4$	$\sigma = 128$ (all records), 3.78 (user-level), 4.18 (cap 2)
Contribution bounding at $\varepsilon = 4$	0.8917 at $k = 1$ down to 0.6401 at $k = 50$
Strategies at $\varepsilon = 4$	0.5713 (all records), 0.9347 (user-level), 0.8810 (cap 2); non-private 0.9612
Heavy users	30.6% of records, at most 3.0% of the user-level update

tests/test_user_level.py checks that the output still matches.

What to take from it. The record-level accountant answers the wrong question when people contribute many records, and asking it the right question, about a user with k records, gives answers that grow faster than k. The fix is in the algorithm, not the accountant: make the person the unit that is sampled and clipped. Implementation needs only a per-user aggregation before clipping; the accountant is unchanged.

44.11. Cheat sheet

U users, user u with n_u records, cap k, sampling rate q, noise multiplier σ, clipping norm C, T steps. Table 44.7 collects the results.

Table 44.7.: Every result of the chapter.

Result	Formula	Conditions
Group privacy	$(k\varepsilon, \delta\frac{e^{k\varepsilon}-1}{e^{\varepsilon}-1})$	Any example-level (ε, δ) mechanism
User with k records, example-level DP-SGD	$\mathcal{N}(0, \sigma^2)$ against $\sum_m \binom{k}{m} q^m (1-q)^{k-m} \mathcal{N}(m, \sigma^2)$	Tight (Charles et al. 2024, Theorem 3)
Its moments	$A_\alpha = \mathbb{E}[\exp(\sigma^{-2} \sum_{i<j} H_i H_j)]$, $H_i \sim \mathrm{Bin}(k, q)$	Integer α
Quick estimate	Record-level accountant at rate kq	Small kq; errs slightly low
User-level DP-SGD	DP-SGD's accountant with users as units, q = user sampling rate	One clipped vector per user, from that user's data alone
Capped sum per user	Noise multiplier σ/k	Per-record clipping, at most k records, users sampled whole
Contribution bounding	Accountant for k records on $n_k = \sum_u \min(n_u, k)$ records	Cap chosen per user, independently of others
Expected user-level update	$\frac{1}{U} \sum_u \min(1, C/\lVert\bar{g}_u\rVert)\bar{g}_u$	Each user weighs at most $1/U$
Running example	Records: $\varepsilon = 6.71$; user with 2 records 15.54, with 10 records 146.20	$q = 0.01$, $\sigma = 1$, $T = 10{,}000$

Rules of thumb

- Name the privacy unit with every ε. A record-level ε says little about a person with many records.
- To estimate what an example-level model gives a user with k records, rerun the accountant at rate kq, and expect the truth to be a little worse.
- Don't use group privacy for DP-SGD; account for the user's records directly, or better, sample and clip users.
- Prefer user-level DP-SGD with per-user averaging. It pays for the number of people, not their records, and uses all their data.
- If the pipeline must stay record-based, cap records per user, choose the cap from public knowledge, and account for the cap with the user accountant.
- Decide deliberately how heavy users should count: averaging weights people equally, summing before clipping weights records until the clip.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

45. Disparate impact

45.1. Why this matters

The chapter on private gradient descent showed that training the part's running example with differential privacy (DP) at $\varepsilon = 4$ costs less than one point of test accuracy: 0.9548 against 0.9610 without privacy. That number is an average over the test set. It says nothing about who loses the point. Bagdasaryan, Poursaeed & Shmatikov (2019) asked that question and found an uncomfortable answer: when a network is trained with stochastic gradient descent (SGD) with per-example clipping and Gaussian noise, DP-SGD, the accuracy it loses is concentrated on the classes and subgroups that are under-represented in the training data. In their gender classifier, for example, the drop in accuracy was much larger on Black faces than on white faces, and the gap between groups that the non-private model already had grew under DP. They called this the **disparate impact** of DP on model accuracy.

This matters in two ways. A model that is "less than a point worse" can be ten points worse on a group of people, and an average hides it. And the groups that pay are often the ones a privacy guarantee is meant to protect: small populations, rare conditions, unusual records. This chapter explains why it happens, from the two ingredients of DP-SGD, measures it on the running example, and asks what can be done about it.

45.1.1. The one idea: every record gets the same budget of influence, and every group gets the same noise

DP-SGD caps each record's pull on the update at C, then adds noise whose size depends only on C and σ, not on the data. Both rules are blind to groups, and that is exactly why they are not neutral. A group's pull on the expected update is at most its share of the records times C, however badly the model fits it, so a group whose gradients are large is cut back more than a group whose gradients are small: that is the **clipping** mechanism. And the noise is the same for everyone, while a group's signal is proportional to its size, so a small group's signal-to-noise ratio is smaller by its share: that is the **noise** mechanism. Small groups and groups the model finds hard suffer from both, and the two compound, because clipping shrinks a group's effective share and the noise then acts on the shrunk share.

Table 45.1 lists the results and where each is used.

Table 45.1.: The results of this chapter and where each is used.

Result	Where it is used
Measuring disparate impact: privacy cost per group	Reporting a private model; choosing ε

Result	Where it is used
Clipping reweights groups and turns the update	Choosing C; group-aware clipping
The noise floor of a small group	Deciding whether a group is large enough to train on privately
Confidence intervals for per-group accuracy	Every per-group evaluation, private or not
Mitigations and what each costs	Training a private model that serves every group

Notation. As in DP-SGD, n records $z_i = (x_i, y_i)$ train a model with weights θ, g_i is record i's gradient, C the clipping norm, σ the noise multiplier, q the sampling rate, $B = qn$ the expected batch size, T the number of steps and η the learning rate. The records are split into **groups** $g = 1, \dots, K$; group g has n_g records and **share** $s_g = n_g/n$. A record's **clipping weight** is $\min(1, C/\|g_i\|)$, the factor clipping multiplies its gradient by, and a group's clipping weight w_g is its average over the group's records. acc_g is a model's accuracy on test records of group g. A subscript i always names a record and a subscript g or h a group, so g_i is a record's gradient and $\bar{g}_g$, defined below, a group's average gradient.

The running example. The part's running example classifies 50-dimensional inputs with a two-layer network (DP-SGD). This chapter adds a minority group. Of the $n = 10{,}000$ training records, 9,500 are the first records of the running example's fixed training set: standard normal inputs, labelled by the random teacher network. The other 500, a share of 5%, come from a different region and follow a different rule. Their inputs are $x = 8u + z$, where u is a fixed unit vector and z is standard normal in a fixed 15-dimensional subspace orthogonal to u, and their label is the sign of one coordinate of z. So the minority's records lie far from the majority's, have larger inputs (average length 8.89 against 7.04), and need a rule that the majority does not teach. The non-private model learns both: it reaches 0.9529 on the majority and 0.9411 on the minority. Each group is tested on 20,000 fresh records of its own, so that the test error is small compared with the effects being measured. DP-SGD runs with the running example's settings: $q = 0.01$, $C = 0.5$, $\eta = 0.5$, $T = 10{,}000$ steps and $\delta = 10^{-5}$.

How to read this chapter. Section 45.3 defines what to measure and shows the effect. Section 45.4 and Section 45.5 explain it, one mechanism each; they are the core of the chapter. Section 45.6 is about measuring per-group accuracy honestly, and applies to any model. Section 45.7 discusses what can be done and what each fix costs.

45.2. Toolkit: four facts every derivation uses

45.2.1. Fact 1 — The expected update is a reweighted average gradient

Each DP-SGD step adds up the clipped gradients of a Poisson batch, adds Gaussian noise of standard deviation σC to each coordinate, and divides by the public expected batch size $B = qn$. Each record is in the batch with probability q, so the expected sum is q times the sum over all records, and dividing by qn gives

$$\mathbb{E}\Big[\frac{G_t}{B}\Big] = \frac{1}{n}\sum_{i=1}^{n} \min\Big(1, \frac{C}{\|g_i\|}\Big) g_i, \tag{45.1}$$

the average gradient with each record weighted by its clipping weight (DP-SGD). The noise on the averaged update has standard deviation $\tau = \sigma C/B$ per coordinate, whatever the data. In the running example at $\varepsilon = 4$, $\sigma = 1.36$ and $\tau = 1.36 \times 0.5/100 = 0.0068$.

45.2.2. Fact 2 — A drift beats a random walk after (noise/signal)² steps

Suppose each step moves the weights by a signal of length ℓ_{sig} that keeps pointing the same way, plus independent noise of length ℓ_{noise}. After a number t of steps the signals add up to length $t\ell_{\text{sig}}$. The noise vectors are independent with mean zero, so their squared lengths add, and their sum has length about $\ell_{\text{noise}}\sqrt{t}$. The signal is longer once $t\ell_{\text{sig}} > \ell_{\text{noise}}\sqrt{t}$, that is after

$$t > \left(\frac{\ell_{\text{noise}}}{\ell_{\text{sig}}}\right)^2 \tag{45.2}$$

steps. DP-SGD uses this to explain why training works when every step's noise is ten times longer than its signal: at $\varepsilon = 4$ the noise on the averaged gradient has length $\tau\sqrt{3{,}329}$ for the network's 3,329 weights, and the signal emerges after a few hundred steps.

45.2.3. Fact 3 — A shrinking recursion with noise settles at a fixed variance

Let a number evolve as $x_{t+1} = (1-a)x_t + e_t$, where $0 < a < 2$ and the e_t are independent with mean zero and variance v. Each step shrinks x toward zero by the factor $1-a$ and adds fresh noise. Because the noise is independent of the current value, variances add: $\operatorname{Var} x_{t+1} = (1-a)^2 \operatorname{Var} x_t + v$. Since $(1-a)^2 < 1$, this converges, and the limit V solves $V = (1-a)^2 V + v$:

$$V = \frac{v}{1-(1-a)^2} = \frac{v}{a(2-a)}. \tag{45.3}$$

For example, with $a = 0.1$ and $v = 1$ the variance settles at $1/(0.1 \times 1.9) = 5.26$: a weak pull toward zero lets the noise accumulate to more than five times one step's variance. Halving the pull roughly doubles the stationary variance. The number of steps to forget the starting point is about $1/a$, since $(1-a)^t \approx e^{-at}$.

45.2.4. Fact 4 — An accuracy measured on m records is a binomial proportion

If a model classifies each test record of a group correctly with probability p, independently, then the number correct out of m is binomial with mean mp and variance $mp(1-p)$, and the measured accuracy k/m has standard deviation $\sqrt{p(1-p)/m}$. The **Clopper–Pearson interval** (Hypothesis testing) inverts the binomial distribution exactly: at the 95% level its upper end u is the accuracy at which k or fewer correct answers would have probability 0.025, and its lower end l the accuracy at which k or more would have probability 0.025. It covers the true accuracy with probability at least 0.95. The smaller the group, the wider the interval, in proportion to $1/\sqrt{m}$.

45.3. Disparate impact, measured

45.3.1. Context

What exactly should you measure to say that DP hurts one group more than another, and does it happen on the running example? An accuracy gap between groups is not enough, because the non-private model may already have one. The question is how much *privacy* adds to each group's error.

45.3.2. Statement

The **privacy cost** of group g is the accuracy the group loses when the same training recipe is made private:

$$\pi_g = \mathrm{acc}_g(\text{non-private}) - \mathbb{E}\big[\mathrm{acc}_g(\text{private})\big], \tag{45.4}$$

where the expectation is over the randomness of private training (Esipova et al. 2023 use this definition; Bagdasaryan et al. 2019 compare the same differences). DP has **disparate impact** when the privacy costs of groups differ, $\pi_a \neq \pi_b$, and the **privacy cost gap** $|\pi_a - \pi_b|$ measures how much.

On the running example with a 5% minority, Table 45.2 gives each group's accuracy over three training runs per row.

Table 45.2.: Test accuracy of each group (mean ± standard deviation over 3 runs) of the running example with a 5% minority, trained with DP-SGD at four budgets ($\delta = 10^{-5}$), with clipping alone, and without privacy. The privacy cost is Equation 45.4.

Training	Majority accuracy	Minority accuracy	Gap	Privacy cost: majority	minority
Non-private SGD	0.9529 ± 0.0018	0.9411 ± 0.0052	0.0119	—	—
Clipping only, $\sigma = 0$	0.9581 ± 0.0015	0.9007 ± 0.0048	0.0574	−0.0051	0.0404
$\varepsilon = 8$, $\sigma = 0.917$	0.9550 ± 0.0006	0.8553 ± 0.0110	0.0997	−0.0020	0.0858
$\varepsilon = 4$, $\sigma = 1.36$	0.9470 ± 0.0037	0.8477 ± 0.0211	0.0993	0.0059	0.0934
$\varepsilon = 2$, $\sigma = 2.28$	0.9366 ± 0.0082	0.7574 ± 0.0379	0.1791	0.0163	0.1836
$\varepsilon = 1$, $\sigma = 4.13$	0.8822 ± 0.0032	0.6133 ± 0.0173	0.2689	0.0707	0.3278

45.3.3. Derivation

This statement is a definition and a measurement, so its "derivation" is the experiment's design, and each choice in it is there to make the comparison fair.

1. **Same data, same recipe.** Every row trains on the same 10,000 records with the same sampling rate, learning rate and number of steps. The only differences are the clipping (absent in the non-private row) and the noise multiplier, which the accountant of DP-SGD sets for each ε.
2. **Large test sets.** Each group is tested on 20,000 records, so by Fact 4 a measured accuracy near 0.9 has a standard deviation of $\sqrt{0.9 \times 0.1/20{,}000} = 0.0021$. The differences in the table are much larger than that.
3. **Several runs.** Private training is random, and its spread differs between groups. Each row averages three runs and reports their standard deviation; the privacy cost subtracts the average private accuracy from the average non-private accuracy.
4. **A non-private model that serves both groups.** The minority's non-private accuracy, 0.9411, is within 1.2 points of the majority's, 0.9529. Any large gap in the private rows is therefore caused by privacy, not inherited from the data.

45.3.4. Interpretation

The minority pays almost all of it. At $\varepsilon = 4$ the majority loses 0.59 points of accuracy and the minority 9.34, 15.7 times as much. At $\varepsilon = 8$, a budget at which DP-SGD found the running example nearly as accurate as non-private training, the majority loses nothing (its accuracy is 0.20 points higher) and the minority loses 8.58 points. The ratio is smaller at $\varepsilon = 1$, 4.6, only because there the majority starts to lose too: 7.07 points against the minority's 32.78. An average over a test set drawn like the training set, 95% majority, would report a loss of $0.95 \times 0.0059 + 0.05 \times 0.0934 = 0.0103$ at $\varepsilon = 4$, about one point.

Both mechanisms are visible. The clipping-only row has no noise at all, yet the minority loses 4.04 points while the majority gains 0.51: clipping alone is disparate. Adding noise then widens the gap steadily as ε falls. The next two sections explain each part.

The minority's runs also vary more. At $\varepsilon = 4$ the standard deviation over runs is 0.0211 for the minority and 0.0037 for the majority. A single private run says less about a small group than about a large one, a point Section 45.6 returns to.

45.3.5. Example: what the published experiments found

Bagdasaryan, Poursaeed & Shmatikov (2019) trained classifiers with DP-SGD on images and text and found the same pattern: the under-represented classes and subgroups, and the more complex ones, lost the most accuracy, and an existing gap between groups grew. Esipova et al. (2023) report, for MNIST digits where class 8 was undersampled to about 1% of the training set, a privacy cost of 8.9 points for the typical class 2 and 57.9 points for class 8 under DP-SGD (their Table 2, $\varepsilon = 5.90$). On the running example, Figure 45.1 shows the same shape: the majority's curve is the curve of DP-SGD, the minority's lies far below it.

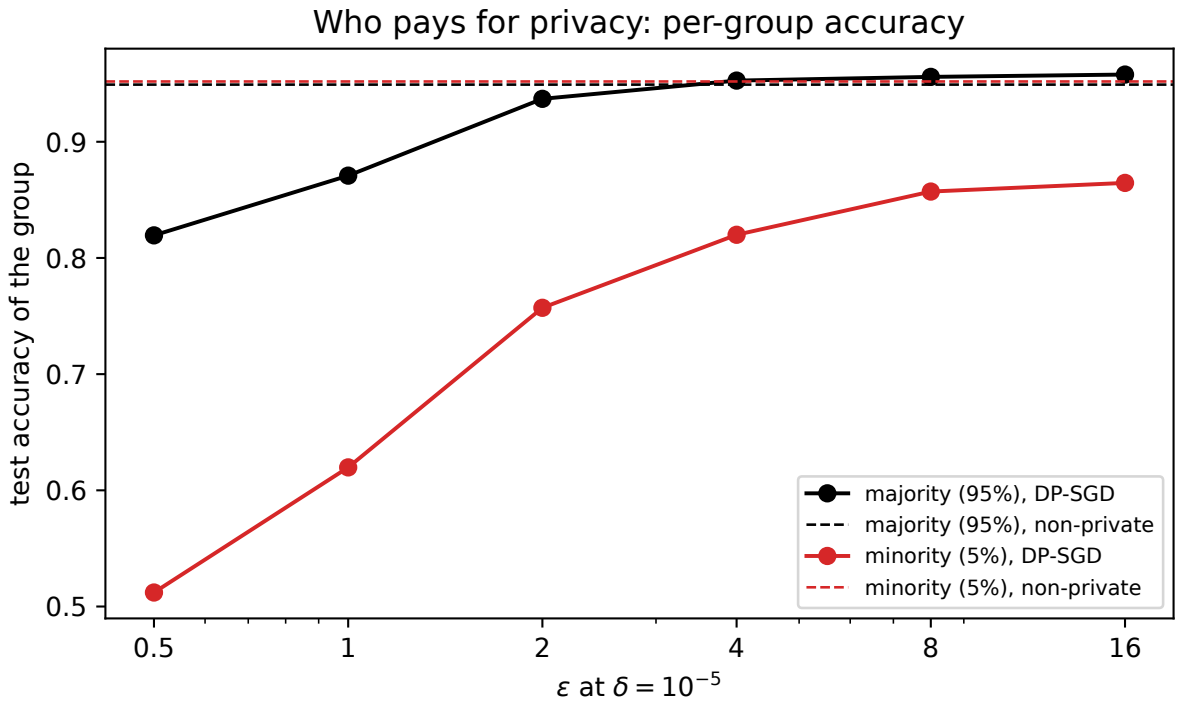

Figure 45.1.: Test accuracy of each group of the running example against ε (log scale, one run per point, $\delta = 10^{-5}$), with each group's non-private accuracy dashed. The majority is close to its non-private accuracy down to $\varepsilon = 2$; the minority falls far below it at every budget.

45.3.6. Check yourself

- Why is the privacy cost a better measure than the gap between the private model's group accuracies? *(Because part of the gap may be inherited from non-private training, which DP did not cause. The privacy cost subtracts each group's own non-private accuracy.)*
- At $\varepsilon = 4$, a test set with the training proportions shows an overall loss of under one point. What would a test set with equal numbers of both groups show? *(The average of the two privacy costs,* $(0.0059 + 0.0934)/2 = 0.0497$*: about five points. The overall number depends on the test set's mix as much as on the model.)*

45.4. Clipping reweights the groups

45.4.1. Context

Clipping without noise changes nothing about privacy (without noise there is none), yet in Table 45.2 it costs the minority 4.04 points. How does a rule that treats every record the same way end up treating groups differently?

45.4.2. Statement

Split the expected update of Fact 1 by group. Write $\bar{g}_g = \frac{1}{n_g}\sum_{i\in g} g_i$ for group g's average gradient and $m_g = \frac{1}{n_g}\sum_{i\in g} \min(1, C/\|g_i\|)\, g_i$ for its average *clipped* gradient. Then

$$\mathbb{E}\Big[\frac{G_t}{B}\Big] = \sum_g s_g\, m_g, \qquad \|s_g\, m_g\| \le s_g\, C : \tag{45.5}$$

each group pulls with its share times its average clipped gradient, and that pull is never longer than its share times C, however large the group's gradients are.

When the records within each group have parallel gradients, each group's average clipped gradient is its average gradient scaled by a number, and the expected update becomes the gradient of a **reweighted** mixture of the groups:

$$\mathbb{E}\Big[\frac{G_t}{B}\Big] = \Big(\sum_h s_h\, c_h\Big) \sum_g \tilde{s}_g\, \bar{g}_g, \qquad \tilde{s}_g = \frac{s_g\, c_g}{\sum_h s_h\, c_h}, \tag{45.6}$$

where $c_g = \|m_g\|/\|\bar{g}_g\|$ is the fraction of the group's average gradient that survives clipping and $\tilde{s}_g$ is its **effective share**. When all of a group's records have the same norm, c_g is the group's clipping weight w_g.

45.4.3. Derivation

1. **Split the sum.** Fact 1's expected update is $\frac{1}{n}\sum_i \min(1, C/\|g_i\|) g_i$. Group the records: $\frac{1}{n}\sum_g \sum_{i\in g}(\cdots) = \sum_g \frac{n_g}{n} \cdot \frac{1}{n_g}\sum_{i\in g}(\cdots) = \sum_g s_g m_g$.

2. **Bound the pull.** Each clipped gradient has length at most C, and the length of an average is at most the average of the lengths (the triangle inequality), so $\|m_g\| \le C$ and $\|s_g m_g\| \le s_g C$.
3. **Parallel gradients.** If every g_i in group g points along the same unit vector e_g, then $g_i = \|g_i\| e_g$ and $\min(1, C/\|g_i\|) g_i = \min(\|g_i\|, C) e_g$. Averaging, m_g and $\bar{g}_g$ both point along e_g, so $m_g = c_g \bar{g}_g$ with $c_g = \|m_g\| / \|\bar{g}_g\|$.
4. **Factor out the total.** $\sum_g s_g c_g \bar{g}_g = (\sum_h s_h c_h) \sum_g \frac{s_g c_g}{\sum_h s_h c_h} \bar{g}_g$, which is Equation 45.6. The effective shares are non-negative and add up to 1.
5. **Equal norms.** If all of group g's records also have the same norm ν_g, then $c_g = \min(\nu_g, C)/\nu_g = \min(1, C/\nu_g) = w_g$.

45.4.4. Interpretation

Two errors: length and direction. Equation 45.6 separates what clipping does into two parts. The factor $\sum_h s_h c_h$ shortens the update, which a larger learning rate can undo. The effective shares change *which* mixture of the groups is being descended, and no learning rate undoes that. Esipova et al. (2023) make this distinction for a whole batch: they compare training with the clipped batch gradient's length but the true direction against the true length but the clipped direction, and find the direction error far more harmful, especially to the under-represented class (their Table 1). In Figure 45.2, clipping shortens the update and also turns it toward the majority.

Which groups are cut back. A group's effective share falls when its clipping weight falls, that is when its gradients are long compared with C. Gradients are long for two reasons. The model fits the group badly: for the logistic loss, the derivative with respect to the output is $-y\,\mathrm{sigmoid}(-yf)$, close to 1 in size for a misclassified record and close to 0 for a record classified with a wide margin. And the group's inputs are large: a dense layer's per-example gradient is the outer product of the back-propagated error and the layer's input, whose norm is the product of the two norms (DP-SGD), so at the same error a record with a longer input has a longer gradient. Tran, Dinh & Fioretto (2021) identify both factors, gradient norms and the input norms behind them, as the source of the clipping part of disparate impact. A small group the model has not yet learned has both.

A feedback loop. Early in training every record is clipped and every group has a similar weight. As the majority is learned, its gradients shrink below C and its weight rises toward 1, while the minority, not yet learned, keeps long gradients and a low weight. Its effective share falls below its true share, so it is learned more slowly, so its gradients stay long. The loop ends only when the minority's gradients fall below C too.

Where training stops. Clipped gradient descent stops where the expected update is zero, $\sum_g s_g m_g = 0$, not where the true average gradient $\sum_g s_g \bar{g}_g$ is zero. If the groups' gradients conflict, the stopping point is that of the reweighted objective, which has moved toward the majority.

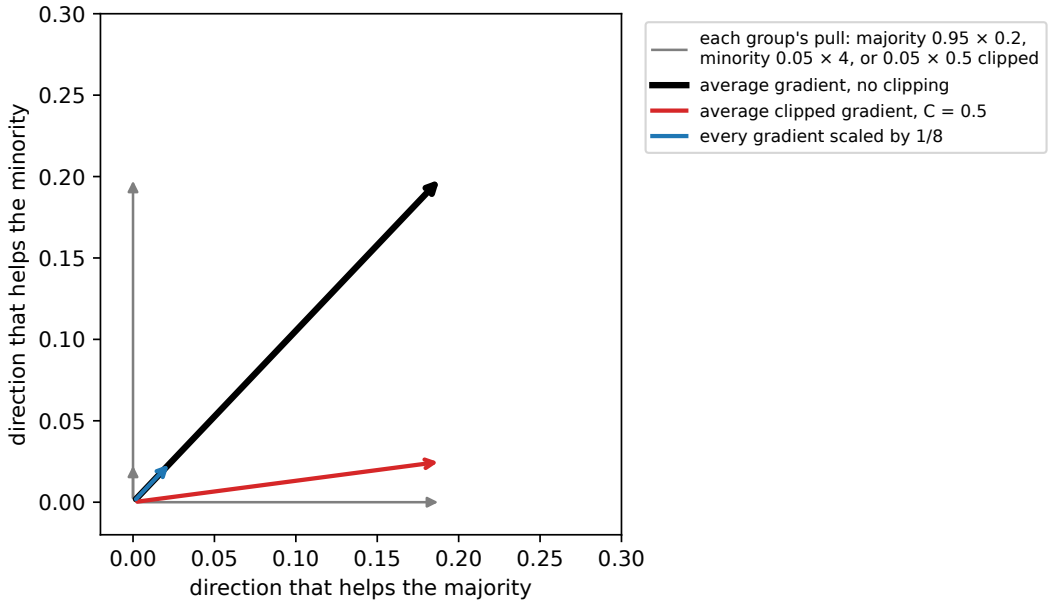

Figure 45.2.: The clipping example in two dimensions: 95 majority records with gradient (0.2, 0) and 5 minority records with gradient (0, 4). Without clipping the two groups pull about equally hard (black); clipping at C = 0.5 cuts the minority's pull eightfold and turns the update toward the majority (red). Scaling every gradient by the same factor 1/8 instead keeps the direction (blue).

45.4.5. Example: two dimensions, then the running example

Take 95 majority records whose gradient is $(0.2, 0)$, already short, and 5 minority records whose gradient is $(0, 4)$, long because the model fits them badly. Without clipping the average gradient is $(0.95 \times 0.2, 0.05 \times 4) = (0.19, 0.2)$, of length 0.2759: the five minority records pull as hard as the ninety-five others, and the minority's component is a fraction $0.2/0.39 = 0.513$ of the sum of the two components. Clip at $C = 0.5$. The majority's gradients are untouched; the minority's shrink to length 0.5. The average becomes $(0.19, 0.05 \times 0.5) = (0.19, 0.025)$, of length 0.1916, and the minority's fraction falls to 0.116. The update has turned by 39.0 degrees toward the majority. Here $c_{\text{maj}} = 1$ and $c_{\text{min}} = 0.5/4 = 0.125$, and Equation 45.6 gives the minority an effective share of $0.05 \times 0.125/(0.05 \times 0.125 + 0.95) = 0.0065$ instead of 0.05. Scaling every gradient by C/C_{max} with $C_{\text{max}} = 4$, the largest norm, instead gives $(0.0238, 0.0250)$: eight times shorter, but at an angle of 0.0 degrees to the true average.

In the running example, Table 45.3 follows each group's gradients during training with clipping and no noise, on 1,000 majority and the 500 minority training records.

Table 45.3.: Per-group gradient statistics during training with clipping at $C = 0.5$ and no noise. "Clipped" is the fraction of records with gradient norm above C. The effective share is $s\,w_{\min}/(s\,w_{\min} + (1-s)\,w_{\mathrm{maj}})$ with $s = 0.05$, Equation 45.6 with $c_g = w_g$.

Step	Median norm: majority	Median norm: minority	Clipped: majority	Clipped: minority	Weight w_g: majority	Weight w_g: minority	Effective share of the minority	Test accuracy: majority	Test accuracy: minority
0	3.4	3.7	1.00	1.00	0.165	0.163	0.0495	0.5064	0.5019
2,500	3.8×10^{-4}	2.7	0.18	0.70	0.869	0.424	0.0251	0.9569	0.6724
5,000	1.4×10^{-4}	0.71	0.14	0.54	0.891	0.579	0.0331	0.9607	0.8137
7,500	7.7×10^{-5}	0.30	0.13	0.45	0.906	0.651	0.0364	0.9621	0.8661
10,000	7.0×10^{-5}	0.16	0.11	0.39	0.917	0.702	0.0387	0.9613	0.8900

At step 0 both groups are fully clipped, with similar weights, and the minority's effective share, 0.0495, is its true share. By step 2,500 the majority's median gradient norm has fallen to 3.8×10^{-4}, though 18% of its records, those still near the decision boundary, are clipped. The minority's median norm is still 2.7 and 70% of its records are clipped. Its effective share has fallen to 0.0251, half its true share, exactly while it most needs to be learned: its test accuracy is 0.6724 against the majority's 0.9569. It recovers only as the minority is learned, to 0.0387 at the end. The same happens with noise (Figure 45.3): at $\varepsilon = 4$ the minority's effective share is 0.0261 at step 2,500 and 0.0358 at the end, where its weight is 0.637 against the majority's 0.902. The noise keeps the minority's gradients long, so clipping keeps cutting them back.

45.4.6. Check yourself

- If you multiply the minority's loss by 10, does its pull on the update grow tenfold? *(Not for clipped records. Their gradients grow tenfold and are then rescaled back to length C; only records whose upweighted gradient stays below C gain. Exercise 1 in the exercise book works it out.)*
- Why does a larger clipping norm reduce the clipping part of disparate impact? *(It raises the clipping weights of the groups with long gradients more than those of groups whose gradients are already below C, whose weight is already 1, so the effective shares move back toward the true shares.)*

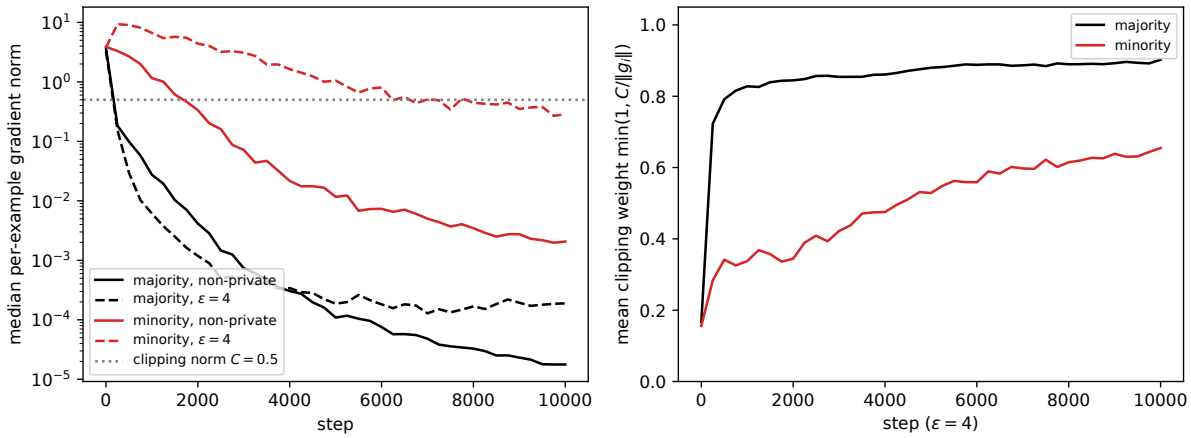

Figure 45.3.: Left: the median per-example gradient norm of each group during non-private training (solid) and DP-SGD at $\varepsilon = 4$ (dashed), on a log scale, with the clipping norm dotted. The majority's gradients fall far below C within the first thousand steps; the minority's stay above it much longer. Right: each group's mean clipping weight during DP-SGD at $\varepsilon = 4$.

45.5. The noise floor of a small group

45.5.1. Context

Noise is added to the sum, the same for everyone. Why should it hurt a small group more than a large one? Because what the noise competes with is each group's signal, and a group's signal in the sum is proportional to its size.

45.5.2. Statement

A drift that is a fraction of the population's. If the part of the expected update that serves group g is a fraction s_g of what the whole population's signal would be, and the noise is unchanged, Fact 2 says that group's signal emerges from the noise only after

$$t_g = \frac{1}{s_g^2}\left(\frac{\ell_{\text{noise}}}{\ell_{\text{sig}}}\right)^2 \tag{45.7}$$

steps, $1/s_g^2$ times as many as for a signal the whole population shares.

A quadratic model of the noise floor. Suppose group g's loss depends on its own block θ_g of d_g weights, which the other groups' losses do not touch, as $L_g = \frac{\lambda}{2}\|\theta_g - \theta_g^*\|^2$, and the training objective is the share-weighted average $\sum_g s_g L_g$. Run gradient descent with noise of standard deviation τ per coordinate on the averaged gradient, as DP-SGD adds. Then group g's excess loss settles at

$$\mathbb{E}[L_g] = \frac{d_g\,\eta\,\tau^2}{2\,s_g\,(2-\eta s_g \lambda)} \approx \frac{d_g\,\eta\,\tau^2}{4\,s_g}, \tag{45.8}$$

and it takes about $1/(\eta s_g \lambda)$ steps to get there. With clipping, s_g is replaced by $s_g c_g$, the group's share times the fraction of its gradient that survives clipping; when the majority is hardly clipped, this is close to the effective share $\tilde{s}_g$ of Equation 45.6.

45.5.3. Derivation

1. **The group's gradient.** The objective's gradient with respect to θ_g is $s_g \lambda(\theta_g - \theta_g^*)$: only group g's loss depends on these weights, and it enters with weight s_g.
2. **One step.** With $x = \theta_g - \theta_g^*$ and noise $\tau\xi$ on the averaged gradient, ξ standard normal, the update $\theta_g \leftarrow \theta_g - \eta(s_g \lambda x + \tau\xi)$ gives $x \leftarrow (1 - \eta s_g \lambda)x - \eta\tau\xi$, coordinate by coordinate.
3. **Stationary variance.** This is Fact 3 with $a = \eta s_g \lambda$ and $v = \eta^2 \tau^2$: each coordinate settles at variance $\eta^2\tau^2/(a(2-a)) = \eta\tau^2/(s_g\lambda(2 - \eta s_g \lambda))$.
4. **Excess loss.** $L_g = \frac{\lambda}{2}\sum_j x_j^2$ over the d_g coordinates, so its expectation is $\frac{\lambda}{2} d_g$ times the variance, which is Equation 45.8. For a small group $\eta s_g \lambda$ is small and $2 - \eta s_g \lambda \approx 2$.
5. **Time scale.** By Fact 3 the starting point is forgotten after about $1/a = 1/(\eta s_g \lambda)$ steps.
6. **The break-even law.** If the population's signal has length ℓ_{sig} per step, the part that serves group g has length $s_g \ell_{\text{sig}}$ and the noise length is still ℓ_{noise}; Fact 2 with $s_g \ell_{\text{sig}}$ in place of ℓ_{sig} gives Equation 45.7.
7. **With clipping.** By Equation 45.6, with parallel gradients within the group, group g's term in the expected update is $s_g c_g \bar{g}_g$ instead of $s_g \bar{g}_g$, while the noise is unchanged. Treating c_g as constant over the steps considered, steps 1 to 6 apply with $s_g c_g$ in place of s_g. If the majority's c is close to 1, then $\sum_h s_h c_h$ is close to 1 and $s_g c_g$ is close to $\tilde{s}_g$.

45.5.4. Interpretation

The floor scales like one over the share. A group with a twentieth of the records sits at about twenty times the excess loss of a group with all of them. The curvature λ cancels: a group whose loss is sharper is pulled back harder, but each unit of noise also costs it more, and the two effects balance. What does not cancel is the share, because the noise is not scaled by it. It also takes the small group $1/s_g$ times longer to reach even that floor.

Why waiting does not help. At a fixed budget, more steps require more noise per step. Under the small-q law of DP-SGD, multiplying the number of steps by m multiplies the noise variance per step by about m, so the break-even count of Equation 45.7 grows as fast as the run (Exercise 3 in the exercise book).

The two mechanisms compound. Clipping lowers a group's pull from s_g to $s_g c_g$; the noise floor scales like one over the pull. A group that is 5% of the data and whose gradients clipping halves pays the floor of a group of 2.5%.

How good is the model. The quadratic model is exact for what it assumes, as the simulation below confirms, but a network is not quadratic and its groups do not use disjoint weights. Where the minority's task overlaps the majority's, the majority's gradient does part of the minority's work, and the penalty is smaller. Tran, Dinh & Fioretto (2021) derive a related per-step decomposition for DP-SGD without assuming disjoint weights: the expected change in a group's loss has a clipping term, driven by the group's gradient norms, and a noise term proportional to $\eta^2\sigma^2C^2$ times the trace of the group's loss Hessian, which they relate to the group's distance to the

decision boundary and its input norms. Section M.5 in the appendices derives this decomposition, which is exact for quadratic losses, and shows that it contains Equation 45.8. The quadratic model makes the role of the share explicit, which their per-step terms leave implicit.

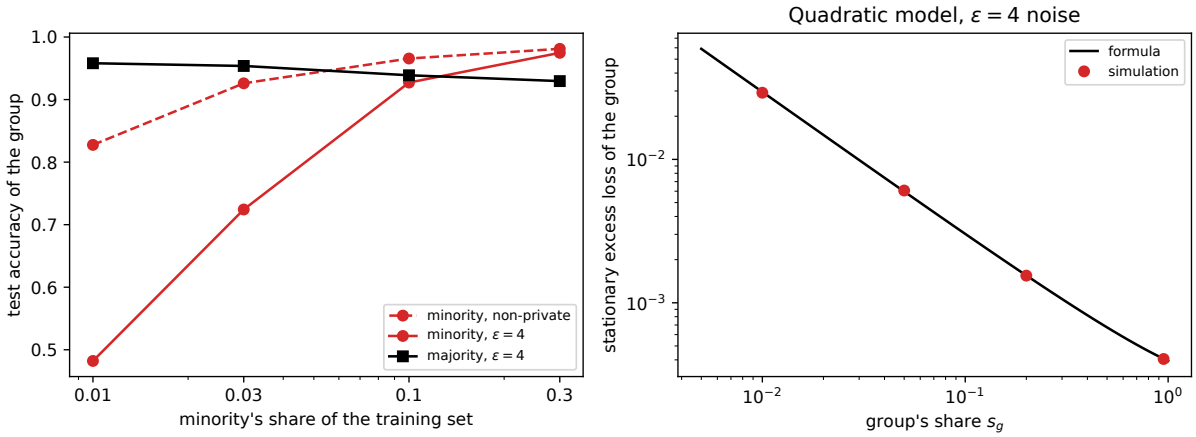

Figure 45.4.: Left: each group's test accuracy of the running example against the minority's share of the 10,000 training records (one run per point), non-private and at $\varepsilon = 4$. Right: the stationary excess loss of a group in the quadratic model, Equation 45.8, against its share, with the noise of $\varepsilon = 4$, compared with simulation.

45.5.5. Example: the model, then the running example

At $\varepsilon = 4$ the noise on the averaged gradient has $\tau = 0.0068$ per coordinate. Take $d_g = 51$ weights per group, $\lambda = 1$ and $\eta = 0.5$. Table 45.4 compares Equation 45.8 with a simulation of 40,000 noisy steps, averaged over the second half.

Table 45.4.: The noise floor of a group in the quadratic model with $\varepsilon = 4$ noise ($\tau = 0.0068$, $d_g = 51$, $\lambda = 1$, $\eta = 0.5$).

Share s_g	Excess loss, Equation 45.8	Simulated	Steps to settle, $1/(\eta s_g)$
0.95	4.07×10^{-4}	4.07×10^{-4}	2
0.2	1.55×10^{-3}	1.55×10^{-3}	10
0.05	5.97×10^{-3}	5.99×10^{-3}	40
0.01	2.96×10^{-2}	2.97×10^{-2}	200

The formula and the simulation agree to within 1%, and the floor grows from 4.07×10^{-4} for a group with 95% of the data to 2.96×10^{-2} for a group with 1%, a factor of 73. The approximate form of Equation 45.8 would say 95, the ratio of the shares; the exact form is lower because the factor $2 - \eta s_g \lambda$ is 1.525 for the large group rather than 2. The break-even law is harsher. In DP-SGD the averaged clipped gradient of the running example has length about 0.026 during training, and at $\varepsilon = 4$ the noise has length $\tau\sqrt{3{,}329} = 0.392$. A signal shared by the whole population emerges after $(0.392/0.026)^2 = 228$ steps. A signal that is 20% of it needs 5,693 steps,

5% needs 91,085, nine times the entire run, and 1% needs 2,277,115. A group whose rule the rest of the data does not teach is in this position.

In the network, Table 45.5 varies the minority's share with everything else fixed.

Table 45.5.: Each group's test accuracy for three sizes of the minority, non-private and at $\varepsilon = 4$ (mean ± standard deviation over 2 runs; the 5% row is from Table 45.2, over 3 runs).

Minority share	Records	Non-private: majority	minority	$\varepsilon = 4$: majority	minority	Privacy cost: majority	minority
1%	100	0.9556 ± 0.0015	0.8498 ± 0.0021	0.9558 ± 0.0036	0.5009 ± 0.0102	−0.0002	0.3488
5%	500	0.9529 ± 0.0018	0.9411 ± 0.0052	0.9470 ± 0.0037	0.8477 ± 0.0211	0.0059	0.0934
20%	2,000	0.9395 ± 0.0016	0.9787 ± 0.0004	0.9355 ± 0.0019	0.9507 ± 0.0038	0.0041	0.0280

The minority's privacy cost falls steeply with its share: 34.88 points at 1%, 9.34 at 5%, 2.80 at 20%. Multiplying the share by 5, from 1% to 5%, divides the cost by $0.3488/0.0934 = 3.7$, and multiplying it by 4, from 5% to 20%, divides it by $0.0934/0.0280 = 3.3$: a little less than the ratio of the shares, which is what Equation 45.8 predicts for the loss. Accuracy is not loss, and it saturates: at 1% the private model is at chance on the minority, 0.5009, and cannot lose more. The majority's cost stays below one point throughout. With 20% of the data, the minority is no longer a minority in any sense that matters to the noise, and its privacy cost is within three points of the majority's (Figure 45.4, left).

45.5.6. Check yourself

- The noise multiplier is doubled. By how much does the noise floor of Equation 45.8 grow, and does it grow more for the small group? *(By a factor of 4, since it is proportional to τ^2, for every group alike. The gap between groups grows by the same factor in absolute terms; the ratio between them, s_{major}/s_{minor}, is unchanged.)*
- Why does the curvature λ drop out of the approximate noise floor? *(The pull toward the optimum and the cost of a displacement are both proportional to λ; the stationary variance falls like $1/\lambda$ and the loss per unit of variance rises like λ.)*

45.6. Measuring per-group accuracy

45.6.1. Context

Every number so far was measured on 20,000 test records per group. Real evaluations are not so generous: a test split of 2,000 records with a 5% minority holds 100 minority records. How precisely can a group's accuracy, and the gap between two groups, be measured, and how much does a single training run say?

45.6.2. Statement

The test-set error of a group's accuracy is binomial (Fact 4): with k correct of m records, report the Clopper–Pearson interval. For the gap between two groups measured on disjoint test records, the two estimates are independent and their variances add, so an approximate 95% interval is

$$(\hat{p}_a - \hat{p}_b) \pm 1.96\sqrt{\frac{\hat{p}_a(1-\hat{p}_a)}{m_a} + \frac{\hat{p}_b(1-\hat{p}_b)}{m_b}}, \tag{45.9}$$

with $\hat{p}_g$ the measured accuracies and m_g the numbers of test records. Training randomness is a second, separate source of variation: a group's accuracy varies from run to run, more for small groups, and is estimated only by training several times.

45.6.3. Derivation

1. **One group.** Each test record is classified correctly or not, independently given the model, with probability equal to the group's true accuracy p_g. The count is binomial, and Clopper–Pearson inverts it exactly (Hypothesis testing).
2. **The gap.** The two counts come from disjoint test records, so they are independent given the model. The variance of a difference of independent estimates is the sum of their variances, $p_a(1-p_a)/m_a + p_b(1-p_b)/m_b$. For large counts the difference is approximately normal by the central limit theorem, and 1.96 standard deviations on each side cover 95%.
3. **Two sources.** Conditional on the trained model, the spread comes from the test set alone. Over training runs, the model itself varies; by the law of total variance the spread of a single run's measured accuracy is the test-set variance plus the run-to-run variance of the true accuracy. Only repeated training estimates the second.

45.6.4. Interpretation

Small groups need intervals. The width of the Clopper–Pearson interval falls like $1/\sqrt{m}$ (Figure 45.5). A 5-point gap between groups can be seen only with a few hundred minority test records, and a 1-point gap only with thousands (Exercise 4 in the exercise book). Report the interval, not only the point estimate, for every group.

Report the spread over runs. In Table 45.2 the run-to-run standard deviation at $\varepsilon = 4$ is 0.0211 for the minority against 0.0037 for the majority, almost six times as large. A comparison of two training recipes on one run each can easily be reversed for the small group. This is the same lesson as for the overall accuracy of private models (DP-SGD), sharper for small groups.

The evaluation leaks too. Per-group accuracies computed on private test data are statistics of that data. If they are published, they need their own privacy analysis, which Choosing ε and the selection mechanisms of Hyperparameter tuning address.

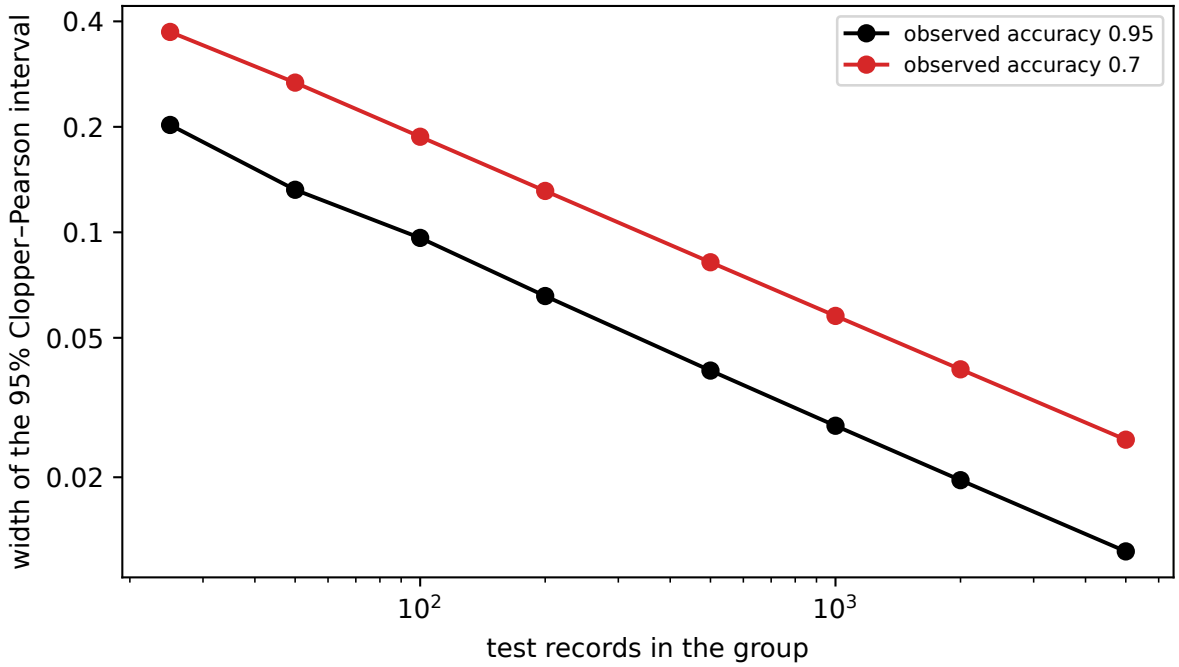

Figure 45.5.: Width of the 95% Clopper–Pearson interval for a group's accuracy against the number of test records in the group, for observed accuracies 0.95 and 0.7, on log scales. The width falls like one over the square root of the number of records.

45.6.5. Example: one model, three test sets

Train the running example at $\varepsilon = 4$ once. On all 20,000 minority test records its accuracy is 0.8641. Table 45.6 measures it on random subsets.

Table 45.6.: Minority accuracy of one model trained at $\varepsilon = 4$, measured on random subsets of the minority's test records, with the majority on 1,900 records for comparison.

Test records	Correct	Estimate	95% Clopper–Pearson interval
100 minority	88	0.880	$[0.800, 0.936]$
500 minority	424	0.848	$[0.813, 0.878]$
2,000 minority	1,742	0.871	$[0.856, 0.885]$
1,900 majority	1,812	0.954	$[0.943, 0.963]$

With 100 minority records, the split a 2,000-record test set with a 5% minority would give, the estimate is 0.880, 1.6 points above the true 0.8641, and the interval is 13.6 points wide. The true accuracy is inside it, as it should be 95% of the time, and the non-private model's 0.9411 from Table 45.2 lies only just above its upper end, 0.936: on this test set alone the minority's privacy cost could be anywhere from about half a point to fourteen points. With 500 records the interval is 6.5 points wide and still contains the true value. The majority's interval, from 1,900 records at a higher accuracy, is 2 points wide. By Equation 45.9 the gap between the groups, measured on the 1,900 and the 100 records, is $0.954 - 0.880 = 0.074$ with

a standard error of $\sqrt{0.954 \times 0.046/1{,}900 + 0.88 \times 0.12/100} = 0.0329$, so its 95% interval is $0.074 \pm 1.96 \times 0.0329 = 0.074 \pm 0.064$, from 0.010 to 0.138: the gap is real, but it could be anywhere from one point to fourteen. And this is one training run: by Table 45.2 the minority's accuracy at $\varepsilon = 4$ varies by 0.0211 from run to run on top of this.

45.6.6. Check yourself

- A report gives a private model's accuracy as 0.84 on a subgroup of 60 test records and 0.85 non-private on the same records. What can you conclude? *(Almost nothing about this subgroup. Each accuracy's 95% interval is about* $2 \times 1.96\sqrt{0.84 \times 0.16/60} = 0.19$ *wide, nineteen times the one-point difference. Because both models were tested on the same records, the difference could be measured more precisely from the records on which they disagree, but the report does not say how many there are.)*
- Why doesn't a larger test set fix the run-to-run variation? *(It removes the test-set error for the model at hand, but a different training run produces a different model. Only repeated training estimates how much a group's accuracy varies with the training noise.)*

45.7. Mitigations and what they cost

45.7.1. Context

Both mechanisms come from DP-SGD's two knobs. Can you choose the knobs, or change the algorithm, so that small groups pay less, without spending more privacy? Each fix in this section moves cost around rather than removing it, and it is worth knowing where to.

45.7.2. Statement

Global scaling is a large clipping norm. Scaling every per-example gradient by $C/C_{\max}$, where $C_{\max}$ is a bound that no gradient's norm exceeds, and adding noise σC, is the same algorithm as DP-SGD with the clipping norm set to $C_{\max}$, the same noise multiplier and learning rate $\eta C/C_{\max}$:

$$\frac{\eta}{B}\Big(\frac{C}{C_{\max}}\sum_{i\in S_t} g_i + \sigma C\xi\Big) = \frac{\eta C/C_{\max}}{B}\Big(\sum_{i\in S_t} g_i + \sigma C_{\max}\xi\Big). \tag{45.10}$$

Oversampling a group costs that group's privacy. If group g's records are sampled at rate vq instead of q, its pull on the update grows by the factor v, and each of its records has the privacy of the subsampled Gaussian at rate vq:

$$\varepsilon_g = \varepsilon_{\text{acct}}(vq, \sigma, T, \delta) \;>\; \varepsilon_{\text{acct}}(q, \sigma, T, \delta), \tag{45.11}$$

where $\varepsilon_{\text{acct}}$ is the accountant of DP-SGD. The algorithm's guarantee is the largest over records, so a fixed target ε requires the noise multiplier for rate vq.

45.7.3. Derivation

1. **Global scaling.** Factor $C/C_{\max}$ out of the left-hand side: $\frac{C}{C_{\max}}\sum_i g_i + \sigma C\xi = \frac{C}{C_{\max}}(\sum_i g_i + \sigma C_{\max}\xi)$. With the clipping norm set to $C_{\max}$ and no gradient longer than $C_{\max}$, DP-SGD's clipped sum is $\sum_i g_i$ and its noise $\sigma C_{\max}\xi$, which is the right-hand side. Both have sensitivity-to-noise ratio $1/\sigma$, so the same accountant applies (Exercise 6 in the exercise book).
2. **Oversampling: the pull.** The expected clipped sum is $\sum_i q_i \min(1, C/\|g_i\|)g_i$, with q_i record i's sampling rate. With $q_i = vq$ for group g and division by the public $B = qn$, group g's term becomes $vs_g m_g$.
3. **Oversampling: the privacy.** The add/remove analysis of record x in DP-SGD compares the output with and without x; the mixture depends only on x's own inclusion probability, because the other records' terms are the same in both. A record sampled at rate vq therefore has the privacy of the subsampled Gaussian at rate vq. The sampling rate may depend on the record's own group, which is part of the record, but the rule must be fixed in advance, not chosen by looking at the data.
4. **The guarantee.** (ε, δ)-DP must hold for every record, so it is the largest of the per-record values, which is Equation 45.11's.

45.7.4. Interpretation

Global scaling trades direction for noise. By Equation 45.10, scaling all gradients by the same factor is the large-C end of the clipping-norm curve of DP-SGD with ηC fixed: nothing is clipped, so the update points in the true direction (the blue arrow of Figure 45.2), but the noise $\sigma C_{\max}$ is as large as possible relative to the gradients. Esipova et al. (2023) propose a version that clips the rare gradients above $C_{\max}$ instead of discarding them and adapts $C_{\max}$ during training from a privately estimated count of how many gradients exceed it; they report that it reduces the privacy cost gap and improves accuracy compared with DP-SGD and with earlier mitigations on MNIST, CelebA and two tabular datasets. Because it treats every record alike, it needs no group labels.

Group-aware methods need group labels. Xu, Du & Wu (2021) adjust each group's contribution according to how much that group is being clipped, giving groups that are clipped more a larger clipping norm, so that the groups' clipping biases are equalized. Tran, Dinh & Fioretto (2021) add to the training objective penalties on the differences between groups in the quantities their decomposition identifies. Both need each training record's group, which is itself sensitive and may not be available or lawful to collect, and the per-group statistics they use must be computed privately.

Oversampling buys little at a fixed budget. Fixed at $\varepsilon = 4$ for every record, sampling the minority four times as often requires $\sigma = 4.71$ instead of 1.36: the minority's pull grows by 4 and the noise by $4.71/1.36 = 3.46$. Its signal-to-noise ratio improves by only $4/3.46 = 1.16$, while the majority's falls by 3.46, and the majority's records are then far more private than the target, $\varepsilon = 0.86$, which is wasted budget (Exercise 5 in the exercise book). Oversampling without changing σ would silently give the minority $\varepsilon = 20.96$: the group that is already disadvantaged in accuracy would also get the weakest privacy.

Some of the cost is unavoidable. Learning a group's own rule privately is, in part, a private estimation problem on that group's n_g records, and private estimation has a price that no algorithm avoids. Lower bounds proves it for the simplest case: releasing d attribute means with constant accuracy under (ε, δ)-DP needs at least about $\sqrt{d}/(e^{\varepsilon}-1)$ records, by the fingerprinting argument, whatever the mechanism. Put differently, the error that n_g records allow shrinks only like $1/(n_g\varepsilon)$, and the Gaussian mechanism, with error about $\sqrt{d\ln(1/\delta)}/(n_g\varepsilon)$, is close to the best possible. A smaller group is a smaller dataset, and no clever clipping makes it larger. Feldman (2020) argues the deeper point for any learner: when the data have a long tail of small subpopulations, fitting them well requires memorizing their few examples, which is exactly what DP forbids. What helps is more data from the group, a larger ε (with its own costs), or a starting point that already serves the group, such as a public pretrained model (Public data and private fine-tuning).

45.7.5. Example: the clipping norm and oversampling on the running example

Table 45.7 compares three changes at $\varepsilon = 4$ for every record.

Table 45.7.: Mitigations at $\varepsilon = 4$ on the running example with a 5% minority (mean ± standard deviation). The first row is from Table 45.2 (3 runs); the clipping norm rows keep $\eta C = 0.25$, 2 runs each; the oversampling row samples minority records at rate $4q$ and sets σ so that they meet $\varepsilon = 4$, 3 runs.

Change	σ	Majority accuracy	Minority accuracy	Gap
None: $C = 0.5$, $\eta = 0.5$	1.36	0.9470 ± 0.0037	0.8477 ± 0.0211	0.0993
Smaller clipping norm: $C = 0.05$, $\eta = 5$	1.36	0.9541 ± 0.0008	0.8313 ± 0.0157	0.1229
Larger clipping norm: $C = 5$, $\eta = 0.05$	1.36	0.9463 ± 0.0027	0.8133 ± 0.0166	0.1330
Oversample the minority four times	4.71	0.8669 ± 0.0079	0.8270 ± 0.0111	0.0399

None of the three changes helps the minority. A ten times smaller clipping norm clips the minority more, and its accuracy falls by 1.64 points while the majority's rises by 0.71: the clipping mechanism of Section 45.4 at work. A ten times larger one clips almost nothing, so the update's direction is right, but with ηC fixed the noise in each step, $\eta\sigma C/B$, is unchanged while the step along every gradient shorter than 0.5 is ten times smaller: the noise is ten times larger relative to that part of the signal, and the minority falls by 3.44 points: the noise mechanism of Section 45.5 at work. The running example's $C = 0.5$ sits between the two failures. These differences are of the size of the run-to-run spread, 0.0157 to 0.0211, so only their direction is clear, not their size.

Oversampling narrows the gap from 9.93 to 3.99 points, but by **levelling down**: the minority's accuracy is 2.07 points lower than without it, and the majority's 8.01 points lower. A smaller gap is not by itself a fairer model. Report both groups' accuracy and privacy cost, never the gap alone.

45.7.6. Check yourself

- Why does oversampling a group require more noise, while upweighting its loss does not? *(Upweighting leaves every record's contribution bounded by C and its sampling rate at q, so the accountant is unchanged, but clipping undoes it. Oversampling raises the group's sampling rate, which the subsampled Gaussian's privacy depends on.)*
- A team proposes to fix disparate impact by setting C to the largest per-example gradient norm observed in the training data. What is wrong? *(The clipping norm then depends on the data, and the sensitivity argument of DP-SGD assumes it is fixed in advance. A data-dependent C must itself be chosen privately, as in Esipova et al.'s adaptive threshold, and the estimate charged to the budget.)*

45.8. Code: check every number by computation

The script code/disparate_impact.py builds the running example with a minority group, trains it with the model, clipping and accountant of DP-SGD through a training loop that samples each group at its own rate and logs per-group gradient statistics, and computes the two-dimensional example, the quadratic model and the Clopper–Pearson intervals. From the repository root:

```
uv run python code/part05-dp-ml/disparate_impact.py
```

Output (seed 0), summarized in Table 45.8:

Table 45.8.: The script's output with the default seed.

Experiment	Result
Per-group accuracy, 5% minority	Privacy cost at $\varepsilon = 4$: 0.0059 majority, 0.0934 minority; clipping alone: -0.0051 and 0.0404
Two-dimensional clipping example	Minority's fraction of the update 0.513 $\rightarrow$ 0.116; the update turns by 39.0 degrees
Clipping weights during training	Minority's effective share 0.0495 at the start, 0.0251 at step 2,500, 0.0387 at the end
Quadratic noise floor	Formula and simulation agree; 4.07×10^{-4} at share 0.95, 2.96×10^{-2} at 0.01
Group size at $\varepsilon = 4$	Minority privacy cost 0.3488 at 1%, 0.0934 at 5%, 0.0280 at 20%
Clopper–Pearson on 100 minority records	88 correct, $[0.800, 0.936]$, against a true accuracy of 0.8641

Experiment	Result
Mitigations at $\varepsilon = 4$	No change of C helps the minority; oversampling four times needs $\sigma = 4.71$ and levels both groups down

tests/test_disparate_impact.py checks that the output still matches.

What to take from it. The disparate impact of DP-SGD needs no special data to appear: a 5% group that lives in another region of input space and follows its own rule is enough. Its two causes can be separated by switching the noise off, and each follows the arithmetic of this chapter: clipping lowers the group's effective share while the majority is learned, and the noise penalizes a small share roughly in proportion to one over the share. Neither knob of DP-SGD removes the effect at a fixed budget; it only moves it between the groups and between the two mechanisms.

45.10. Cheat sheet

Group g has share s_g, average gradient $\bar{g}_g$ and clipping weight w_g, the mean of $\min(1, C/\|g_i\|)$ over its records; $\tau = \sigma C/B$. Table 45.9 collects the results.

Table 45.9.: Every result of the chapter.

Result	Formula	Conditions
Privacy cost of a group	$\pi_g = \mathrm{acc}_g(\text{non-private}) - \mathbb{E}[\mathrm{acc}_g(\text{private})]$	Same data and recipe
A group's pull	$s_g m_g$, of length at most $s_g C$	Any gradients
Effective share	$\tilde{s}_g = s_g c_g / \sum_h s_h c_h$, with $c_g = w_g$ for equal norms	Parallel gradients within each group
Break-even steps	$(\ell_{\text{noise}}/\ell_{\text{sig}})^2 / s_g^2$	Group's signal a fraction s_g of the population's
Noise floor	$\mathbb{E}[L_g] = d_g \eta \tau^2 / (2 s_g (2 - \eta s_g \lambda)) \approx d_g \eta \tau^2 / (4 s_g)$	Quadratic loss on the group's own d_g weights
Accuracy gap interval	$\hat{p}_a - \hat{p}_b \pm 1.96 \sqrt{\sum_g \hat{p}_g (1 - \hat{p}_g) / m_g}$	Disjoint test records, large counts
Global scaling	Same as DP-SGD with the clipping norm set to $C_{\max}$ and learning rate $\eta C / C_{\max}$	No gradient above $C_{\max}$
Oversampling at vq	Those records' ε is the accountant's at rate vq	Rate fixed in advance per group

Rules of thumb

- Always report accuracy per group, with Clopper–Pearson intervals and the spread over several training runs, next to the non-private model's.
- Expect the privacy cost of a group to grow like one over its share of the data, and faster for groups with long gradients: large inputs or a rule the rest of the data does not teach.
- Clipping alone is disparate. A larger clipping norm (with ηC fixed) reduces the clipping part and raises the noise part.
- Do not upweight a group's loss to help it: clipping undoes it. Do not oversample a group without accounting at its higher sampling rate.
- When a group is too small to learn privately, get more data from it or start from a public model that already serves it.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

46. Choosing ε

46.1. Why this matters

Every model trained with differential privacy (DP) ships with a number, its budget ε. DP is the guarantee that one record changes the probability of any output by at most a factor e^{ε}, up to a slack δ. Chapter 39 trained the part's running example, a small neural network on 10,000 records, with stochastic gradient descent (SGD) made private by per-example clipping and Gaussian noise, DP-SGD, at five budgets, and measured what each costs in accuracy: test accuracy 0.9175 at $\varepsilon = 1$, 0.9441 at $\varepsilon = 2$, 0.9548 at $\varepsilon = 4$ and 0.9604 at $\varepsilon = 8$, against 0.9610 without privacy, all at $\delta = 10^{-5}$. That is half of a decision. The other half is what each budget means for the people in the data: what an attacker who sees the model can learn about one of them, and how sure it can be. Without that half, the choice of ε is made by habit ("everyone uses 8") or by the accuracy curve alone, and neither survives a reviewer, a regulator or a data subject who asks what the number promises.

This chapter supplies the privacy half. It reads the guarantee in three operational ways: as a bound on any membership test, as a bound on how far an attacker's belief can move, and as a bound on reconstructing a record. For each it compares two numbers: what the single pair (ε, δ) promises, and what the actual training algorithm, DP-SGD, really allows. It then turns to δ, to the budgets that real deployments have published and the units they are stated in, and to a procedure for choosing and defending a number.

46.1.1. The one idea: ε is one line under a curve

An attacker who wants to know whether a record was in the training set runs a test, and every test has two error rates. The definition of DP is equivalent to a straight-line bound on those rates: at false positive rate FPR, the true positive rate is at most $e^{\varepsilon}\mathrm{FPR} + \delta$. But a training algorithm has a whole **trade-off curve**, the best true positive rate at every false positive rate, and (ε, δ) is only one line that lies above it, touching it at one point. Far from that point, the line can be useless: at $\varepsilon = 8$ it allows a test that catches every member while almost never accusing a non-member, while the curve of DP-SGD at the same ε caps the true positive rate at 0.0589 when the false positive rate is 10^{-3}. Choosing ε well means computing and reporting the curve, not just the line, and reading it at the error rates that matter for your threat.

Table 46.1 lists the results and where each is used.

Table 46.1.: The results of this chapter and where each is used.

Result	Where it is used
What one (ε, δ) pair bounds: true positive rate at most e^{ε} times the false positive rate plus δ, and the advantage	Reading any published budget; the baseline every refinement improves on
The whole trade-off curve of DP-SGD: exactly from the privacy loss distribution, bounded by Rényi DP, approximated by Gaussian DP	Stating what a trained model allows at low false positive rates; Auditing
The Bayesian reading: posterior bounds, the realized privacy loss, the precision of a flagged member	Explaining a budget to someone who thinks in probabilities
Reconstruction: success is at most the membership true positive rate at a false positive rate equal to the baseline	Arguing that large budgets can still prevent reconstruction
What δ means and how small it must be	Choosing δ; reading guarantees with large δ
Deployed budgets and their privacy units	Comparing your budget with practice, honestly
A procedure for choosing and justifying ε	Writing the privacy statement of a model

Notation. A **membership test** sees the trained model (or the whole sequence of iterates) and says "member" or "non-member" about a target record z^*. Its **false positive rate (FPR)** is the probability that it says "member" when z^* was not in the training set, and its **true positive rate (TPR)** is the probability that it says "member" when z^* was. Q is the distribution of the output when z^* is in the data, P the distribution when it is not, and $L = \ln(Q(y)/P(y))$ is the **privacy loss** of an output y. $\delta(\varepsilon)$ is the smallest δ for which a mechanism is (ε, δ)-DP at a given ε, its **privacy profile**. For DP-SGD, q is the sampling rate, σ the noise multiplier and T the number of steps. The running example has $q = 0.01$, $T = 10{,}000$ and $n = 10{,}000$ records, and its noise multiplier is the one the Rényi differential privacy (RDP) accountant of DP-SGD requires for each target ε at $\delta = 10^{-5}$.

How to read this chapter. The toolkit and Section 46.3 restate what the definition of differential privacy proves, in the form this chapter needs. Section 46.4 is the core: the curve of DP-SGD against the line. Section 46.5 and Section 46.6 read the same curve as beliefs and as reconstruction. Section 46.7, Section 46.8 and Section 46.9 are about practice and can be read on their own.

46.2. Toolkit: four facts every derivation uses

46.2.1. Fact 1 — A membership attacker is a test, and DP bounds the probability of every event

Fix the training set without the target, D^-, and the target record z^*. The attacker sees an output y, drawn from $Q = M(D^- \cup \{z^*\})$ if z^* is a member and from $P = M(D^-)$ if not, and says "member" on some set S of outputs. Then $\text{FPR} = P(S)$ and $\text{TPR} = Q(S)$: both error rates are

probabilities of one event. A mechanism M is (ε, δ)-DP when, for every pair of neighbouring datasets and every event S, in both orders,

$$Q(S) \le e^{\varepsilon} P(S) + \delta. \tag{46.1}$$

So DP is a statement about tests before it is a statement about anything else. This chapter uses add/remove neighbours, as DP-SGD with Poisson sampling does (DP-SGD). An attacker that randomizes, saying "member" with probability $\phi(y)$, has $\mathrm{TPR} = \mathbb{E}_Q[\phi]$ and $\mathrm{FPR} = \mathbb{E}_P[\phi]$, and the same bound holds for it, because a randomized test is an average of events (The definition of differential privacy).

46.2.2. Fact 2 — The best test thresholds the privacy loss

Among all tests with a given FPR, the one with the largest TPR says "member" when the likelihood ratio $Q(y)/P(y)$ is large, that is, when the privacy loss $L(y)$ exceeds a threshold τ, randomizing at the threshold if needed. This is the Neyman–Pearson lemma (Hypothesis testing). The reason is an exchange argument: if a test said "member" on an output with a low ratio and "non-member" on one with a higher ratio, swapping the two (in equal amounts of P-probability) would keep its FPR and raise its TPR.

Two consequences follow. First, the best TPR at FPR FPR depends only on the distribution of L. Write ω for the distribution of L when $y \sim Q$, the **privacy loss distribution (PLD)**. Then the best test with threshold τ has

$$\mathrm{TPR}(\tau) = Q[L > \tau], \qquad \mathrm{FPR}(\tau) = P[L > \tau] = \mathbb{E}_Q\big[e^{-L};\ L > \tau\big], \tag{46.2}$$

where the second form is a **change of measure**: $P(y) = e^{-L(y)}Q(y)$ by the definition of L, so the P-probability of any event is the Q-average of e^{-L} over it. Second, the best achievable pairs $(\mathrm{FPR}, \mathrm{TPR})$ form a region whose upper boundary, the **trade-off curve** written here as $\mathrm{TPR}^*(\mathrm{FPR})$, is increasing and concave: increasing because a test with a higher FPR can always say "member" more often, concave because randomizing between two tests reaches every point of the segment between them.

46.2.3. Fact 3 — Beliefs multiply by the likelihood ratio

An attacker who believes beforehand that z^* is a member with probability p, the **prior**, and then sees y, believes afterwards

$$\frac{\Pr[\text{member} \mid y]}{\Pr[\text{non-member} \mid y]} = \frac{p}{1-p} \cdot \frac{Q(y)}{P(y)} = \frac{p}{1-p} e^{L(y)}. \tag{46.3}$$

This is Bayes' rule in odds form: the posterior odds are the prior odds times the likelihood ratio, and the likelihood ratio is e^L. Converting odds o back to a probability, $o/(1+o)$, gives the posterior $pe^L/(pe^L + 1 - p)$.

46.2.4. Fact 4 — DP-SGD's worst case is one pair of distributions, composed

Each step of DP-SGD adds Gaussian noise of standard deviation σC to a sum of per-example gradients clipped to length C, over a batch that contains each record independently with probability q. DP-SGD showed that, for the target record, the worst case over models, data and directions is a one-dimensional pair in units of C: without the record the step's output is $\mathcal{N}(0, \sigma^2)$, with it the output is the mixture $(1-q)\mathcal{N}(0,\sigma^2) + q\mathcal{N}(1,\sigma^2)$. The privacy loss of one step is $L_1(y) = \ln\left((1-q) + q\, e^{(2y-1)/(2\sigma^2)}\right)$, and T steps release T outputs whose losses add, so the PLD of the whole run is the distribution of a sum of T such losses. Three accountants summarize it (Choosing an accountant):

- the **RDP accountant** bounds the Rényi divergence of order α by $\varepsilon(\alpha) = T\varepsilon_{q,\sigma}(\alpha)$ and converts it to (ε, δ); it is a valid upper bound, and it is what DP-SGD used to set σ;
- the **numerical PLD accountant** discretizes the one-step loss on a grid of spacing h, rounding each loss up (pessimistic) or down (optimistic), and composes by fast Fourier transform (FFT) convolution; the truth lies between the two answers, which differ by at most a shift of Th in the total loss (Numerical accounting);
- the **Gaussian differential privacy (GDP)** central limit theorem (CLT) approximates the run by a single Gaussian pair $\mathcal{N}(0,1)$ against $\mathcal{N}(\mu,1)$ with $\mu = q\sqrt{T(e^{1/\sigma^2}-1)}$; it is an approximation, not a bound (f-DP and Gaussian DP).

Table 46.2 gives the noise multipliers of the running example and what the three accountants say about them.

Table 46.2.: The running example's noise multipliers at $q = 0.01$, $T = 10{,}000$, $\delta = 10^{-5}$, chosen by the RDP accountant, and the ε each accountant reports for them. The upper end of the PLD bracket is the larger pessimistic value over the two neighbouring directions, the lower end the optimistic value of the direction a membership test uses.

Target ε (RDP)	σ	RDP ε	PLD ε, bracket	Grid h	GDP μ	GDP ε
0.5	7.72	0.500	[0.445, 0.465]	2×10^{-6}	0.130	0.454
1	4.13	0.999	[0.903, 0.923]	2×10^{-6}	0.246	0.909
2	2.28	1.998	[1.825, 1.845]	2×10^{-6}	0.461	1.819
4	1.36	3.993	[3.629, 3.729]	10^{-5}	0.847	3.615
8	0.917	7.997	[7.317, 7.417]	10^{-5}	1.511	7.116
16	0.695	15.955	[14.582, 14.682]	10^{-5}	2.632	14.097

Against the upper end of the PLD bracket, the RDP accountant overstates the true ε by between 0.035 (at $\varepsilon = 0.5$) and 0.264 (at $\varepsilon = 4$), and by 0.58 at $\varepsilon = 8$, consistent with Part 4. Everything below uses these six values of σ, and calls each run by its target, "the $\varepsilon = 4$ run", even where the true ε is a little smaller.

46.3. What one (ε, δ) pair says about a membership test

46.3.1. Context

A model card says "trained with $(\varepsilon, \delta) = (8, 10^{-5})$". Taken alone, what does that number forbid an attacker to do? This is the question to answer first, because it is the only one you can answer for a model whose algorithm you have not seen.

46.3.2. Statement

If M is (ε, δ)-DP, every membership test, against every target, satisfies

$$\mathrm{TPR} \le \min\left\{1,\ e^{\varepsilon}\,\mathrm{FPR} + \delta,\ 1 - e^{-\varepsilon}(1 - \delta - \mathrm{FPR})\right\}, \tag{46.4}$$

and its **advantage**, $\mathrm{TPR} - \mathrm{FPR}$, the amount by which it beats guessing, satisfies

$$\mathrm{TPR} - \mathrm{FPR} \le \frac{e^{\varepsilon} - 1 + 2\delta}{e^{\varepsilon} + 1}. \tag{46.5}$$

46.3.3. Derivation

1. **The first line.** Apply the definition (Fact 1) with $D^- \cup \{z\}$ first and the event S on which the test says "member": $Q(S) \le e^{\varepsilon} P(S) + \delta$, that is $\mathrm{TPR} \le e^{\varepsilon}\mathrm{FPR} + \delta$.
2. **The second line.** Apply it in the other order to the complement S^c, where the test says "non-member": $P(S^c) \le e^{\varepsilon} Q(S^c) + \delta$, that is $1 - \mathrm{FPR} \le e^{\varepsilon}(1 - \mathrm{TPR}) + \delta$. Solving for TPR gives $\mathrm{TPR} \le 1 - e^{-\varepsilon}(1 - \delta - \mathrm{FPR})$. A probability is at most 1, which is the third term of Equation 46.4.
3. **The advantage.** $\mathrm{TPR} - \mathrm{FPR}$ is largest where the two lines of steps 1 and 2 cross, because below the crossing the first line rises faster than the diagonal (slope $e^{\varepsilon} \ge 1$) and above it the second line rises more slowly (slope $e^{-\varepsilon} \le 1$). Setting $e^{\varepsilon}\mathrm{FPR} + \delta = 1 - e^{-\varepsilon}(1 - \delta - \mathrm{FPR})$ and multiplying by e^{ε} gives $\mathrm{FPR}(e^{2\varepsilon} - 1) = e^{\varepsilon} - 1 + \delta - \delta e^{\varepsilon}$, so $\mathrm{FPR} = (1 - \delta)/(e^{\varepsilon} + 1)$. There the TPR is $e^{\varepsilon}(1 - \delta)/(e^{\varepsilon} + 1) + \delta$, and subtracting FPR gives Equation 46.5.

46.3.4. Interpretation

The bound has three regimes. At small FPR the line $e^{\varepsilon}\mathrm{FPR} + \delta$ binds, and the ratio TPR/FPR is at most e^{ε} plus δ/FPR. Below $\mathrm{FPR} \approx \delta e^{-\varepsilon}$ the δ term dominates, and the guarantee rests on δ alone. At large FPR the second line binds. And once $e^{\varepsilon}\mathrm{FPR} + \delta \ge 1$, which at $\varepsilon = 8$ happens from $\mathrm{FPR} = (1 - 10^{-5})e^{-8} = 3.35 \times 10^{-4}$ on, the bound allows a perfect true positive rate: the pair says nothing at all at the false positive rates where attacks are usually evaluated.

Low FPR is where it matters. Membership inference evaluates attacks by their TPR at an FPR of 10^{-3} or below, because an attack that flags members while almost never flagging non-members is one that confidently identifies people. At $\varepsilon = 1$ the pair caps that TPR at $e \times 10^{-3} + 10^{-5} = 0.002728$, a real constraint. At $\varepsilon = 4$ the cap is 0.05461, at $\varepsilon = 8$ it is 0.9997.

The advantage is an average, and DP's guarantee is not about averages. Equation 46.5 bounds the advantage at a single point of the curve, the one with equal error rates. It is 0.4621 at

$\varepsilon = 1$ and 0.9640 at $\varepsilon = 4$, numbers that make $\varepsilon = 4$ sound hopeless. They are tight only for the worst mechanism with this ε, randomized response, whose curve is exactly the two lines. DP-SGD is not that mechanism, as the next section shows.

46.3.5. Example: the pair at six budgets

Table 46.3 evaluates Equation 46.4 and Equation 46.5 for the six budgets of the running example. For $\varepsilon = 1$ and FPR $= 0.01$, the first line gives $e \times 0.01 + 10^{-5} = 0.02719$.

Table 46.3.: The largest TPR and advantage of any membership test that the pair $(\varepsilon, 10^{-5})$ allows, from Equation 46.4 and Equation 46.5.

ε	TPR at FPR 10^{-3}	TPR at FPR 10^{-2}	TPR at FPR 10^{-1}	Advantage
0.5	0.001659	0.0165	0.1649	0.2449
1	0.002728	0.02719	0.2718	0.4621
2	0.007399	0.0739	0.7389	0.7616
4	0.05461	0.546	0.9835	0.9640
8	0.9997	0.9997	0.9997	0.9993
16	1	1	1	1.0000

Read this way, the pair says that $\varepsilon \leq 2$ is a strong guarantee everywhere, that $\varepsilon = 4$ is meaningful only at very low FPR, and that $\varepsilon \geq 8$ is no guarantee at all against membership inference. The rest of the chapter shows that, for DP-SGD, the second and third conclusions are far too pessimistic.

46.3.6. Check yourself

- An audit reports TPR 0.02 at FPR 0.001 against a model claimed to be $(4, 10^{-5})$-DP. Does it refute the claim? *(No. The pair allows up to 0.05461 there. An audit refutes a claim only when the measured point lies above the line, and for $\varepsilon = 4$ that needs a TPR above about 5.5% at this FPR.)*
- Why can the advantage bound be close to 1 while the TPR at FPR 10^{-3} is tiny? *(They are different points of the curve. The advantage is read where the two error rates are equal, around FPR 0.27 for $\varepsilon = 1$; the low-FPR point is governed by the line $e^{\varepsilon}\text{FPR} + \delta$, which is small there.)*

46.4. The whole curve of DP-SGD

46.4.1. Context

The pair (ε, δ) is one number out of a whole profile: the accountant could equally have reported ε at $\delta = 10^{-6}$ or 10^{-3}, and each of those pairs is another line that every test must satisfy. The best TPR an attacker can reach against DP-SGD is the curve that all those lines enclose, and for DP-SGD it can be computed. How far below the single line does it lie, and how well do cheaper accountants approximate it?

46.4.2. Statement

For a mechanism with PLD ω (the law of L under Q), the best TPR at FPR FPR is reached by thresholding the total loss (Fact 2), and equals the lower envelope of all the lines of its profile:

$$\mathrm{TPR}^*(\mathrm{FPR}) = \inf_{\varepsilon\in\mathbb{R}} \big(e^{\varepsilon}\mathrm{FPR} + \delta(\varepsilon)\big), \qquad \delta(\varepsilon) = Q[L > \varepsilon] - e^{\varepsilon} P[L > \varepsilon]. \tag{46.6}$$

For DP-SGD the curve is traced exactly by

$$(\mathrm{FPR}(\tau), \mathrm{TPR}(\tau)) = (\mathbb{E}_{\omega}[e^{-L};\ L > \tau],\ \omega(L > \tau)), \qquad \tau \in \mathbb{R}, \tag{46.7}$$

where ω is the T-fold convolution of the one-step PLD of Fact 4. Two cheaper curves bracket or approximate it. From the RDP curve $\varepsilon(\alpha)$ of the whole run, every test satisfies

$$\mathrm{TPR} \le \min_{\alpha>1} \big(\mathrm{FPR}\cdot e^{\varepsilon(\alpha)}\big)^{(\alpha-1)/\alpha}, \tag{46.8}$$

a valid bound. The GDP central limit theorem approximates the curve by that of $\mathcal{N}(0,1)$ against $\mathcal{N}(\mu,1)$,

$$\mathrm{TPR}^*(\mathrm{FPR}) \approx 1 - \Phi(\Phi^{-1}(1-\mathrm{FPR}) - \mu), \qquad \mu = q\sqrt{T(e^{1/\sigma^2}-1)}, \tag{46.9}$$

with Φ the standard normal distribution function; this is not a bound.

46.4.3. Derivation

1. **Every line is valid.** For each ε, the mechanism is $(\varepsilon, \delta(\varepsilon))$-DP in this direction by the definition of the profile, so by Equation 46.4 every test has $\mathrm{TPR} \le e^{\varepsilon}\mathrm{FPR} + \delta(\varepsilon)$. Taking the smallest right-hand side over ε gives "$\le$" in Equation 46.6.
2. **The profile in terms of the loss.** For the event $\{L > \varepsilon\}$, $Q(L > \varepsilon) - e^{\varepsilon}P(L > \varepsilon) = \mathbb{E}_Q[(1 - e^{\varepsilon - L});\ L > \varepsilon]$ by the change of measure of Fact 2, and no other event does better, because adding an output with $L \le \varepsilon$ adds $Q(y) - e^{\varepsilon}P(y) = Q(y)(1 - e^{\varepsilon - L}) \le 0$ and removing one with $L > \varepsilon$ removes a positive amount. This is the formula for $\delta(\varepsilon)$.
3. **Each line touches the curve.** Take the Neyman–Pearson test with threshold τ and the line with $\varepsilon = \tau$. By step 2, $\delta(\tau) = \mathrm{TPR}(\tau) - e^{\tau}\mathrm{FPR}(\tau)$, so $\mathrm{TPR}(\tau) = e^{\tau}\mathrm{FPR}(\tau) + \delta(\tau)$: the test lies on the line. Since the tests with thresholds τ (and randomization between them) are the best ones by Fact 2, the infimum is attained and Equation 46.6 holds with equality.
4. **Composition adds losses.** The T steps of DP-SGD use independent noise, so the likelihood ratio of all T outputs is the product of the per-step ratios, and the total loss is the sum of the per-step losses. Even though each step's input depends on the earlier outputs, the worst-case pair of Fact 4 is the same at every step, so the per-step losses are independent and identically distributed under Q, and ω is the T-fold convolution of one step's PLD (Numerical accounting). Fact 2 then gives Equation 46.7.
5. **Computing it with a guarantee.** Round each one-step loss up to the grid $h\mathbb{Z}$ and compose: the total loss is rounded up by at most Th, and the resulting pair is less private than the true one, so its curve lies above the true curve. Rounding down gives a curve below it. The script uses $h = 2 \times 10^{-6}$ for the three smallest budgets and $h = 10^{-5}$ for the others, so that the total loss is pinned within 0.02 and 0.1.

6. **The RDP bound.** The Rényi divergence can only shrink when both distributions are passed through the same test (data processing, Rényi DP). After the test, the two distributions are coins with "member" probabilities TPR and FPR, so $e^{(\alpha-1)\varepsilon(\alpha)} \geq \mathrm{TPR}^{\alpha}\mathrm{FPR}^{1-\alpha} + (1-\mathrm{TPR})^{\alpha}(1-\mathrm{FPR})^{1-\alpha}$. Dropping the second, non-negative term and solving for TPR gives $\mathrm{TPR}^{\alpha} \leq e^{(\alpha-1)\varepsilon(\alpha)}\mathrm{FPR}^{\alpha-1}$, which is Equation 46.8 after taking the power $1/\alpha$; it holds at every order, so at the best one.
7. **The GDP approximation.** For $\mathcal{N}(0,1)$ against $\mathcal{N}(\mu,1)$ the best test thresholds the output at $\Phi^{-1}(1-\mathrm{FPR})$, and the shifted distribution exceeds that threshold with probability $1-\Phi(\Phi^{-1}(1-\mathrm{FPR})-\mu)$. The value of μ is the central-limit approximation of f-DP and Gaussian DP, which matches the mean and variance of the summed loss to leading order in q.

46.4.4. Interpretation

The pair overstates the attacker, and more so the larger ε. Table 46.5 puts the four curves side by side at FPR 10^{-3}. At $\varepsilon = 1$ the pair allows 0.002728 and the true curve is between 0.002209 and 0.00225, a factor of about 1.2. At $\varepsilon = 4$ the pair allows 0.05461 and the curve at most 0.01312, a factor of about 4. At $\varepsilon = 8$ the pair allows 0.9997 and the curve at most 0.0589, a factor of about 17. The reason is visible in Figure 46.1: the curve of DP-SGD is smooth and close to a Gaussian curve, and the line that the accountant reports at $\delta = 10^{-5}$ touches it only at a false positive rate of at most $e^{-\varepsilon}Q[L > \varepsilon]$, below 10^{-4} for every run here (Table 46.8). Everywhere else the line is a loose summary.

The RDP bound is the cheap middle ground. Equation 46.8 uses the same accountant that produced ε, costs nothing extra, and is a guarantee. At $\varepsilon = 8$ it caps the TPR at FPR 10^{-3} at 0.09016 instead of 0.9997. It is still looser than the exact curve, because one Rényi order summarizes the loss distribution by one moment, and because the conversion drops a term; the PLD keeps everything.

GDP is close, but not on the safe side. For budgets up to 8 the GDP curve lies inside the exact bracket at FPR 10^{-3}, and within 0.001 of it at the other operating points: 0.05719 at $\varepsilon = 8$ and FPR 10^{-3}, against the bracket [0.05555, 0.0589]. At $\varepsilon = 16$ it overshoots, 0.3234 against at most 0.2808, because $\mu = 2.632$ is far from the small-$q\sqrt{T}$ regime where the central limit theorem holds. Use it to explain, not to certify.

The curve is the worst case of a strong attacker. It is the best test of an attacker who knows every other record, the architecture, the initialization and every hyperparameter, sees every intermediate iterate, and targets a record whose clipped gradient is as large as clipping allows at every step on which it is sampled. Nasr et al. (2021) showed that an adversary who can choose the target's gradient and see every iterate does reach the accountant's guarantee, so the curve is attainable in that threat model. A typical record attacked through the final model alone is much safer. Table 46.4 measures it for one attack: the loss-threshold attack of Membership inference, which calls a training record a member when its loss is below a threshold, run on one model trained at each budget, with the 10,000 training records as members and the 20,000 test records as non-members.

Table 46.4.: A loss-threshold membership attack on the running example, one trained model per budget. Members are the 10,000 training records, non-members the 20,000 test records. The best advantage is the largest TPR − FPR over 999 thresholds.

ε	Test accuracy	TPR at FPR 10^{-3}	TPR at FPR 10^{-2}	TPR at FPR 10^{-1}	Best advantage
0.5	0.8186	0.0010	0.0102	0.0989	0.0155
1	0.9266	0.0013	0.0108	0.1019	0.0085
2	0.9502	0.0011	0.0096	0.0983	0.0059
4	0.9538	0.0008	0.0072	0.0963	0.0116
8	0.9584	0.0007	0.0098	0.1007	0.0162
16	0.9632	0.0013	0.0102	0.0992	0.0158
Non-private	0.9597	0.0004	0.0099	0.0956	0.0221

The attack is at chance at every budget, and nearly at chance against the non-private model too: the task is noiseless and the network generalizes, so an average record's loss says little about membership. That is a statement about this attack, these records and this task, not a guarantee; Auditing private training builds the attacks that come close to the curve, with canaries chosen to be as exposed as possible.

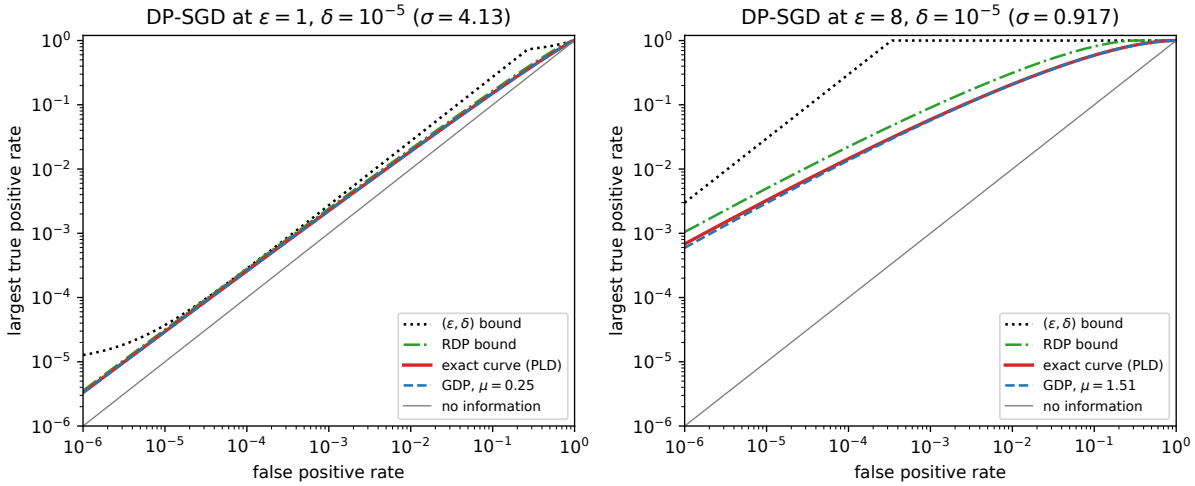

Figure 46.1.: The largest TPR of a membership test against DP-SGD on the running example, on log axes, at $\varepsilon = 1$ (left) and $\varepsilon = 8$ (right), $\delta = 10^{-5}$: the bound from the single pair (dotted), the bound from the whole RDP curve (dash-dotted), the exact curve from the pessimistic PLD (solid red), and the GDP approximation (dashed). The grey diagonal is an attacker with no information.

46.4.5. Example: the curve at six budgets

Table 46.5 gives the four answers at FPR 10^{-3} and Table 46.6 the exact bracket at higher FPR and for the advantage.

Table 46.5.: The largest TPR of a membership test against the running example's DP-SGD at FPR 10^{-3}, $\delta = 10^{-5}$: from the pair, from the RDP curve, exactly (optimistic and pessimistic PLD), and from the GDP approximation.

ε	σ	Pair, Equation 46.4	RDP, Equation 46.8	Exact (PLD bracket)	GDP, Equation 46.9
0.5	7.72	0.001659	0.00161	[0.001524, 0.001554]	0.001537
1	4.13	0.002728	0.002427	[0.002209, 0.00225]	0.002224
2	2.28	0.007399	0.005033	[0.004267, 0.004342]	0.004273
4	1.36	0.05461	0.01668	[0.01215, 0.01312]	0.01244
8	0.917	0.9997	0.09016	[0.05555, 0.0589]	0.05719
16	0.695	1	0.4971	[0.2714, 0.2808]	0.3234

Table 46.6.: The exact trade-off curve of the running example's DP-SGD at two more false positive rates, and its largest advantage, against the advantage the pair allows.

ε	Exact TPR at FPR 10^{-2}	Exact TPR at FPR 10^{-1}	Exact advantage	Pair advantage
0.5	[0.01391, 0.01418]	[0.1236, 0.126]	[0.0472, 0.0567]	0.2449
1	[0.01859, 0.01893]	[0.1489, 0.1515]	[0.0933, 0.1023]	0.4621
2	[0.03088, 0.03141]	[0.2043, 0.2076]	[0.1778, 0.1859]	0.7616
4	[0.06739, 0.0724]	[0.3211, 0.3416]	[0.3094, 0.3429]	0.9640
8	[0.1987, 0.2092]	[0.5682, 0.5901]	[0.5271, 0.5498]	0.9993
16	[0.5447, 0.5588]	[0.8637, 0.8752]	[0.7647, 0.7758]	1.0000

The advantage tells the same story as the low-FPR column. The pair allows 0.9640 at $\varepsilon = 4$; DP-SGD allows at most 0.3429. Figure 46.2 draws the six exact curves together. Each is nearly a straight line on log axes at low FPR, with a slope a little below 1, which means TPR/FPR, the factor by which the attacker's flag is more likely on a member, grows slowly as FPR falls: at $\varepsilon = 8$ it is about 21 at FPR 10^{-2} and about 59 at 10^{-3}, nowhere near $e^8 \approx 2{,}981$.

46.4.6. Check yourself

- Why does the line $e^{\varepsilon}\mathrm{FPR} + \delta$ at $\delta = 10^{-5}$ touch the curve only at a tiny FPR? *(By step 3 it touches the curve at the Neyman–Pearson test with threshold $\tau = \varepsilon$, whose FPR is*

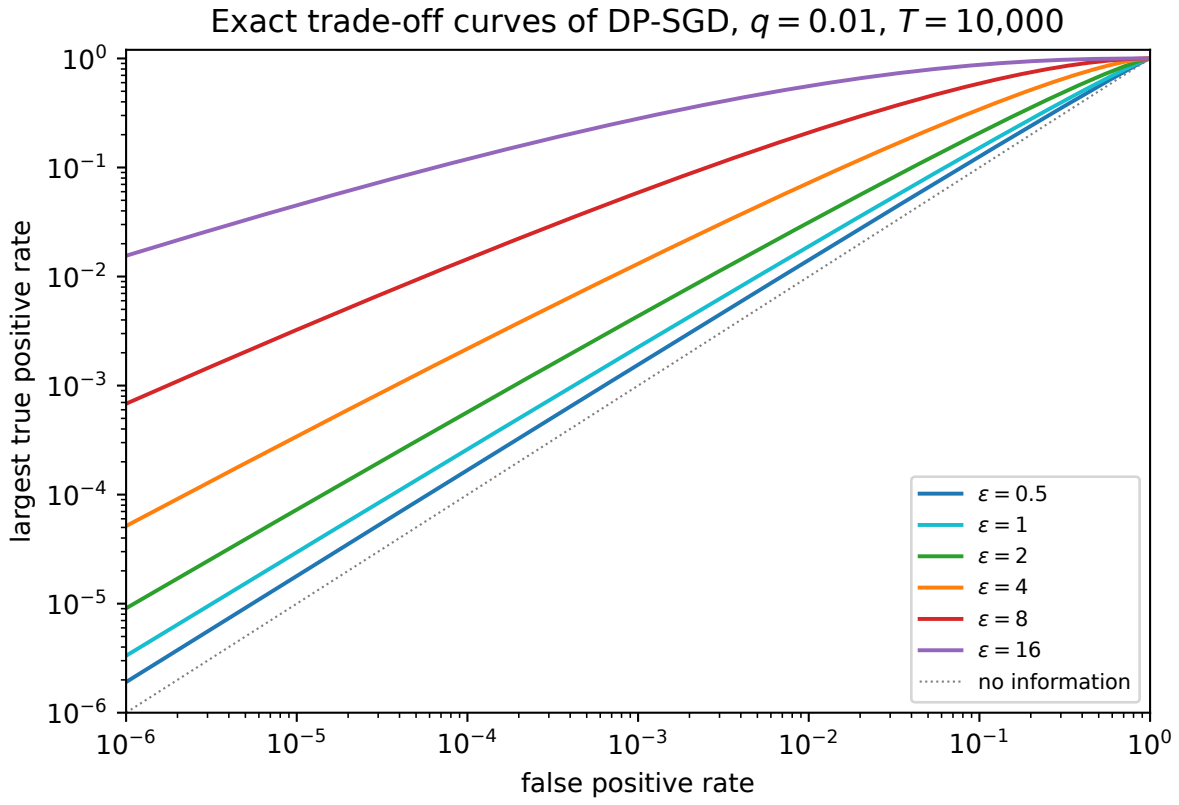

Figure 46.2.: The exact trade-off curves (pessimistic PLD) of DP-SGD on the running example at the six budgets, on log axes. The dotted diagonal is an attacker with no information.

$P[L > \varepsilon] \le e^{-\varepsilon} Q[L > \varepsilon]$, *because* $P = e^{-L}Q$ *and* $L > \varepsilon$ *on that event. The accountant chose* ε *so that the loss rarely exceeds it, so that FPR is tiny.)*

- A colleague proposes to report only the GDP μ of a run with $\mu = 2.6$. What do you tell them? *(That the GDP curve is an approximation that can be too optimistic, as at* $\varepsilon = 16$ *here, or too pessimistic. Report the PLD curve or the RDP bound as the guarantee, and* μ *as an explanation.)*

46.5. The Bayesian reading

46.5.1. Context

People who are not statisticians rarely think in error rates. They ask "if someone sees the model, how sure can they be that I was in the data?" That is a question about posterior probabilities. What do ε, and the actual curve of DP-SGD, say about it, and why does the answer depend so much on the prior?

46.5.2. Statement

If every output has privacy loss at most ε, then for every prior p the posterior probability of membership is at most

$$\Pr[\text{member} \mid y] \le \frac{p\, e^{\varepsilon}}{p\, e^{\varepsilon} + 1 - p}. \tag{46.10}$$

Under (ε, δ)-DP this holds at a level $\varepsilon' > \varepsilon$ except on outputs whose total probability is at most $\delta/(1 - e^{\varepsilon - \varepsilon'})$. For DP-SGD the posterior after the run is exactly $p\, e^{L}/(p\, e^{L} + 1 - p)$, with L drawn from the PLD ω. An attacker who acts only on a flag ("the test said member") is right with probability

$$\Pr[\text{member} \mid \text{flag}] = \frac{p\,\mathrm{TPR}}{p\,\mathrm{TPR} + (1-p)\,\mathrm{FPR}} \le \frac{p\,(e^{\varepsilon}\mathrm{FPR} + \delta)}{p\,(e^{\varepsilon}\mathrm{FPR} + \delta) + (1-p)\,\mathrm{FPR}}. \tag{46.11}$$

46.5.3. Derivation

1. **The posterior is a function of the loss.** By Fact 3, the posterior odds are $\frac{p}{1-p} e^{L(y)}$, and the posterior is $pe^{L}/(pe^{L} + 1 - p)$. This is increasing in L.
2. **Pure bound.** If $L \le \varepsilon$, substitute ε for L: Equation 46.10.
3. **Rare outputs.** Let S be the outputs with $L > \varepsilon'$. On S, $P(y) < e^{-\varepsilon'} Q(y)$, so $P(S) < e^{-\varepsilon'} Q(S)$. The definition gives $Q(S) \le e^{\varepsilon} P(S) + \delta < e^{\varepsilon - \varepsilon'} Q(S) + \delta$, so $Q(S)(1 - e^{\varepsilon - \varepsilon'}) < \delta$ (The definition of differential privacy).
4. **The precision of a flag.** Bayes' rule with the event "flag" in place of y: the flag has probability TPR for a member and FPR for a non-member, so the posterior odds are $\frac{p}{1-p} \cdot \frac{\mathrm{TPR}}{\mathrm{FPR}}$. Bounding TPR by Equation 46.4, which can only increase the odds, gives Equation 46.11. With $\delta = 0$ the bound equals Equation 46.10: a flag can never be more convincing than the most convincing single output.

46.5.4. Interpretation

DP bounds the change of belief, not the belief. Small priors stay small at small ε. Table 46.7 gives Equation 46.10 at three priors. At $\varepsilon = 1$ an attacker who thinks there is a 1% chance that you are in the data can reach at most 2.67%. At $\varepsilon = 4$ it can reach 35.55%, at $\varepsilon = 8$ 96.79%: read through the pure bound, $\varepsilon = 8$ permits near certainty.

Table 46.7.: The largest posterior probability of membership when the privacy loss is at most ε, Equation 46.10.

ε	Prior 0.01	Prior 0.1	Prior 0.5
0.5	0.0164	0.1548	0.6225
1	0.0267	0.2320	0.7311
2	0.0695	0.4509	0.8808
4	0.3555	0.8585	0.9820
8	0.9679	0.9970	0.9997
16	1.0000	1.0000	1.0000

The realized loss is usually much smaller than ε. The bound is attained only by outputs whose loss is ε. For DP-SGD, the loss is a random variable, and Table 46.8 reads its distribution off the pessimistic PLD for a member: the median, and the values exceeded with probability 10^{-3} and 10^{-5}. In the $\varepsilon = 8$ run, half of all members have total loss at most 1.136, and the posterior of an attacker with prior 1% moves to at most 0.0305 for them; only one member in a thousand has loss above 5.971 (posterior 0.7984), and one in a hundred thousand above 7.910 (posterior 0.9649). Figure 46.3 draws these curves against the prior.

Table 46.8.: The total privacy loss of a worst-case member in the running example's DP-SGD runs, from the pessimistic PLD (so slightly overstated), and the posterior it produces from a prior of 1%.

Run	Median loss	Loss exceeded w.p. 10^{-3}	Loss exceeded w.p. 10^{-5}	$Q[L > \varepsilon]$	Posterior from prior 0.01: median, 10^{-3}, 10^{-5}
$\varepsilon = 0.5$	0.018	0.421	0.575	1.10×10^{-4}	0.0102, 0.0152, 0.0176
$\varepsilon = 1$	0.040	0.802	1.093	5.04×10^{-5}	0.0104, 0.0220, 0.0293
$\varepsilon = 2$	0.115	1.549	2.099	2.52×10^{-5}	0.0112, 0.0454, 0.0762
$\varepsilon = 4$	0.401	3.059	4.092	1.59×10^{-5}	0.0149, 0.1771, 0.3768
$\varepsilon = 8$	1.136	5.971	7.910	7.86×10^{-6}	0.0305, 0.7984, 0.9649
$\varepsilon = 16$	3.032	11.661	15.314	3.78×10^{-6}	0.1732, 0.9991, 1.0000

This is the Bayesian face of the gap between the line and the curve. The pure bound treats every output as the worst one; the actual loss is concentrated far below ε, with a thin tail that reaches it. The column $Q[L > \varepsilon]$ shows how thin: the probability that the run's loss for the worst-case member exceeds the reported ε is of the order of δ, between 3.78×10^{-6} and 1.10×10^{-4}.

Base rates make flags unconvincing. In Equation 46.11 the attacker's precision depends on the prior through $p/(1-p)$, and at a small prior even a strong ratio TPR/FPR leaves most flags wrong. At $\varepsilon = 8$, prior 1% and FPR 10^{-2}, the pair allows a precision of 0.5024, while the exact curve allows 0.1744: five flags out of six are false. At $\varepsilon = 4$ and FPR 10^{-3}, the pair allows 0.3555 and the curve 0.1170. Who the attacker is matters: an insider who already knows that you are one of two candidates has prior 0.5; a stranger scanning a population has a prior near the fraction of the population in the dataset.

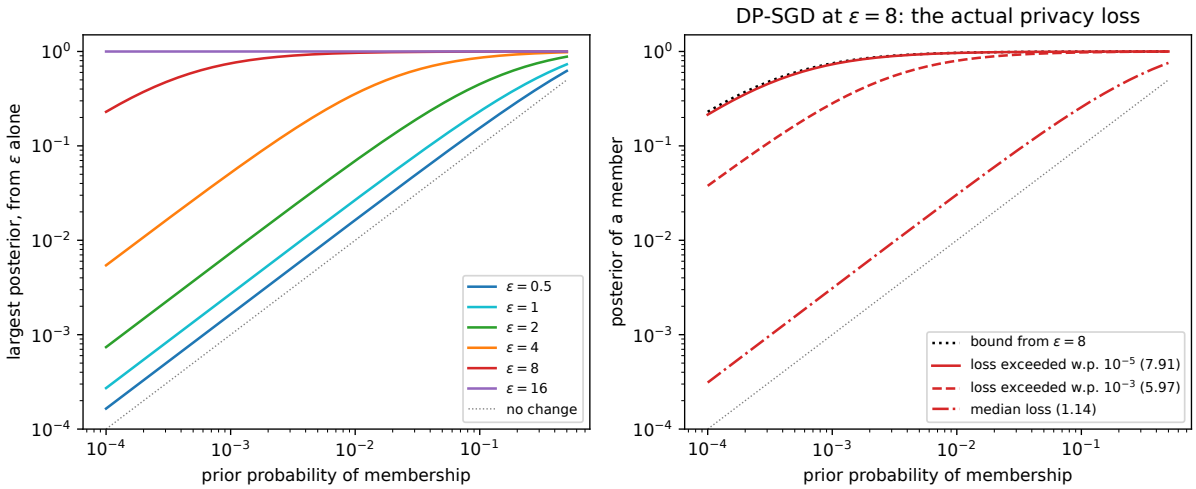

Figure 46.3.: Left: the largest posterior probability of membership against the prior, from Equation 46.10, for the six budgets (log axes). Right: for the $\varepsilon = 8$ run, the bound (dotted) and the posterior of a member whose total privacy loss is the median of the PLD, or is exceeded with probability 10^{-3} or 10^{-5}.

46.5.5. Example: an insider and a stranger

An insider knows that the training set is one of two: with you, or with your colleague in your place. Its prior is 0.5. Against the $\varepsilon = 2$ run, Table 46.7 caps its posterior at 0.8808 on the worst output. Against the same run, a stranger with prior 0.01 reaches at most 0.0695 on the worst output and, for a typical member, $0.01e^{0.115}/(0.01e^{0.115} + 0.99) = 0.0112$, the value in Table 46.8. The guarantee is the same; what it protects against depends on how much the attacker knew before.

46.5.6. Check yourself

- Can DP make an attacker less sure than its prior? *(Yes, for outputs with negative loss, which are typical for non-members. Equation 46.10 bounds the increase; the lower bound $pe^{-\varepsilon}/(pe^{-\varepsilon} + 1 - p)$ bounds the decrease.)*

- Why is $Q[L > \varepsilon]$ for the $\varepsilon = 8$ run below $\delta = 10^{-5}$, while for the $\varepsilon = 4$ run it is above? *(Because $\delta(\varepsilon) = \mathbb{E}_Q[(1 - e^{\varepsilon - L})_+]$ is at most $Q[L > \varepsilon]$, but not equal to it; and because the RDP accountant overstates ε, by more at $\varepsilon = 8$, so the true loss rarely reaches the reported value.)*

46.6. Reconstruction

46.6.1. Context

Membership is a demanding standard: the attacker is given the target record and only has to decide whether it was used. Many harms need more: recovering a record the attacker does not know, such as a patient's diagnosis or a person's face. Balle, Cherubin & Hayes (2022) formalize this as **reconstruction robustness**: an informed adversary knows every training record except the target Z, knows a prior π from which Z was drawn, sees the trained model, and outputs a guess; it succeeds if the guess is within a distance ξ of Z, its error radius. The baseline is the best success without seeing the model,

$$\kappa = \sup_{z_0} \Pr_{Z \sim \pi} \left[\mathrm{err}(Z, z_0) \le \xi \right], \tag{46.12}$$

for example $\kappa = 1/m$ when Z is uniform over m candidates and only an exact guess counts. How much can the model raise the success above κ?

46.6.2. Statement

If every neighbouring pair of M has trade-off curve at or below TPR^*, then every reconstruction attack succeeds with probability at most

$$\Pr[\text{success}] \le \mathrm{TPR}^*(\kappa). \tag{46.13}$$

With the pair (ε, δ) this is $e^\varepsilon \kappa + \delta$; with pure ε-DP, $e^\varepsilon \kappa$, and with one RDP order, $(\kappa e^{\varepsilon(\alpha)})^{(\alpha-1)/\alpha}$, which are Balle, Cherubin & Hayes's bounds; with the exact curve of DP-SGD it is the bound of Hayes, Mahloujifar & Balle (2023), who write it as a "blow-up function", the largest probability under Q of an event whose probability under P is at most κ, which is the trade-off curve under another name.

46.6.3. Derivation

1. **A reconstruction attack defines one test per candidate.** Fix D^- and the attack $\mathcal{A}$. For a candidate z, let S_z be the set of models θ for which $\mathcal{A}(\theta)$ is within ξ of z. The attack succeeds on z exactly when the model trained on $D^- \cup \{z\}$ falls in S_z.
2. **Each test is bounded by the curve.** "Say member when $\theta \in S_z$" is a membership test for z against the pair $Q_z = M(D^- \cup \{z\})$, $P = M(D^-)$. Its FPR is $\mathrm{FPR}_z = P(S_z)$, so its TPR satisfies $Q_z(S_z) \le \mathrm{TPR}^*(\mathrm{FPR}_z)$.
3. **Average over the prior.** The success probability is $\mathbb{E}_{Z \sim \pi}[Q_Z(S_Z)] \le \mathbb{E}_Z[\mathrm{TPR}^*(\mathrm{FPR}_Z)] \le \mathrm{TPR}^*(\mathbb{E}_Z[\mathrm{FPR}_Z])$, by Jensen's inequality, since the curve is concave (Fact 2).

4. **The average FPR is at most the baseline.** $\mathbb{E}_Z[\mathrm{FPR}_Z] = \Pr_{Z\sim\pi,\,\theta\sim M(D^-)}[\mathrm{err}(Z, \mathcal{A}(\theta)) \leq \xi]$. Here θ is trained without Z, so it is independent of Z, and for each fixed θ the guess $\mathcal{A}(\theta)$ is a fixed z_0, which succeeds with probability at most κ. So $\mathbb{E}_Z[\mathrm{FPR}_Z] \leq \kappa$, and since the curve is increasing, Equation 46.13 follows.
5. **The special cases.** Substitute the line of Equation 46.4, or the RDP bound Equation 46.8 at one order, for TPR^*.

The (ε, δ) form $e^\varepsilon\kappa + \delta$ is this chapter's corollary; Balle, Cherubin & Hayes state the pure-DP, RDP and zero-concentrated cases.

46.6.4. Interpretation

Reconstruction is membership at FPR κ. The derivation turns any reconstruction attack into a membership test whose false positive rate is the baseline. So the trade-off curve, read at FPR $1/m$, answers "can the attacker pick the right one of m candidates?". A large prior uncertainty is a small FPR, and that is where the curve of DP-SGD is far below the line.

Large budgets can still prevent reconstruction. Table 46.9 reads the curves of Figure 46.2 at $\kappa = 1/m$. At $\varepsilon = 8$ the pair gives no bound for any m up to 1,000, but the curve caps the success of choosing among 1,000 equally likely candidates at 0.0589, against 0.001 by guessing. Balle, Cherubin & Hayes observed the same in experiments: in their words, DP with large values of ε can protect against reconstruction attacks if the target is high-dimensional and the adversary's prior contains a large degree of uncertainty. Hayes, Mahloujifar & Balle found their bound close to their best attack in all their settings, and that different DP-SGD hyperparameters with the same ε can give quite different reconstruction success: the curve, not ε, is what matters.

Small priors are the honest assumption only if you can defend them. If the attacker can narrow the target to two candidates, $\kappa = 0.5$ and reconstruction is as easy as membership at FPR 0.5. A defensible reconstruction claim states the prior: "an attacker who knows the target is one of m records".

Guo, Karrer, Chaudhuri & van der Maaten (2022) bound reconstruction differently, for continuous targets: under RDP of order 2 at level ε, any unbiased reconstruction of a target that ranges over an interval of width w has expected squared error at least $w^2/(4(e^\varepsilon - 1))$, and Fisher information gives a tighter, data-dependent bound. The bound needs unbiasedness: for small ε a constant guess at the middle of the interval does better. Section N.4 in the appendices derives the bound and shows why it needs that condition.

46.6.5. Example: one of m candidates

Table 46.9.: The largest probability of reconstructing a record drawn uniformly from m candidates (baseline $1/m$), from the pair $e^\varepsilon\kappa + \delta$ and from the exact (pessimistic) curve of the running example's DP-SGD.

ε	$m = 10$: pair	$m = 10$: curve	$m = 100$: pair	$m = 100$: curve	$m = 1{,}000$: pair	$m = 1{,}000$: curve
0.5	0.1649	0.126	0.0165	0.01418	0.001659	0.001554

ε	$m = 10$: pair	$m = 10$: curve	$m = 100$: pair	$m = 100$: curve	$m = 1{,}000$: pair	$m = 1{,}000$: curve
1	0.2718	0.1515	0.02719	0.01893	0.002728	0.00225
2	0.7389	0.2076	0.0739	0.03141	0.007399	0.004342
4	1	0.3416	0.546	0.0724	0.05461	0.01312
8	1	0.5901	1	0.2092	1	0.0589
16	1	0.8752	1	0.5588	1	0.2808

Ten candidates is a strong prior: at $\varepsilon = 4$ the curve allows the attacker 0.3416 against a baseline of 0.1. At a thousand candidates even $\varepsilon = 16$ keeps the success at 0.2808.

46.6.6. Check yourself

- Why does the derivation need the curve to be concave? *(To move the average over candidates inside: the average of the per-candidate bounds is at most the bound at the average FPR. Without concavity, a few candidates with large FPR could do better than their average.)*
- An attacker knows a patient's record except one binary field. What is κ, and what does $\varepsilon = 4$ guarantee? *(If both values are equally likely a priori, $\kappa = 0.5$; the exact curve at FPR 0.5 is far above 0.5, so little. Attribute inference with a strong prior is membership inference in disguise.)*

46.7. Interpreting δ

46.7.1. Context

Every number so far was at $\delta = 10^{-5}$. What does δ mean, how small must it be, and what does a smaller one cost in ε for DP-SGD?

46.7.2. Statement

The mechanism that publishes each record in full, independently with probability δ, is $(0, \delta)$-DP and publishes at least one of n records with probability

$$1 - (1 - \delta)^n \approx 1 - e^{-n\delta}. \tag{46.14}$$

So $\delta = 1/n$ permits exposing a record with probability about 0.63, and a meaningful guarantee needs $n\delta \ll 1$. For a Gaussian-type mechanism such as DP-SGD, δ is not a probability of catastrophe: the privacy loss has a light tail, $\delta(\varepsilon) \leq Q[L > \varepsilon]$, and shrinking δ by orders of magnitude raises ε only moderately.

46.7.3. Derivation

1. **The release mechanism is $(0, \delta)$-DP.** Run it on $D^- \cup \{z^*\}$ by running it on D^- and tossing one more coin for z^*. The two outputs differ only when that coin publishes z^*, which has probability δ, so for every event S the two probabilities differ by at most δ in either direction (The definition of differential privacy).
2. **Exposure.** Each record escapes with probability $1 - \delta$, independently, so all escape with probability $(1-\delta)^n = e^{n\ln(1-\delta)} \approx e^{-n\delta}$, which gives Equation 46.14.
3. **δ is at most the tail of the loss.** $\delta(\varepsilon) = \mathbb{E}_Q[(1 - e^{\varepsilon - L})_+]$ (step 2 of Section 46.4), and the integrand is at most 1 and is 0 unless $L > \varepsilon$.
4. **Smaller δ for DP-SGD.** Run the RDP conversion of DP-SGD at several δ for the same σ; Table 46.10 and Figure 46.4 show the result.

46.7.4. Interpretation

Two kinds of δ. In the release mechanism, δ is spent at infinite loss: the published record is identified with certainty. In DP-SGD it is spent at moderate losses, just above ε, and the loss distribution has a Gaussian-like tail (Table 46.8). That is why NIST's guidelines recommend, where possible, guarantees such as Rényi DP, zero-concentrated differential privacy (zCDP) or GDP, which do not allow catastrophic failure, and why a full privacy profile, or the curve, is better than any one pair.

How small. Near, Darais, Lefkovitz & Howarth (NIST SP 800-226, 2025) write that a common recommendation is $\delta \le 1/n^2$, that $\delta \le 1/(n \ln n)$ is another sensible choice, and that values of δ exceeding 10^{-5} are suspicious and should be justified. The running example, with $n = 10{,}000$ and $\delta = 10^{-5}$, has $n\delta = 0.1$: acceptable for DP-SGD, whose δ is not catastrophic, but not by the $1/n^2 = 10^{-8}$ rule. Table 46.10 shows what the stricter rule costs: the $\varepsilon = 4$ run is $(5.209, 10^{-8})$-DP.

The unit decides n. If one person can contribute many records, n is the number of people and δ must be small relative to that; and the per-record guarantee is not a per-person guarantee at all (User-level differential privacy).

Table 46.10.: The ε of three DP-SGD runs of the running example at five values of δ, from the RDP accountant.

σ (run)	$\delta = 10^{-4}$	10^{-5}	10^{-6}	10^{-8}	10^{-10}
4.13 ($\varepsilon = 1$)	0.852	0.999	1.129	1.354	1.548
1.36 ($\varepsilon = 4$)	3.501	3.993	4.432	5.209	5.890
0.917 ($\varepsilon = 8$)	7.088	7.997	8.821	10.301	11.627

46.7.5. Example: ten thousand records

For $n = 10{,}000$, Equation 46.14 gives an exposure probability of 0.6321 at $\delta = 10^{-4} = 1/n$, 0.09516 at $\delta = 10^{-5}$ and 0.00995 at 10^{-6} for the release mechanism. For DP-SGD the same tenfold reductions of δ cost little: from 10^{-5} to 10^{-6} the $\varepsilon = 4$ run's budget rises from 3.993 to

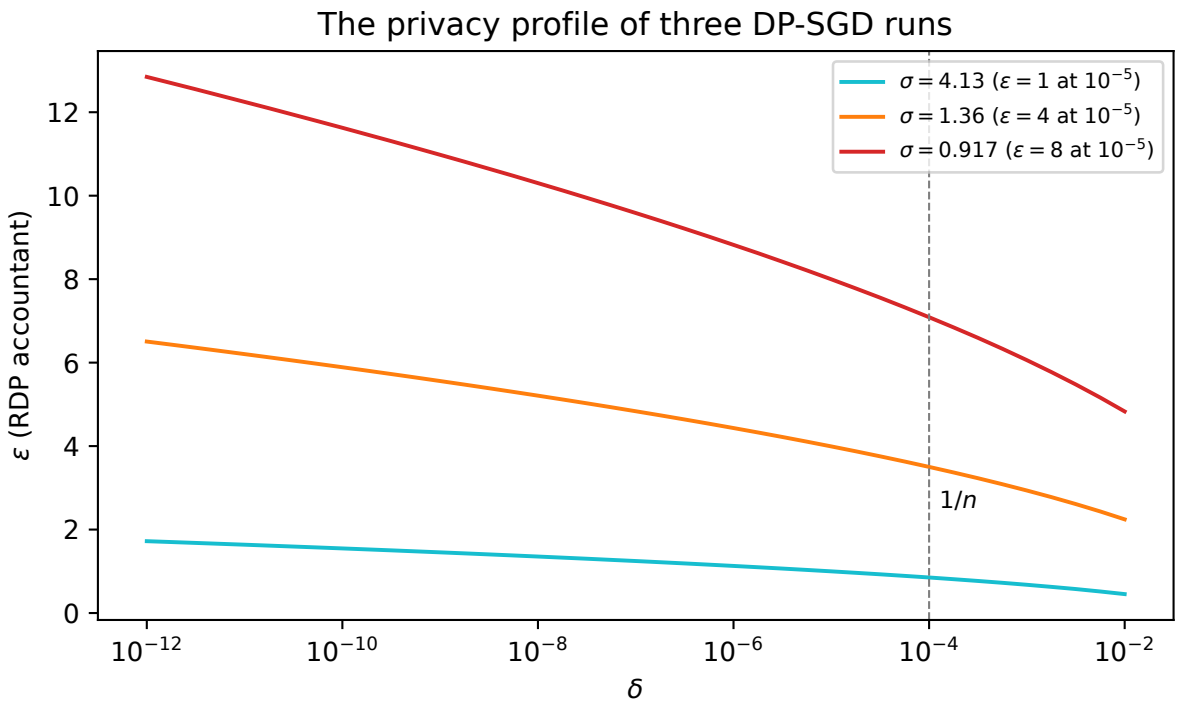

Figure 46.4.: The privacy profile $\varepsilon(\delta)$ of three DP-SGD runs of the running example, from the RDP accountant. The dashed line marks $\delta = 1/n$.

4.432, and down to 10^{-10} it reaches 5.890. Every factor of 100 in δ costs between about 0.2 and 0.9 in ε for these two runs. When in doubt, use a smaller δ; it is cheap.

46.7.6. Check yourself

- A model is reported as $(1, 10^{-3})$-DP on 50,000 records. What is wrong? *(It allows $n\delta = 50$: the release mechanism with this δ would publish about 50 records. Unless the loss distribution is shown to be light-tailed, the guarantee permits catastrophic failure for some people.)*
- Why does the ε in Table 46.10 grow roughly like $\sqrt{\ln(1/\delta)}$? *(For a nearly Gaussian loss with mean $\bar{L}$ and variance v, the tail beyond ε falls like $e^{-(\varepsilon-\bar{L})^2/(2v)}$, so reaching a tail of δ needs $\varepsilon - \bar{L}$ of order $\sqrt{2v\ln(1/\delta)}$.)*

46.8. Deployed values and their units

46.8.1. Context

"Industry uses ε between 1 and 10" is a common justification. What have real deployments published, and in which units? An ε means nothing without the **privacy unit** (what one neighbouring change is: one record, one user's data for a day, one user's data forever) and the **period** over which the budget is spent.

46.8.2. Statement

Table 46.11 lists deployments whose parameters are documented in a primary source. The privacy unit and period differ from row to row, and so do the accounting notions, so the ε values are not comparable without conversion. The zCDP guarantees convert to (ε, δ) by the simple bound

$$\varepsilon = \rho + 2\sqrt{\rho \ln(1/\delta)}, \tag{46.15}$$

of Bun & Steinke (2016), and tighter numerical conversions give somewhat smaller values; pure ε-DP guarantees for independent reports compose by adding. The Gboard models were trained by follow the regularized leader (FTRL) with noise added to sums of gradients, DP-FTRL (DP-FTRL and matrix factorization), in federated learning, where the data stay on users' devices.

Table 46.11.: Published differential-privacy parameters of real deployments, with their privacy units. Sources are in the references; values are as stated there, except the RAPPOR ε_∞, computed here from the paper's formula. The Facebook values are those of the release's table of noise per kind of action.

Deployment	Mechanism and accounting	Privacy unit and period	Published parameters
US Census Bureau, 2020 Census redistricting data	Discrete Gaussian, zCDP	One person's (or housing unit's) record, replace-one; one release	$\rho = 2.63$ in total, 2.56 for persons and 0.07 for housing units; reported as $\varepsilon = 17.14$ (persons) plus 2.47 (housing), 19.61 in total, at $\delta = 10^{-10}$
US Census Bureau, 2020 Demographic and Housing Characteristics file	Discrete Gaussian, zCDP	As above	$\rho \approx 4.96$ for persons, ≈ 7.70 for households
Google Gboard language models	DP-FTRL in federated learning, zCDP	One device's data, whole training run	ρ from 0.25 to 1.86 across the models of the paper's privacy statement; $\rho = 0.25$ is $\varepsilon = 4.49$ and $\rho = 1.86$ is $\varepsilon = 13.69$ at $\delta = 10^{-10}$ (numerical conversion)
Google Gboard, Spanish model (2022)	As above	As above	$\rho = 0.81$, $(8.9, 10^{-10})$; later models down to $\varepsilon = 0.994$

Deployment	Mechanism and accounting	Privacy unit and period	Published parameters
Apple, local DP on iOS and macOS	Local randomizers, pure ε	One donation; limited donations per day; data kept up to three months	Emoji $\varepsilon = 4$, one donation per day; QuickType $\varepsilon = 8$, two per day; Health types $\varepsilon = 2$, one per day; Lookup Hints and Safari domains $\varepsilon = 4$, two per day
Google RAPPOR in Chrome (homepages)	Local randomized response, pure ε	One report (ε_1); one unchanging value over all reports (ε_∞)	$\varepsilon_1 = 0.5343$; $\varepsilon_\infty = 2.043$ from the paper's formula
Microsoft Windows app-usage telemetry	Local one-bit mean, pure ε, with memoization and α-point rounding	One user, one collection round every 6 hours; across rounds, only changes of behaviour are covered	$\varepsilon = 1$ per round and app; 0.686 per round after output perturbation; 1.672 per round across all apps
LinkedIn Audience Engagements API	Gaussian and Laplace noise on counts	One member, per analyst, per month	$(0.15, 10^{-10})$ per returned result; $(34.9, 7 \times 10^{-9})$ per month
Facebook URLs dataset for researchers	Gaussian noise, zCDP	One action (one user, one URL, one kind of action); user level, for each kind of action, for users at or below its 99th percentile of URLs	Per action ε from 0.00 (views) to 0.45 (kinds that users rarely repeat, such as comments) at $\delta = 10^{-5}$; per user and kind of action ρ about 0.005, chosen so that $\varepsilon = 0.45$ at $\delta = 10^{-5}$

46.8.3. Derivation: making the rows comparable

1. **zCDP to (ε, δ).** Equation 46.15 with $\rho = 2.56$ and $\delta = 10^{-10}$ gives $2.56 + 2\sqrt{2.56 \times 23.026} = 17.915$, the persons' figure of Kazan & Reiter (2022); the Bureau's 17.14 comes from a tighter conversion. For the Spanish Gboard model, $\rho = 0.81$ gives 9.447 by Equation 46.15, against the 8.9 Google reports from a numerical conversion. The Bureau's 19.61 adds the ε of persons and housing units; converting the summed $\rho = 2.63$ once would give a smaller number (18.194 by Equation 46.15).
2. **Replace-one to add/remove.** The Census guarantee is for replacing one person's record, which is a removal followed by an addition, so its ε is not directly comparable with the add/remove ε of DP-SGD; an add/remove guarantee of ε implies a replace-one guarantee of

2ε (The definition of differential privacy).

3. **Local reports over time.** A local randomizer with ε per donation, run a number k of times, has a total loss of at most $k\varepsilon$ by basic composition, and a person whose data are correlated across reports can lose all of it. Apple's documentation states ε per donation and the number of donations per day, so QuickType's two donations of $\varepsilon = 8$ are up to 16 per day. Tang, Korolova et al. (2017) measured macOS 10.12 independently, by reverse-engineering it. They found a privacy loss of 1 or 2 per submitted datum. Because many data are submitted each day, the loss reached 16 per day for four applications, namely Emojis, New words, Deeplinks and Lookup Hints. They also found that the budget renews every day, so the total grows with the number of days since a user opted in. Tang et al.'s figures are for macOS 10.12 and count each submitted datum, while Apple's documentation states ε per donation, so the two need not match. RAPPOR's memoization makes all the reports of a value that does not change cost at most its permanent level ε_∞, which depends on the number H of hash functions and the probability f of replacing a bit by a coin,

$$\varepsilon_\infty = 2H \ln \frac{1 - f/2}{f/2}. \tag{46.16}$$

   With $H = 2$ and $f = 0.75$ that is $4 \ln(5/3) = 2.043$. But a value that changes is reported afresh (Local, shuffle and distributed trust models).

4. **Microsoft's rounds.** Ding, Kulkarni & Yekhanin (2017) collect one bit per app every six hours at $\varepsilon = 1$. To blur when a report changes, they flip each sent bit with a probability $\nu = 0.2$. They report 0.686 for one round after the flip, which they call output perturbation. Their own bound for one round after the flip is

$$\varepsilon' = \ln \frac{(1 - 2\nu)e^\varepsilon/(e^\varepsilon + 1) + \nu}{(1 - 2\nu)/(e^\varepsilon + 1) + \nu}, \tag{46.17}$$

   which gives 0.569 at these values. The paper does not explain the difference, and 0.686 is the more cautious figure. Their bound for all apps at once, whose usage adds up to at most the length of a round, is $\varepsilon + e^\varepsilon - 1$, which is 1.672 from 0.686. Across rounds, memoization means that a user whose behaviour does not change reveals nothing new, while each change of behaviour can show. A user whose usage changes every round could lose up to $4 \times 0.686 = 2.744$ per day.

5. **Action to user level.** The Facebook release adds Gaussian noise with standard deviation σ to counts of distinct user–URL pairs, separately for each kind of action. One action moves one count by 1, so it is ρ-zCDP with $\rho = 1/(2\sigma^2)$. A user with k distinct URLs moves k counts by 1 each, so by composition of zCDP the user is $k/(2\sigma^2)$-zCDP. The release sets k at the 99th percentile of URLs per user for each kind of action. It then picks σ so that the user level is $\varepsilon = 0.45$ at $\delta = 10^{-5}$, using a tighter conversion from the same paper of Bun & Steinke (2016),

$$\varepsilon = \rho + \sqrt{4\rho \ln(\sqrt{\pi\rho}/\delta)}. \tag{46.18}$$

   For clicks the release uses $k = 17$ and $\sigma = 40$. So one click has $\rho = 0.00031$, which is $\varepsilon = 0.10$, and a user's 17 clicks have $\rho = 0.0053$, which is $\varepsilon = 0.454$. For views, with $k = 51{,}914$ and $\sigma = 2{,}228$, one view costs almost nothing, while a user's views still add up to $\varepsilon = 0.450$. Users above the 99th percentile get proportionally more: twice the actions, twice the ρ.

6. **Per day versus total.** A budget per user per day of $\varepsilon = 1$ adds up to 365 over a year for someone whose behaviour is the same every day. NIST SP 800-226 uses exactly this example to warn that event-level and user-day units can be surprisingly weak.

46.8.4. Interpretation

The model rows are the comparable ones. For training a model on user data, the Gboard models are the best documented: device-level guarantees for a whole training run, ε between about 1 and 14 at $\delta = 10^{-10}$. The running example's budgets of 1 to 8 at $\delta = 10^{-5}$ are in that range, but at a much larger δ and with records, not users, as the unit.

Large published values are not rare. The Census Bureau published $\varepsilon = 17.14$ for persons. Many local deployments spend several units of ε per day. NIST SP 800-226 notes that many deployments have used $1 < \varepsilon \leq 20$. These are facts about practice, not evidence that a value is safe; Dwork, Kohli & Mulligan (2019) found no clear consensus on how deployments choose ε, and proposed an Epsilon Registry, a public record of deployed parameters, so that choices could be compared and criticized.

Compare like with like. Desfontaines' list of real-world uses of DP converts guarantees to $\delta = 10^{-5}$ and, for Apple, to a user-day unit, so its numbers differ from the primary sources on purpose. When you compare your budget with a deployment, convert both to the same unit, neighbouring relation, accounting and δ, or say that you did not.

The deployments also teach what a published ε leaves out. Five lessons recur, and each is a question to ask of any budget, including your own.

A budget that renews has no lifetime bound. The local deployments state ε per report, per donation or per day, and refresh it. Rogers et al. (2021, Table 2) put several of them on a monthly scale for a user whose records change, so that memoization never applies. One RAPPOR report every 30 minutes at $\varepsilon_1 = 0.534$ then adds up to $0.534 \times 48 \times 30 = 769$ per month. Microsoft's four rounds a day at 0.686 add up to 82.3 per month. Apple's Safari domains, with two donations a day at $\varepsilon = 4$, add up to 240. These are upper bounds by basic composition, and memoization makes them much smaller for users whose data do not change, which is why the local deployments memoize. But no single number covers a user's lifetime.

Some protections sit outside ε. According to Apple's Differential Privacy Team (2017), Apple's devices send reports over an encrypted channel, Apple strips IP addresses before the reports are stored, and only a random sample of reports is sent. RAPPOR's instantaneous randomized response also makes a user's reports hard to link to each other, a benefit that ε_1 does not express. These measures matter, but the stated ε does not cover them. A privacy statement should list them separately.

Some guarantees rest on assumptions that are not mathematical. LinkedIn's Audience Engagements API answers queries chosen by outside analysts, such as advertisers, and keeps a budget per analyst per month (Rogers et al. 2021). Two analysts who pooled their answers would together exceed it. The guarantee therefore assumes that analysts do not collude, which LinkedIn enforces by vetting and by contract, not by noise. It does blunt one form of collusion, because every analyst who asks the same query on the same day receives the same noisy answer, so pooling identical answers reveals nothing new.

A value can be argued from a specific attack. LinkedIn chose its per-result $\varepsilon = 0.15$ by modelling an analyst who asks the same count on each of the 30 days the data are kept and averages the noisy answers. With the API's Laplace noise of scale $2/\varepsilon$ on each answer, the source's normal approximation gives a probability of 0.115 that the average lands within $\frac{1}{2}$ of the true count, which would reveal it after rounding. That is the "about 11%" chance the authors accepted.

This is the procedure of Section 46.9 in miniature: name the attack, compute its success, and choose the number from it.

Partial user-level guarantees should say whom they cover. The Facebook URLs release protects each action strongly, and protects whole users at $\varepsilon = 0.45$ for each kind of action only up to the 99th percentile of activity. Users above the 99th percentile get a weaker guarantee, whose ε grows with how far they exceed it (Exercise 7 in the exercise book). That is an honest way to state a guarantee that cannot cover everyone, and User-level differential privacy explains why bounding each user's contribution is the price of covering all of them.

46.8.5. Example: the Census as a training run

Could the running example's $\varepsilon = 8$ run be described as "less than half the Census budget"? The Census $\varepsilon = 17.14$ is replace-one at $\delta = 10^{-10}$; the run's 7.997 is add/remove at $\delta = 10^{-5}$. At $\delta = 10^{-10}$ the run is at 11.627 (Table 46.10), and replace-one doubles an add/remove guarantee in the worst case. After converting, the honest statement is that the two are of the same order, which is a weaker claim than the slogan.

46.8.6. Check yourself

- A product reports "$\varepsilon = 2$ per user per day" for data kept a year. What total should you assume for a user whose behaviour never changes? *(Up to* $2 \times 365 = 730$ *by basic composition, unless the mechanism memoizes or the accounting shows otherwise.)*
- Why can the Census Bureau's 19.61 be larger than the ε of the combined $\rho = 2.63$? *(Because adding two* ε *values computed at the same* δ *is a valid but loose composition, while zCDP composes by adding* ρ *and converts once.)*

46.9. Justifying a choice

46.9.1. Context

You must pick a target for the running example and write a statement that a sceptical reviewer will check. What should the procedure be, and what does it give here?

46.9.2. Statement

A defensible choice of ε fixes the claim before the number:

1. **The unit and the neighbouring relation.** Record, user, device; add/remove or replace-one; the period over which the budget is spent, including every training run and hyperparameter search that touched the data (Hyperparameter tuning).
2. **The threat.** Membership, attribute inference or reconstruction; the attacker's knowledge and prior; what it observes (the final model, the iterates, an API).

3. **The whole guarantee.** The privacy profile $\varepsilon(\delta)$ or the trade-off curve, computed by a tight accountant, with $\delta \ll 1/n$, and read at the operating points of the threat: TPR at FPR 10^{-3} and below for membership, at FPR κ for reconstruction.
4. **The evidence.** An empirical audit (Auditing private training) whose lower bound is consistent with the claim, and a check of the implementation against the assumptions of the proof (DP-SGD).
5. **The utility.** The accuracy curve against ε, and where it bends: the smallest budget past the bend is the natural candidate.
6. **The comparison.** The tiers of Ponomareva et al. (2023): $\varepsilon \leq 1$ gives strong formal guarantees; $\varepsilon \leq 10$ is the widely used goal they call a reasonable level of anonymization for many applications; above 10, the guarantee alone cannot be taken as sufficient evidence of anonymization and additional measures such as auditing may be necessary. NIST SP 800-226 offers no specific rule for choosing ε, cites a study suggesting that ε of 0.1 generally provides strong protection and values below 1 are reasonable, and warns that large values may not provide meaningful privacy, that releases with ε of 10 or more can leave outliers vulnerable, and that organizations should evaluate the risk of the final data, especially for ε above 1. It also recommends publishing the parameters, which it says creates no additional risk.

46.9.3. Derivation: why each step is needed

1. **Unit.** Without it, the same number can mean protection of a single click or of a person's whole history (Section 46.8).
2. **Threat.** The curve answers different questions at different points: a prior of 0.5 reads the curve near FPR 0.5, a thousand candidates read it at 10^{-3} (Section 46.5, Section 46.6).
3. **Whole guarantee.** The single pair can overstate the attacker by a factor of 17 at FPR 10^{-3} and $\varepsilon = 8$ (Table 46.5), so a statement based on the pair alone either undersells the model or tempts the reader to dismiss DP as vacuous.
4. **Evidence.** The curve is a theorem about an algorithm; whether the code runs that algorithm is an empirical fact, and audits are how bugs that break the proof are found.
5. **Utility.** The accuracy curve is steeply non-linear (Figure 46.5), so the cost of halving ε varies by an order of magnitude along it.
6. **Comparison.** Tiers and practice give a reader a reference point; they cannot replace steps 1 to 5.

46.9.4. Interpretation

The accuracy curve and the risk curve together. Figure 46.5 puts the accuracies of DP-SGD against the largest membership TPR at FPR 1%, from the pair and from the exact curve. Going from $\varepsilon = 1$ to 2 gains 2.66 points of accuracy (0.9175 to 0.9441) and moves the exact TPR at FPR 1% from at most 0.01893 to at most 0.03141. From 2 to 4 gains 1.07 points for a TPR of at most 0.0724. From 4 to 8 gains 0.56 points (0.9548 to 0.9604), the gap to the non-private model falling from 0.0062 to 0.0006, and nearly triples the TPR, to at most 0.2092. Past $\varepsilon = 4$, each unit of accuracy is bought with a much larger increase in worst-case risk.

Rules of thumb are where the reasoning stops, not where it starts. "$\varepsilon \leq 1$ is strong" is true of every mechanism, because Equation 46.4 is already tight enough. "1 to 10 is common

in machine learning" is true of practice, and this chapter shows why it can be reasonable for DP-SGD: at those budgets the actual curve is far below the line. "Above 10 needs justification" is true because there even the actual curve allows attacks with substantial power on worst-case records (TPR above 0.27 at FPR 10^{-3} at $\varepsilon = 16$).

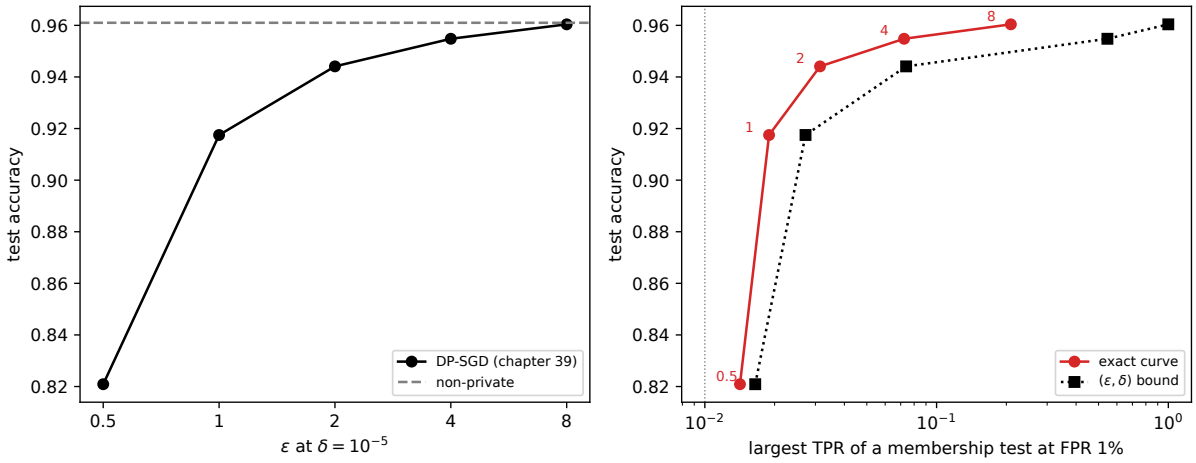

Figure 46.5.: Left: test accuracy of the running example against ε at $\delta = 10^{-5}$, from the DP-SGD chapter's table (three runs each), with the non-private model dashed. Right: the same accuracies against the largest TPR of a membership test at FPR 1%, from the exact curve (circles, labelled by ε) and from the pair alone (squares). The dotted vertical line is an attacker with no information.

46.9.5. Example: a privacy statement for the running example

Following the procedure, a team might choose the $\varepsilon = 4$ run and write:

> The model was trained with DP-SGD (Poisson sampling rate 0.01, noise multiplier 1.36, clipping norm 0.5, 10,000 steps) on 10,000 records, one record per person. The privacy unit is one record under add/remove neighbours; no other run touched the training data. The RDP accountant gives $(3.993, 10^{-5})$-DP and $(5.209, 10^{-8})$-DP; a PLD accountant gives $\varepsilon \leq 3.729$ at $\delta = 10^{-5}$. Against an attacker who knows every other record and sees every iterate, any membership test has TPR at most 0.01312 at FPR 10^{-3} and at most 0.0724 at FPR 10^{-2}, and any attack that picks a record out of 100 equally likely candidates succeeds with probability at most 0.0724. Test accuracy is 0.9548, against 0.9610 without privacy.

Every number in it is checkable, and each comes with its unit, its accountant and the attacker it refers to. A reviewer who thinks $\varepsilon = 4$ is too large can now argue with the TPR at a specific FPR, which is the substance, rather than with the number.

46.9.6. Check yourself

- Your accuracy curve is flat above $\varepsilon = 2$. Which budget should you choose, and why? *(About 2, or slightly above to leave room for run-to-run variation: past the bend, more budget buys*

almost no accuracy and raises the worst-case risk.)

- A reviewer asks why you report the TPR at FPR 10^{-3} rather than the advantage. *(Because an attack is dangerous when its flags are reliable, which is a low-FPR property, and because the advantage is read at one point near the middle of the curve, where it says little about confident identification.)*

46.10. Code: check every number by computation

The script code/choosing_epsilon.py calibrates the running example's noise multipliers with the RDP accountant of DP-SGD, discretizes the one-step privacy loss of the subsampled Gaussian pessimistically and optimistically, composes it 10,000 times by FFT, and reads off the trade-off curve, the privacy loss quantiles and the bounds of this chapter. It also trains one model per budget and runs the loss-threshold attack. From the repository root:

```
uv run python code/part05-dp-ml/choosing_epsilon.py
```

It takes two to three minutes, most of it in the PLD compositions. **Output** (seed 0), summarized in Table 46.12:

Table 46.12.: The script's output with the default seed.

Experiment	Result
Accountants	RDP ε = target; PLD brackets 0.02 to 0.1 wide and below it; GDP ε below the PLD lower end except at $\varepsilon = 0.5$ and 1 (Table 46.2)
Membership at FPR 10^{-3}	Pair 0.002728 / 0.05461 / 0.9997 at $\varepsilon = 1$ / 4 / 8; exact curve at most 0.00225 / 0.01312 / 0.0589
Advantage	Pair 0.9640 at $\varepsilon = 4$; exact at most 0.3429
Bayes	Median total loss 0.401 at $\varepsilon = 4$, 1.136 at $\varepsilon = 8$; $Q[L > \varepsilon]$ between 3.78×10^{-6} and 1.10×10^{-4}
Reconstruction, 1,000 candidates	At most 0.0589 at $\varepsilon = 8$, 0.2808 at $\varepsilon = 16$
δ	$\varepsilon = 4$ run: 3.993 at 10^{-5}, 5.209 at 10^{-8}, 5.890 at 10^{-10}
Conversions	$\rho = 2.56$ gives 17.915 at $\delta = 10^{-10}$ by Equation 46.15; RAPPOR $\varepsilon_\infty = 2.043$
Deployment checks	Facebook clicks: $\rho = 0.0053$, $\varepsilon = 0.454$ per user; Microsoft one round by Theorem 6: 0.569 (reported 0.686); LinkedIn averaging attack at $\varepsilon = 0.15$: 0.115; monthly totals 769 (RAPPOR) and 82.3 (Microsoft)
Loss-threshold attack	TPR within 0.004 of the FPR at every budget and every FPR (Table 46.4)

tests/test_choosing_epsilon.py checks that the output still matches.

What to take from it. The exact trade-off curve of DP-SGD is cheap to compute, with the same machinery as a numerical accountant, and it changes the conversation: at the budgets machine learning uses, the curve is far below the line that the reported (ε, δ) draws, and it, not the line, is what an attacker faces.

46.12. Cheat sheet

Q, P: output laws with and without the target; $L = \ln(Q/P)$ its privacy loss; ω the law of L under Q; $\delta(\varepsilon)$ the privacy profile; p the attacker's prior; κ the reconstruction baseline. Table 46.13 collects the results.

Table 46.13.: Every result of the chapter.

Result	Formula	Conditions
One pair	$\mathrm{TPR} \le e^{\varepsilon}\mathrm{FPR} + \delta$; advantage $\le \frac{e^{\varepsilon}-1+2\delta}{e^{\varepsilon}+1}$	Any (ε, δ)-DP mechanism
Whole curve	$\mathrm{TPR}^*(\mathrm{FPR}) = \inf_{\varepsilon}(e^{\varepsilon}\mathrm{FPR} + \delta(\varepsilon))$	Exact, from the full profile
Curve from the PLD	$(\mathbb{E}_{\omega}[e^{-L}; L > \tau], \omega(L > \tau))$	Composition: convolve per-step PLDs
From RDP	$\mathrm{TPR} \le \min_{\alpha}(\mathrm{FPR}\, e^{\varepsilon(\alpha)})^{(\alpha-1)/\alpha}$	Valid bound, cheap
GDP	$\mathrm{TPR} \approx 1 - \Phi(\Phi^{-1}(1-\mathrm{FPR}) - \mu)$, $\mu = q\sqrt{T(e^{1/\sigma^2}-1)}$	Approximation, not a bound
Posterior	$\le pe^{\varepsilon}/(pe^{\varepsilon} + 1 - p)$; exactly $pe^{L}/(pe^{L} + 1 - p)$	Fails with probability $\le \delta/(1 - e^{\varepsilon-\varepsilon'})$ at level ε'

Result	Formula	Conditions
Precision of a flag	$p\,\mathrm{TPR}/(p\,\mathrm{TPR}+(1-p)\mathrm{FPR})$	Base rates dominate at small p
Reconstruction	Success $\le \mathrm{TPR}^*(\kappa)$; pair: $e^{\varepsilon}\kappa+\delta$	Informed adversary, prior baseline κ
δ	Release mechanism exposes $1-(1-\delta)^n$; use $\delta \ll 1/n$, NIST: $\le 1/n^2$	Per privacy unit
zCDP to (ε,δ)	$\varepsilon=\rho+2\sqrt{\rho\ln(1/\delta)}$	Simple, slightly loose
Action to user level	k actions, each ρ-zCDP, give $k\rho$	Covers only users with at most k actions
Running example, $\varepsilon=4$	TPR ≤ 0.01312 at FPR 10^{-3} (pair: 0.05461); accuracy 0.9548	$q=0.01$, $\sigma=1.36$, $T=10{,}000$
Running example, $\varepsilon=8$	TPR ≤ 0.0589 at FPR 10^{-3} (pair: 0.9997); accuracy 0.9604	$\sigma=0.917$

Rules of thumb

- Report the curve, not just the pair: the TPR at FPR 10^{-3} and 10^{-2}, computed with a PLD accountant or bounded with RDP.
- State the unit, the neighbouring relation, the period and δ with every ε; convert before comparing with anyone else's.
- $\varepsilon \le 1$ is strong for any mechanism. Between 1 and 10, DP-SGD's actual curve is far below the pair's line, and that curve is your justification. Above 10, show the curve and an audit, and expect worst-case records to be exposed.
- Choose δ well below $1/n$ for the right n; for Gaussian-type mechanisms a smaller δ costs little ε.
- Put the accuracy curve next to the risk curve, and pick the smallest budget past the bend in accuracy.
- Ask of every published budget how it grows over time, which protections sit outside it, which assumptions it rests on, and which users it covers.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

47. Auditing private training

47.1. Why this matters

Every chapter of this part ended with a number: train with stochastic gradient descent (SGD) under differential privacy (DP), that is, with per-example clipping and Gaussian noise (DP-SGD), at a sampling rate q of 0.01, noise multiplier $\sigma = 1$ and 10,000 steps, and the accountant reports $\varepsilon = 6.71$ at $\delta = 10^{-5}$. That number is the conclusion of a proof. The proof is about an algorithm on paper, and what ships is code. Between the two sit a dozen places where an implementation can quietly differ from the algorithm the proof analysed: noise scaled for the averaged gradient but added to the sum, the wrong dataset size handed to the accountant, batches sampled one way and accounted another, a random seed reused. None of these changes the accuracy much, so none is caught by the usual tests. **Is the trained model as private as the accountant says?**

An **audit** answers this the only way an empirical check can: it attacks. It plants records of its own, **canaries**, trains with and without them, runs a membership test, and counts how often the test is right. The definition of DP limits how often any test can be right, so the measured error rates imply a **lower bound** on ε: the algorithm cannot be private with any smaller ε. A lower bound cannot prove privacy. It can disprove a claim, when it lands above the claimed value, and it says how much of the accountant's worst case a given attacker can actually realize.

47.1.1. The one idea: privacy caps every test, so a measured test bounds privacy from below

An (ε, δ)-DP algorithm guarantees that every test, for every pair of neighbouring datasets, has a true positive rate (TPR) of at most e^{ε} times its false positive rate (FPR) plus δ. Read backwards, a test with a measured FPR and TPR forces $\varepsilon \geq \ln \frac{\mathrm{TPR}-\delta}{\mathrm{FPR}}$. Everything in this chapter is about making that inequality bite. The rates are estimated from a finite number of trials, so they come with confidence intervals, and the bound must use the pessimistic end of each; this caps what any audit with n trials can certify at about $\ln n$. The test is only as strong as the attack, so the auditor chooses the most detectable canary and the most informative view of training; with the right canary and a view of every step, the audit faces exactly the pair of distributions the accountant analyses. And training thousands of models is unaffordable, so two tricks get many trials out of one or two runs: many canaries in one run, or one observation per step.

Table 47.1 lists the results and where each is used.

Table 47.1.: The results of this chapter and where each is used.

Result	Where it is used
A test's FPR and TPR, with Clopper–Pearson intervals, give an ε lower bound	Every audit; reading audit results in papers
The ceiling: n trials certify at most about $\ln(n/\ln(2/\beta))$	Planning an audit; why audits of large ε are expensive
A Dirac canary seen at every step faces exactly the accountant's pair	Strongest audits of DP-SGD; testing implementations
The likelihood-ratio statistic, and what the sum of projections loses	Choosing the attack's score
Where ε at $\delta = 10^{-5}$ lives on the trade-off curve	Why audits stop short of the accountant
One-run auditing: correct guesses are dominated by a binomial	Auditing real training runs
Black-box audits with input canaries	What a realistic attacker learns from a released model
Per-step and end-to-end audits find bugs	Testing DP-SGD implementations before release

Notation. The training algorithm is M, the dataset without the canary D and with it $D' = D \cup \{z^*\}$, where z^* is the canary; neighbours differ by adding or removing one record. A **trial** is one run of M on D or on D', with fresh randomness, followed by the attack's score s. The attack says "canary in" when $s \geq \tau$, a threshold. Its **false positive rate** is $\text{FPR} = \Pr[s \geq \tau \mid D]$ and its **true positive rate** $\text{TPR} = \Pr[s \geq \tau \mid D']$; the false negative rate (FNR) is $1 - \text{TPR}$. With n trials of each kind, the counts are k_0 false positives and k_1 true positives. β is the probability that an audit's bound is wrong (5% throughout), and ε_{lo} is the bound itself. DP-SGD's notation is that of DP-SGD: clipping norm C, noise multiplier σ, sampling rate q, expected batch size B (the sampling rate times the number of records, 100 here), learning rate η and T steps. In this chapter n always counts trials, not records.

The running example. The part's network: a two-layer tanh network trained on the 10,000 records of DP-SGD with $q = 0.01$, $C = 0.5$, $\sigma = 1$, learning rate 0.5 and $T = 10{,}000$ steps. The Rényi differential privacy (RDP) accountant reports $\varepsilon = 6.71$ at $\delta = 10^{-5}$; this is the **claim** every audit below tests.

How to read this chapter. Read the toolkit and Section 47.3, which turns an attack into a bound and says what it costs. Section 47.4 chooses the attack, Section 47.5 runs the strongest one many times and explains why even it stops short of 6.71. Section 47.6 and Section 47.7 audit a real training run in one go, and Section 47.8 uses audits to catch broken implementations. This chapter comes last in the part because it checks the claims of all the others.

47.2. Toolkit: four facts every derivation uses

47.2.1. Fact 1 — Differential privacy caps every test, in both directions

M is (ε, δ)-DP when, for all neighbours D, D' and every set of outputs S, $\Pr[M(D') \in S] \leq e^{\varepsilon} \Pr[M(D) \in S] + \delta$, and the same with D and D' swapped. A test that says "canary in" on the event S has $\mathrm{TPR} = \Pr[M(D') \in S]$ and $\mathrm{FPR} = \Pr[M(D) \in S]$, so the definition reads $\mathrm{TPR} \leq e^{\varepsilon}\,\mathrm{FPR} + \delta$. Applying the definition with the roles swapped to the complement of S, where the test says "canary out", gives $1 - \mathrm{FPR} \leq e^{\varepsilon}(1 - \mathrm{TPR}) + \delta$: a test cannot be almost always right about absent canaries while rarely missing present ones. Together,

$$\mathrm{TPR} \leq e^{\varepsilon}\,\mathrm{FPR} + \delta, \qquad 1 - \mathrm{FPR} \leq e^{\varepsilon}\,(1 - \mathrm{TPR}) + \delta. \tag{47.1}$$

These are the two lines of the hypothesis-testing interpretation of DP (The definition of differential privacy); they hold for randomized tests too.

47.2.2. Fact 2 — Clopper–Pearson bounds on a rate

If k of n independent trials succeed, each with unknown probability p, then k is binomial, $\mathrm{Bin}(n, p)$. The **one-sided Clopper–Pearson upper bound** at level κ is the rate u at which seeing k or fewer successes has probability exactly κ, $\Pr[\mathrm{Bin}(n, u) \leq k] = \kappa$; the **lower bound** l solves $\Pr[\mathrm{Bin}(n, l) \geq k] = \kappa$. Then $\Pr[p \leq u] \geq 1 - \kappa$ and $\Pr[p \geq l] \geq 1 - \kappa$, for every true p. The reason is that a true rate above u would make the observed count implausibly small, and the probability of an observation that implausible is at most κ (Hypothesis testing proves it, and Section F.3 in the appendices shows that u and l exist and are unique). With $k = 10$ and $n = 10{,}000$, the bounds at $\kappa = 0.025$ are 0.00048 and 0.00184, the two ends of the usual two-sided 95% interval. With $k = 0$ and $n = 3{,}000$, the 95% upper bound is 9.9808×10^{-4}, about $3/n$: the **rule of three**.

47.2.3. Fact 3 — The best test thresholds the likelihood ratio

Among all tests with a given FPR, the one with the largest TPR says "canary in" when the likelihood ratio, the density of the observation under D' divided by its density under D, exceeds a threshold. This is the Neyman–Pearson lemma (Hypothesis testing). The reason is a budgeting argument: each observation costs its probability under D in false positives and earns its probability under D' in true positives, and the best way to spend a fixed false-positive budget is on the observations with the best ratio of earnings to cost. The curve of the best TPR against FPR is the pair's **trade-off curve** (written as best FNR against FPR in f-DP and Gaussian DP). For two unit-variance normals at distance μ, the best TPR at a given FPR is

$$\mathrm{TPR}_{\mu}(\mathrm{FPR}) = 1 - \Phi\big(\Phi^{-1}(1 - \mathrm{FPR}) - \mu\big), \tag{47.2}$$

where Φ is the standard normal distribution function; a mechanism whose curve is this one, or better, satisfies Gaussian differential privacy (GDP) with parameter μ, or **μ-GDP**.

47.2.4. Fact 4 — One DP-SGD step, seen along one direction

A DP-SGD step releases $G_t = \sum_{i \in S_t} \bar{g}_i + \xi_t$, the sum of the clipped gradients of the records in the batch S_t plus Gaussian noise $\xi_t \sim \mathcal{N}(0, \sigma^2 C^2 I)$. Project G_t on a fixed unit vector u and divide by C. The noise becomes σz_t with z_t standard normal, because the projection of an isotropic Gaussian vector on a unit vector is a one-dimensional Gaussian with the same standard deviation. A record whose clipped gradient is exactly Cu adds 1 when it is sampled, which under Poisson sampling happens with probability q, independently at every step. So if no other record's gradient has a component along u, the projection is

$$x_t \sim \mathcal{N}(0, \sigma^2) \text{ without the record}, \qquad x_t \sim (1-q)\,\mathcal{N}(0, \sigma^2) + q\,\mathcal{N}(1, \sigma^2) \text{ with it}, \tag{47.3}$$

independently over steps, because both the sampling and the noise are drawn afresh at every step. This is the pair of distributions the accountant of Amplification by subsampling analyses: the worst case for one step under add/remove neighbours.

47.3. From an attack to a lower bound on ε

47.3.1. Context

You ran an attack: n training runs without the canary and n with it, a score per run, a threshold. You counted k_0 false positives and k_1 true positives. What can you conclude about ε, with what confidence, and how much could you possibly conclude with n trials?

47.3.2. Statement

The measured rates are k_0/n and k_1/n. Write $\overline{\mathrm{FPR}}$ and $\underline{\mathrm{TPR}}$ for the one-sided Clopper–Pearson upper bound on the FPR and lower bound on the TPR, each at level $\beta/2$ (Fact 2). If the threshold was chosen without looking at these $2n$ trials, then with probability at least $1-\beta$ the algorithm is not (ε, δ)-DP for any ε below

$$\varepsilon_{\mathrm{lo}} = \max\left\{ \ln \frac{\underline{\mathrm{TPR}} - \delta}{\overline{\mathrm{FPR}}},\ \ln \frac{1 - \overline{\mathrm{FPR}} - \delta}{1 - \underline{\mathrm{TPR}}} \right\}. \tag{47.4}$$

The most that n trials per hypothesis can certify is the bound of a perfect attack, $k_0 = 0$ and $k_1 = n$:

$$\varepsilon_{\max}(n) = \ln \frac{(\beta/2)^{1/n} - \delta}{1 - (\beta/2)^{1/n}} \approx \ln \frac{n}{\ln(2/\beta)}. \tag{47.5}$$

47.3.3. Derivation

1. **The rates bound ε.** Solve the two inequalities of Equation 47.1 for ε: $e^\varepsilon \geq (\mathrm{TPR} - \delta)/\mathrm{FPR}$ and $e^\varepsilon \geq (1 - \mathrm{FPR} - \delta)/(1 - \mathrm{TPR})$. Any (ε, δ)-DP algorithm satisfies both, at the true rates of every test.
2. **Both expressions grow with the TPR and shrink with the FPR.** So replacing the true FPR by something larger and the true TPR by something smaller can only lower them.

3. **The intervals hold together with probability** $1-\beta$**.** By Fact 2, FPR $\leq \overline{\text{FPR}}$ fails with probability at most $\beta/2$, and TPR $\geq \underline{\text{TPR}}$ fails with probability at most $\beta/2$. The probability that at least one of them fails is at most the sum, β (the union bound). This needs the counts to be binomial: independent trials, and a threshold fixed before the counting.
4. **Combine.** On the event that both intervals hold, step 2 gives $\varepsilon_{\text{lo}} \leq \max\{\ln \frac{\text{TPR}-\delta}{\text{FPR}}, \ln \frac{1-\text{FPR}-\delta}{1-\text{TPR}}\}$, and step 1 says this is at most the ε of any valid guarantee. So the event "M is (ε, δ)-DP with $\varepsilon < \varepsilon_{\text{lo}}$" has probability at most β.
5. **The ceiling.** With $k_0 = 0$, $\Pr[\text{Bin}(n, u) \leq 0] = (1-u)^n = \beta/2$ gives $\overline{\text{FPR}} = 1 - (\beta/2)^{1/n}$. With $k_1 = n$, $\Pr[\text{Bin}(n, l) \geq n] = l^n = \beta/2$ gives $\underline{\text{TPR}} = (\beta/2)^{1/n}$. Substituting in the first form of Equation 47.4 gives Equation 47.5; the second form gives the same value here. For large n, $(\beta/2)^{1/n} = e^{-\ln(2/\beta)/n} \approx 1 - \ln(2/\beta)/n$, so $\overline{\text{FPR}} \approx \ln(2/\beta)/n$, $\underline{\text{TPR}} \approx 1$ and $\varepsilon_{\max} \approx \ln(n/\ln(2/\beta))$; with $\beta = 0.05$, $\ln(2/\beta) = \ln 40 = 3.69$.

47.3.4. Interpretation

A lower bound, and only that. ε_{lo} says "no smaller ε is possible", never "this ε is enough". A weak attack gives a small ε_{lo} for a leaky model as easily as for a private one. That asymmetry is the whole logic of auditing: a bound above the claim refutes the claim, and a bound below it only says that this attacker, on this canary, could not do better.

The ceiling grows like $\ln n$**.** Each factor of e in the bound costs a factor of e in trials, because a false positive rate cannot be distinguished from zero with fewer than about 3/FPR trials (the rule of three), and ε is about $\ln(1/\text{FPR})$ when the TPR is near 1. Table 47.2 shows what that means. Certifying the running example's 6.71 needs at least 3,038 trials per hypothesis, so 6,076 training runs, even for an attack that never errs. Each run of the running example takes a few seconds; for a real network each is a full training job.

Table 47.2.: The most a perfect attack can certify with n trials per hypothesis, at 95% confidence and $\delta = 10^{-5}$. Conversely, certifying $\varepsilon = 1$, 2, 4, 6.71 and 8 takes at least 12, 30, 204, 3,038 and 10,999 trials per hypothesis.

Trials per hypothesis n	100	1,000	10,000	100,000	1,000,000
Largest certifiable ε, Equation 47.5	3.28	5.60	7.90	10.21	12.51

Choose the threshold on separate trials. Step 3 assumes the threshold does not depend on the counts. Sweeping the threshold over the same data and reporting the best bound is the norm in parts of the literature, and it makes the confidence level wrong: among many thresholds, one is lucky. Every audit in this chapter chooses its threshold on half of the trials and counts on the other half.

Both inequalities matter. The first form of Equation 47.4 rewards tests that flag few absent canaries; the second rewards tests that rarely miss present ones. A test that says "canary in" almost always, with FPR 0.5 and TPR 0.999, has a useless first form, $\ln(0.999/0.5) = 0.69$, and a second form of $\ln(0.5/0.001) = 6.21$. An audit should try both (Exercise 1 in the exercise book).

47.3.5. Example: what confidence costs

Suppose 1,000 runs with the canary and 1,000 without give 500 true positives and 1 false positive. The point estimate is $\ln \frac{0.5-10^{-5}}{0.001} = 6.21$. The Clopper–Pearson bounds at $\beta/2 = 0.025$ are $\overline{\text{FPR}} = 0.00556$ and $\underline{\text{TPR}} = 0.4685$: one false positive in 1,000 is consistent with a true FPR five times larger. The certified bound is $\ln \frac{0.4685-10^{-5}}{0.00556} = 4.43$, almost two less than the point estimate. With ten times the trials and the same rates, 10 false positives and 5,000 true positives out of 10,000 each, $\overline{\text{FPR}} = 0.00184$, $\underline{\text{TPR}} = 0.4902$, and the bound rises to 5.59. The point estimate does not change; the price of confidence falls, slowly, as the counts grow.

47.3.6. Check yourself

- An audit with 500 trials per hypothesis reports $\varepsilon_{\text{lo}} = 7$ at 95% confidence. What went wrong? *(500 trials can certify at most about* $\ln(500/3.69) = 4.9$*, by Equation 47.5. The threshold was probably chosen on the same trials, or the trials were not independent.)*
- Why does the bound use the upper end of the FPR interval and the lower end of the TPR interval? *(Because the bound must hold whatever the true rates are within their intervals, and* $\ln \frac{\text{TPR}-\delta}{\text{FPR}}$ *is smallest when the FPR is as large and the TPR as small as the data allow.)*

47.4. Canaries and threat models

47.4.1. Context

DP is a promise about the worst pair of neighbouring datasets and the worst test. An audit must instantiate both: it picks the dataset, the canary record and what the attacker sees, then the score. A typical training record and a loss threshold give a valid but nearly useless bound (Membership inference shows that most records are barely exposed). What is the strongest audit of DP-SGD, and what does it face?

47.4.2. Statement

The auditor has two choices of canary and two threat models.

An **input-space canary** is a record (x, y), inserted into the training data like any other: a mislabeled example, or one far from the data, so that its gradient is large and points where few others do. A **gradient-space canary** lets the auditor write the canary's gradient directly, as if it controlled the training code; the strongest is a **Dirac canary**, a gradient equal to C on one coordinate and zero elsewhere (Nasr et al. 2023), on a coordinate where the other records' gradients are zero. In the **black-box** threat model the attacker sees only the final model; in the **white-box** model it sees every iterate $\theta_0, \dots, \theta_T$, and therefore every noisy sum $G_t = -B(\theta_{t+1} - \theta_t)/\eta$.

For a Dirac canary seen white-box, the audit faces the accountant's pair exactly. The projections $x_t = G_{t,j}/C$ on the canary's coordinate j follow Equation 47.3, independently over

the T steps. The most powerful test at every FPR thresholds the **likelihood-ratio statistic**

$$\Lambda = \sum_{t=1}^{T} \ln\left(1 - q + q\, e^{(x_t - 1/2)/\sigma^2}\right), \tag{47.6}$$

and by the central limit theorem (CLT) its trade-off curve is close to that of μ-GDP with $\mu = q\sqrt{T(e^{1/\sigma^2} - 1)}$. The simpler **sum of projections** $\sum_t x_t$, which is the canary coordinate of the total displacement $\theta_0 - \theta_T$ times $B/(\eta C)$, has a curve close to μ-GDP with $\mu_{\text{sum}} = q\sqrt{T}/\sigma$.

47.4.3. Derivation

1. **The canary is the only difference.** With a Dirac canary on a coordinate j no other record's gradient touches, every other record contributes 0 to $G_{t,j}$. The canary's clipped gradient is itself, since its norm is exactly C, and it contributes C when sampled. Dividing by C gives Fact 4: $x_t = \sigma z_t$ without the canary and $\sigma z_t + b_t$ with it, $b_t \sim \text{Bern}(q)$.
2. **The steps are independent.** The sampling coin b_t and the noise z_t are fresh at each step, and the canary's gradient is the same at every step whatever the weights are. So $(x_1, \dots, x_T)$ are independent and identically distributed under each hypothesis, even though training is adaptive.
3. **The likelihood ratio of one step.** The density of $\mathcal{N}(1, \sigma^2)$ divided by that of $\mathcal{N}(0, \sigma^2)$ at x is $e^{(2x-1)/(2\sigma^2)} = e^{(x-1/2)/\sigma^2}$, because the squares x^2 cancel in the ratio of the two exponentials. The mixture's density over the null's is therefore $(1 - q) + q\, e^{(x-1/2)/\sigma^2}$.
4. **Multiply over steps.** Independence (step 2) makes the joint likelihood ratio a product, and its logarithm the sum Equation 47.6. By Fact 3, thresholding Λ is the most powerful test at every FPR. No attacker, whatever it sees, can do better against this canary: the whole training run is a function of the projections x_t and of randomness that has the same distribution under both hypotheses (the other records' sampling and the noise on the other coordinates), so it carries no evidence beyond the x_t.
5. **The two statistics in Gaussian terms.** The CLT applied to the per-step privacy loss gives $\mu = q\sqrt{T(e^{1/\sigma^2} - 1)}$ for Λ (f-DP and Gaussian DP derives it from the mean and variance of $\ln(1 + qW)$, with $W = e^{(x-1/2)/\sigma^2} - 1$). For the sum, the shift between the hypotheses is the expected number of times the canary is sampled, qT, and the noise standard deviation is $\sigma\sqrt{T}$; their ratio is $q\sqrt{T}/\sigma$. (With the canary the sum has a little extra variance, $Tq(1 - q)$, from the random number of samples.)

47.4.4. Interpretation

Why the likelihood ratio beats the sum. The sum treats every step alike. The likelihood ratio does not: a step with $x_t = 3$ is much stronger evidence of the canary than three steps with $x_t = 1$, because a value three noise standard deviations out is very unlikely without the canary. The exponential in Equation 47.6 weighs it accordingly. The two coincide when σ is large, since then the exponential is nearly linear, and differ most at small σ; the ratio of their μ is $\sigma\sqrt{e^{1/\sigma^2} - 1}$, 1.311 at $\sigma = 1$ (Exercise 4 in the exercise book).

Why black-box audits are weaker. Three things separate a black-box audit with an input canary from the white-box Dirac audit. The final model is one function of all the noisy sums, so it carries at most as much information as all of them (post-processing), and usually much less:

the noise of 10,000 steps is summed into the weights, and later steps partly overwrite earlier ones. An input canary's gradient is not of norm C at every step: once the model fits it, or gives up on it, its gradient shrinks or turns. And it shares directions with the other records' gradients, whose contributions act as extra noise. Nasr, Song, Thakurta, Papernot & Carlini (2021) built a ladder of such adversaries for DP-SGD and found the lower bound tight for the strongest, which sees every iterate and chooses a worst-case dataset and canary, and much weaker as the adversary was restricted towards a realistic one. Jagielski, Ullman & Oprea (2020), an early audit of DP-SGD, used black-box poisoning canaries crafted to have large gradients in a direction where the other data's gradients are small (their ClipBKD), with Clopper–Pearson intervals; they report bounds about ten times better than standard membership inference and within about a factor of ten of the theoretical ε.

Which threat model to audit. They answer different questions. A white-box gradient audit tests the *mechanism*: it asks whether the code adds the noise and clips the gradients the proof assumes, and its bound should match the accountant. A black-box input audit tests the *deployment*: it measures what an attacker with a released model and a planted record can do. A gap between the black-box bound and the accountant is not a bug; it is a measure of how far this attacker is from the proof's worst case.

47.4.5. Example: the running example's two statistics

At $q = 0.01$, $\sigma = 1$ and $T = 10{,}000$, the likelihood-ratio statistic has $\mu = 0.01 \times \sqrt{10{,}000 \times 1.7183} = 1.3108$, and the sum of projections $\mu_{\text{sum}} = 0.01 \times 100 = 1.00$ (0.9951 with the extra variance). Read through the Gaussian privacy profile, the conversion from μ to ε at a given δ (f-DP and Gaussian DP), these are $\varepsilon = 6.01$ and 4.35 at $\delta = 10^{-5}$. Choosing the sum lowers μ from 1.31 to 1.00, and the ε the audit can ever reach from 6.01 to 4.35, before a single trial is run.

47.4.6. Check yourself

- Why must the Dirac canary sit on a coordinate the other records do not touch? *(Otherwise their gradients add an unknown amount to x_t, which acts as extra noise and as a bias that differs from step to step; the audit no longer faces Equation 47.3 but a harder problem, and its bound drops.)*
- An attacker sees only θ_0 and θ_T of a run with a Dirac canary. Which statistic can it compute, and what does it lose? *(The total displacement on the canary coordinate, which is the sum of projections; it loses the per-step values, so it cannot weigh the large steps more, and its μ falls from 1.31 to 1.00.)*

47.5. Tight audits of the mechanism

47.5.1. Context

The white-box Dirac audit faces the accountant's own pair. With enough trials, does it recover the accountant's 6.71? With the trials an auditor can afford, how close does it get?

47.5.2. Statement

For any pair of distributions P (without the canary) and Q (with it), the smallest ε for which $Q(S) \le e^{\varepsilon} P(S) + \delta$ holds for every event S is

$$\varepsilon^*(\delta) = \sup_S \ \ln \frac{Q(S) - \delta}{P(S)}, \tag{47.7}$$

the supremum over events with $Q(S) > \delta$, and the supremum may be taken over likelihood-ratio thresholds only. For a μ-GDP curve the supremum is reached at the threshold whose false positive rate is

$$\mathrm{FPR}^* = \Phi\Big(-\frac{\varepsilon}{\mu} - \frac{\mu}{2}\Big), \qquad \mathrm{TPR}^* = \Phi\Big(-\frac{\varepsilon}{\mu} + \frac{\mu}{2}\Big). \tag{47.8}$$

For the running example, $\mu = 1.3108$ and $\varepsilon = 6.01$ give $\mathrm{FPR}^* = 8.1 \times 10^{-8}$ and $\mathrm{TPR}^* = 4.3 \times 10^{-5}$: certifying the full ε at $\delta = 10^{-5}$ needs to measure a false positive rate below one in ten million.

47.5.3. Derivation

1. **Equation 47.7 is the definition, solved for ε.** If ε is at least the supremum, then $\ln \frac{Q(S)-\delta}{P(S)} \le \varepsilon$ for every S, which rearranges to $Q(S) \le e^{\varepsilon} P(S) + \delta$. If ε is below it, some event has $\ln \frac{Q(S)-\delta}{P(S)} > \varepsilon$ and violates the inequality.
2. **Only likelihood-ratio thresholds matter.** For a fixed $P(S) = \mathrm{FPR}$, the ratio grows with $Q(S)$, and by Fact 3 the event with the largest $Q(S)$ among those with $P(S) = \mathrm{FPR}$ is a likelihood-ratio threshold.
3. **So a perfect audit is exact.** An audit that thresholds Λ (Equation 47.6) and measures FPR and TPR without error at every threshold computes Equation 47.7, the true $\varepsilon^*(\delta)$ of the canary's pair. For the Dirac canary this is the pair the accountant bounds, so the audit converges to DP-SGD's true ε in this direction of neighbours.
4. **The touching point.** For a μ-GDP curve, the ratio $\frac{\mathrm{TPR}-\delta}{\mathrm{FPR}}$ is largest where the line $\mathrm{TPR} = e^{\varepsilon}\,\mathrm{FPR} + \delta$ touches the curve, that is where the curve's slope is e^{ε}. The slope of a trade-off curve at a threshold is the likelihood ratio there (Fact 3's budgeting argument at the margin), which for two normals at distance μ with threshold τ is $e^{\mu\tau - \mu^2/2}$. Setting it to e^{ε} gives $\tau = \varepsilon/\mu + \mu/2$, whose FPR is $1 - \Phi(\tau) = \Phi(-\tau)$ and TPR $1 - \Phi(\tau - \mu)$: Equation 47.8.

47.5.4. Interpretation

The accountant's number is not the audit's target. The audit converges to the true ε^*, not to what an accountant reports. The RDP accountant's 6.71 is an upper bound, and a loose one: the numerical accountant of f-DP and Gaussian DP puts the true value of the running example between 6.14 and 6.24, and the CLT approximation gives 6.01. Even an audit with infinitely many trials stops about half a unit below 6.71. That gap belongs to the accountant, not to the audit.

ε at small δ lives in the extreme tail. Equation 47.8 is the main reason audits fall short. With n trials you can measure false positive rates down to about $3/n$; below that, the threshold admits no false positive and its rate is only bounded by the rule of three. At the rates you can measure, the curve's ratio TPR/FPR is far below e^{ε}. For $\mu = 1.3108$ it is $\ln(\mathrm{TPR}/\mathrm{FPR}) = 2.74$

at FPR 10^{-2}, 3.63 at 10^{-3} and 4.38 at 10^{-4}, by Equation 47.2. Reaching 6 needs FPR near 10^{-7}, and about 1.2×10^8 trials without the canary to see ten false positives there (Exercise 3 in the exercise book). Figure 47.1 shows both sides: the measured trade-off curve sits well inside the $(6.71, 10^{-5})$ limit, and the ε each threshold certifies keeps rising until FPR 10^{-7}.

Assume the shape, and extrapolate. Nasr, Hayes, Steinke, Balle, Tramèr, Jagielski, Carlini & Terzis (2023) avoid the tail by assuming the trade-off curve has a known shape. If the mechanism is μ-GDP for some μ, a single test bounds μ from below: by Equation 47.2, $\mathrm{TPR} \le \mathrm{TPR}_\mu(\mathrm{FPR})$ rearranges to

$$\mu \ge \Phi^{-1}(\mathrm{TPR}) - \Phi^{-1}(\mathrm{FPR}), \tag{47.9}$$

and a lower bound on μ converts to a lower bound on ε through the Gaussian privacy profile. The rates can be measured at a moderate FPR, where trials are cheap, and the shape carries the bound into the tail. The statement "M is not μ-GDP for any μ below this" is rigorous; the conversion to ε is valid only if the curve really is Gaussian. For the subsampled Gaussian of DP-SGD it is not exactly: its tail is heavier, and the μ that Equation 47.9 gives depends on where you read it. In the example below, the measured rates give 1.300 at FPR 10^{-1}, 1.303 at 10^{-2}, 1.371 at 10^{-3} and 1.492 at 2×10^{-4}, against the CLT's 1.3108. Their audits mostly insert the canary at every step, so that each step is an exact Gaussian mechanism, and compose the per-step result with an accountant; Section 47.8 does the same.

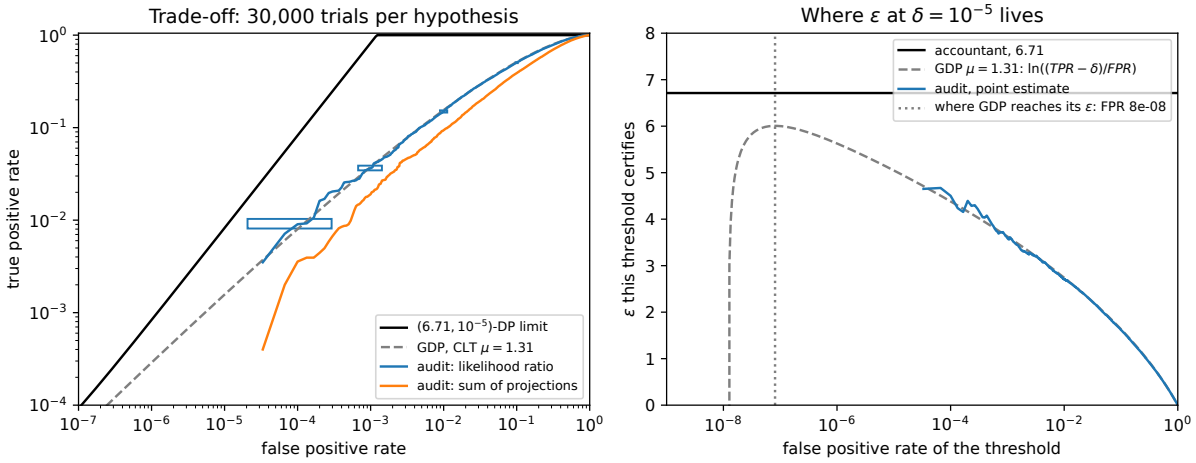

Figure 47.1.: Left: the trade-off of the white-box audit of the running example on log axes, from 30,000 trials per hypothesis. The black line is the most any test can achieve under $(6.71, 10^{-5})$-DP; the dashed grey curve is μ-GDP with the CLT's $\mu = 1.31$. The blue curve is the likelihood-ratio statistic, the orange one the sum of projections; boxes are 95% Clopper–Pearson regions at four thresholds. Right: the ε a threshold would certify if its rates were known exactly, $\ln((\mathrm{TPR} - \delta)/\mathrm{FPR})$, against its false positive rate. The Gaussian curve reaches its ε of 6.01 only at FPR 8×10^{-8} (dotted line), far below the rates a feasible audit can measure.

47.5.5. Example: auditing the running example's mechanism

The script simulates the white-box Dirac audit directly from Equation 47.3: each trial draws 10,000 projections, adds the canary on a $\mathrm{Bin}(10{,}000, 0.01)$ number of steps when it is present,

and computes Λ. This is statistically identical to training the network with a Dirac canary on an untouched coordinate, and thousands of times cheaper.

With 50,000 trials per hypothesis, the measured curve is heavier-tailed than the Gaussian approximation. At the threshold that lets through 500 false positives (FPR 10^{-2}) the TPR is 0.1530 and $\ln((\text{TPR} - \delta)/\text{FPR}) = 2.73$, as the Gaussian predicts; at 10 false positives (FPR 2.0×10^{-4}) the TPR is 0.0203 and the point value 4.62, and at 5 false positives (FPR 10^{-4}) it is 4.84, above the Gaussian's 4.38. These are point estimates, without confidence intervals. Table 47.3 gives the certified bounds, each with the threshold chosen on the first half of the trials and the counts taken on the second.

Table 47.3.: The white-box Dirac audit of the running example with the likelihood-ratio statistic, against the accountant's $\varepsilon = 6.71$. All bounds hold with probability 95%.

Trials per hypothesis	1,000	3,000	10,000	50,000
ε_{lo}, Equation 47.4	1.64	1.88	2.84	3.63
μ_{lo}, Equation 47.9 with Clopper–Pearson	0.795	1.064	1.147	1.185
ε of μ_{lo}-GDP (assumes the Gaussian shape)	3.36	4.70	5.13	5.33
Ceiling, Equation 47.5, at half the trials	4.91	6.01	7.21	8.82

The rigorous bound reaches 3.63 with 100,000 simulated training runs, about half the claim. With 10,000 runs per hypothesis its threshold lets through 6 false positives among 5,000 and catches 254 of 5,000 canaries; with 50,000 it lets through 3 among 25,000 and catches 368. The Gaussian-shape estimate climbs faster, to 5.33, and approaches the CLT's 6.01 from below. The sum of projections needs far more trials for less: its rigorous bound is 1.97 with 10,000 trials per hypothesis and 3.26 with 100,000. With 1,000,000 it is 2.27 in this run, lower than with 100,000, because a threshold chosen on 500,000 trials to let through a handful of false positives let through more on the other half. Bounds read in the far tail are noisy, and Figure 47.2 shows the same scatter. Every number in Table 47.3 is below the claim, as it must be for a correct implementation.

47.5.6. Check yourself

- A white-box audit with unlimited trials converges to 6.2, not 6.71. Is the implementation broken? *(No. The audit converges to the true $\varepsilon^*(\delta)$ of the pair, which the numerical accountant puts between 6.14 and 6.24; the RDP accountant's 6.71 is an upper bound that is loose by about half a unit.)*

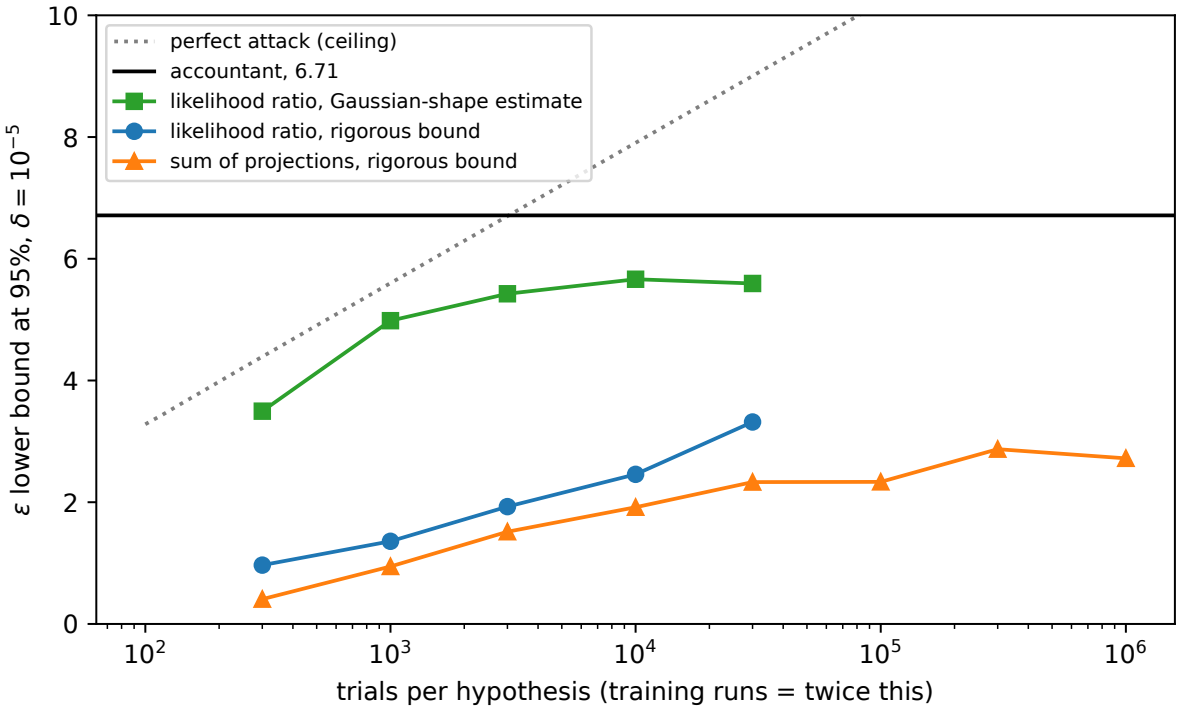

Figure 47.2.: The certified ε lower bound of the white-box audit of the running example against the number of trials per hypothesis, at 95% confidence and $\delta = 10^{-5}$: the likelihood-ratio statistic (circles), the sum of projections (triangles) and the Gaussian-shape estimate from the likelihood ratio (squares), with the accountant's 6.71 and the ceiling of a perfect attack. The bounds grow roughly like the logarithm of the number of trials.

- Why does the Gaussian-shape estimate exceed the rigorous bound with the same trials? *(It measures μ where rates are well estimated and extrapolates to the tail using the Gaussian curve; the rigorous bound only uses what was measured. The estimate is a valid bound only if the curve really is Gaussian.)*

47.6. One-run auditing

47.6.1. Context

The audits so far need one training run per trial, thousands of runs in all. For a model that takes a day to train, that is out of the question. Can one training run give a valid bound?

47.6.2. Statement

Insert m canaries, each independently with probability $\frac{1}{2}$: $S_i = +1$ if canary i is in the training set and -1 if not. Train once. Score every canary, and guess $\hat{S}_i = +1$ ("in") for the $r/2$ highest scores, $\hat{S}_i = -1$ ("out") for the $r/2$ lowest, and abstain ($\hat{S}_i = 0$) on the rest. Let W be the number of correct guesses. If training is ε-DP, then for every v

$$\Pr[W \geq v] \leq \Pr\left[\mathrm{Bin}(r, p_\varepsilon) \geq v\right], \qquad p_\varepsilon = \frac{e^\varepsilon}{1 + e^\varepsilon}. \tag{47.10}$$

If training is (ε, δ)-DP, then with $F(v) = \Pr[\mathrm{Bin}(r, p_\varepsilon) \geq v]$,

$$\Pr[W \geq v] \leq F(v) + 2m\delta \max_{i=1,\ldots,m} \frac{F(v-i) - F(v)}{i} \tag{47.11}$$

(Steinke, Nasr & Jagielski 2023, Corollary 5.4). Observing v correct guesses rejects every ε whose right-hand side is below β; the largest such ε is the bound.

47.6.3. Derivation (pure DP; the δ term is in the paper)

1. **Each inclusion bit is protected.** Fix every inclusion bit except S_i. Changing S_i adds or removes one record, so the training run, and the guesses computed from it (post-processing), are ε-DP as a function of S_i: for every vector of guesses s, $\Pr[\hat{S} = s \mid S_i = +1, S_{-i}] \leq e^\varepsilon \Pr[\hat{S} = s \mid S_i = -1, S_{-i}]$.
2. **Average over the later bits.** Order the guessed canaries. Conditioning only on the earlier bits $S_{<i}$, average step 1 over the later ones $S_{>i}$: they are independent of S_i, so the same weights appear on both sides, and $\Pr[\hat{S} = s \mid S_i = +1, S_{<i}] \leq e^\varepsilon \Pr[\hat{S} = s \mid S_i = -1, S_{<i}]$.
3. **No guess is right more than p_ε of the time.** By Bayes' rule with the prior $\frac{1}{2}$ on S_i, $\Pr[S_i = +1 \mid \hat{S} = s, S_{<i}] = \frac{x}{x+y}$ with $x = \Pr[s \mid S_i = +1, S_{<i}]$ and $y = \Pr[s \mid S_i = -1, S_{<i}]$. The fraction grows with x, and step 2 says $x \leq e^\varepsilon y$, so it is at most $\frac{e^\varepsilon y}{e^\varepsilon y + y} = \frac{e^\varepsilon}{e^\varepsilon + 1} = p_\varepsilon$. The same holds for $S_i = -1$. So whichever way canary i is guessed, it is correct with probability at most p_ε given the guesses and the earlier bits, which fix whether the earlier guesses were correct.

4. **A sum of such indicators is dominated by a binomial.** Write the j-th guess's correctness as $\mathbf{1}[U_j \le p_j]$ with U_j independent uniform numbers and $p_j \le p_\varepsilon$ its conditional probability from step 3. Then $\mathbf{1}[U_j \le p_j] \le \mathbf{1}[U_j \le p_\varepsilon]$, and the right-hand indicators sum to a $\mathrm{Bin}(r, p_\varepsilon)$ variable. So W is at most a binomial variable, and Equation 47.10 follows. Section N.1 in the appendices builds this coupling step by step and proves the domination lemma it relies on.

47.6.4. Interpretation

Randomized response is the worst case, and that sets the scale. The binomial of Equation 47.10 is what you get when each guess is ε-randomized response on the true bit (The definition of differential privacy), so the bound is tight for that mechanism (Exercise 6 in the exercise book). The paper's worked example: 75 correct out of 100 is what $\varepsilon = \ln 3$ produces on average, and Equation 47.10 gives the lower bound 0.702 at 95% confidence; the script reproduces it, and the paper's 0.699 and 0.673 for $\delta = 10^{-4}$ with 100 and 1,000 canaries.

The ceiling is again logarithmic. If all r guesses are right, the bound is the ε with $p_\varepsilon^r = \beta$, about $\ln(r/\ln(1/\beta))$: 3.49 for 100 canaries, 5.81 for 1,000 and 8.11 for 10,000, with $\delta = 0$. Certifying 6.71 needs about 2,500 canaries guessed without a single error (Exercise 5 in the exercise book). Each canary is a trial, so a one-run audit has the same ln ceiling as the many-run audit with $n \approx m$; it saves runs, not trials.

The δ term grows with the number of canaries. The correction in Equation 47.11 is at most $2m\delta$. With $m = 1{,}000$ and $\delta = 10^{-5}$ that is 0.02, small next to $\beta = 0.05$; with 10,000 canaries all guessed right the bound falls from 8.11 to 7.83. When $2m\delta$ approaches the significance level, the correction can swallow the whole budget: no number of correct guesses rejects anything.

One run is not tight for DP-SGD. Even with white-box Dirac canaries, the one-run bound stays well below the many-run bound. Each canary is guessed once, at a fixed fraction of guesses, so the audit reads the trade-off curve near FPR $1/m$ at best; and the binomial is calibrated to randomized response, whose curve has a sharp corner, while the curve of DP-SGD is smooth. Steinke et al. show that their bound is exact for randomized response; for DP-SGD their one-run bounds stay below the theoretical ε even with white-box gradient canaries.

47.6.5. Example: Dirac canaries in one run

Simulate one run of the running example with 1,000 Dirac canaries on distinct untouched coordinates, about half included, each scored by Λ. The auditor tries six list lengths r and pays for trying them with a Bonferroni correction: each test runs at level $\beta/6$, so that the chance that any of the six is wrong is at most β. Table 47.4 gives the result.

Table 47.4.: One-run audit of the running example's mechanism with 1,000 white-box Dirac canaries, at 95% overall confidence and $\delta = 10^{-5}$.

Guesses r	20	50	100	200	500	1,000
Correct, white-box Dirac canaries	20	50	92	185	425	745
ε_{lo} (Bonferroni over the six)	1.21	2.22	1.58	1.88	1.43	0.90

All 50 most confident guesses are right, which certifies 2.22; the 100-guess list makes 8 mistakes and certifies less. With 5,000 canaries the best bound is 2.53, from 479 correct out of 500. There the δ correction shows its teeth: $2m\delta = 0.1$ exceeds the per-test level $\beta/8$, and 20 correct guesses out of 20 certify nothing at all. One run certifies 2.22, against 2.84 for 10,000 runs per hypothesis in Table 47.3, at a twenty-thousandth of the cost.

47.6.6. Check yourself

- Why must each canary be included by an independent fair coin, rather than, say, the first half included? *(Step 3 uses the prior $\frac{1}{2}$ on S_i and step 2 the independence of the bits. With a deterministic split, the guesses could be right for reasons that have nothing to do with the training run, for example the order of the canaries.)*
- 960 correct guesses out of 1,000 under pure DP: is $\varepsilon = 2$ rejected? *(Yes. Under $\varepsilon = 2$, $p_\varepsilon = 0.881$, so the binomial has mean 881 and standard deviation about $\sqrt{1{,}000 \times 0.881 \times 0.119} = 10.2$; 960 is almost eight standard deviations above.)*

47.7. Black-box audit of the trained network

47.7.1. Context

The white-box Dirac audit tests the mechanism. What does an attacker learn from the released network itself, with canaries that are ordinary records?

47.7.2. Statement: the protocol

Take 1,000 records from the held-out test set of the running example and flip their labels: **mislabeled canaries**, which the model can only fit by memorizing them. Include each in the 10,000 training records with probability $\frac{1}{2}$, train once with DP-SGD at the claimed configuration, and score each canary by minus its loss on the final model: a canary the model fits well was probably trained on. Guess with the six list lengths of Section 47.6 and bound ε with Equation 47.11,

Bonferroni-corrected. As controls, run the same audit on a model trained with clipping but no noise, and on a model trained without clipping or noise.

The bound is valid for the add/remove neighbours of any canary, because including a canary is adding a record, and all the guarantees of DP-SGD hold for every dataset, including one with planted records.

47.7.3. Interpretation

Before the numbers, what to expect. The black-box attacker sees one function of the 10,000 noisy sums, the canary's gradient changes as it is fitted, and its direction is shared with the gradients of the 10,000 real records, which pull the other way since the canary's label is wrong. Each of these weakens the audit relative to Section 47.5. Nothing in the accountant knows about them: the accountant bounds the worst dataset, the worst record and an attacker who sees every step. So the black-box bound should be far below 6.71, and the gap measures this attacker, not the privacy of the algorithm.

The no-noise control separates the two. A model trained with clipping and no noise has no finite ε at all. If the black-box audit of that model also gives a small bound, then the audit's weakness, not the noise, is what keeps the bound small.

47.7.4. Example: three training runs

Table 47.5 gives the three audits, one training run each.

Table 47.5.: Black-box one-run audit of the running example's network with 1,000 mislabeled canaries, one training run each, at 95% overall confidence and $\delta = 10^{-5}$. Test accuracy is on the 19,000 test records not used as canaries.

Training	Test accuracy	Mean loss, in	Mean loss, out	Correct of $r = 100$	Correct of $r = 1{,}000$	Best ε_{lo}
DP-SGD, $\sigma = 1$, claim $\varepsilon = 6.71$	0.9645	5.565	6.013	59	556	0.13
Clipping only, $\sigma = 0$, $\varepsilon = \infty$	0.9638	5.511	6.155	67	589	0.24
Non-private, no clipping	0.9155	0.023	9.041	91	967	2.96

The non-private model memorizes the canaries it trained on: their mean loss is 0.023 against 9.041 for those it did not see, 967 of 1,000 guesses are right, and the audit certifies 2.96; 1,000 perfect

guesses would certify 5.78 at $\delta = 10^{-5}$ even without the Bonferroni correction, so 33 mistakes cost almost three units. Memorizing 481 contradictory labels costs it almost five points of test accuracy, 0.9155 against the DP model's 0.9645. DP-SGD does not memorize: the losses of included and excluded canaries differ by less than half a unit on average, 59 of the 100 most confident guesses are right, and the certified bound is 0.13 (from 293 of 500, the best list). The clipping-only model is barely easier, 0.24. So with $\sigma = 1$ removed, the black-box attacker still learns almost nothing. Clipping alone bounds each canary's pull on the weights to C per step, against the combined pull of 10,000 correctly labelled records, and that is what defeats this attacker. Figure 47.3 shows the loss distributions and how the fraction of correct guesses falls as the list grows.

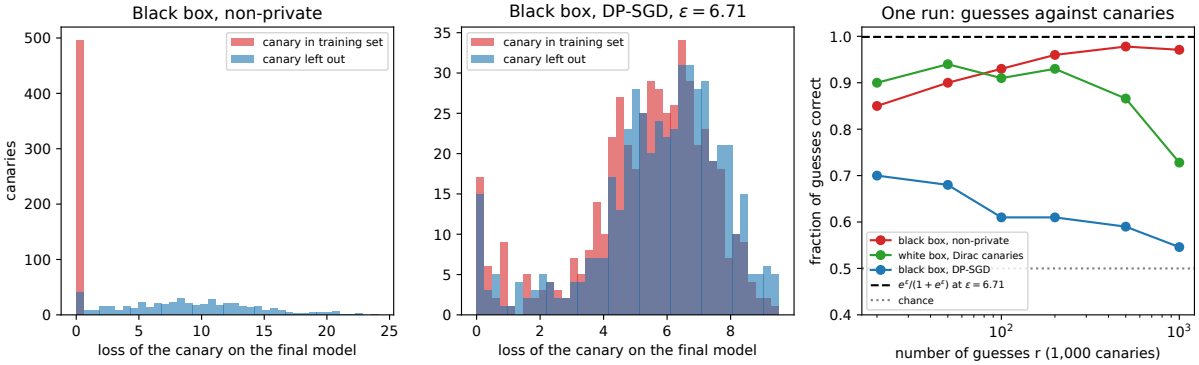

Figure 47.3.: One-run audits with 1,000 canaries. Left and middle: the loss of each mislabeled canary on the final model, for canaries in the training set (red) and left out (blue), without privacy and with DP-SGD at $\varepsilon = 6.71$. Right: the fraction of the r guesses that are correct, against r, for the non-private network (black box), the DP-SGD network (black box) and the mechanism with white-box Dirac canaries; the dashed line is the most a 6.71-DP algorithm allows on average, $e^{\varepsilon}/(1 + e^{\varepsilon})$.

What this says about the claim. Nothing contradicts 6.71, and nothing confirms it. The black-box bound of 0.13 says that a realistic attacker, with one model and planted mislabeled records, extracts very little; the white-box audits of Section 47.5 say that an attacker who sees every step and controls a gradient extracts much more. Reporting both, with the threat model of each, is what an honest privacy statement does (Choosing an accountant lists what else it must contain).

47.7.5. Check yourself

- The audit of the clipping-only model gives 0.24. Does that mean clipping alone is 0.24-DP? *(No. The model has no finite ε: a Dirac gradient canary seen white-box would identify membership perfectly. The bound says only that this black-box attack, with these canaries, cannot show more.)*
- Why mislabeled canaries rather than random test records? *(A correctly labelled record from the data distribution has a small gradient and nearly the same loss whether or not it was trained on, so the audit would learn even less; a mislabeled one can only be fitted by memorizing it, which is the leakage the audit looks for.)*

47.8. Finding bugs

47.8.1. Context

An audit bound below the claim proves nothing. A bound above it proves, with confidence $1-\beta$, that the claim is false. That makes audits a test suite for private training code: the test passes silently on a correct implementation and fails loudly on a broken one. Which bugs does it catch, and how cheaply?

47.8.2. Statement

A **per-step audit** inserts a Dirac canary at every step (a sampling rate of 1 for the canary, $q_c = 1$) in one run and leaves it out in another, and treats each step's projection as one trial: T trials per hypothesis from two runs. In a correct implementation each step is a Gaussian mechanism with sensitivity C and noise σC, so the projections are

$$x_t \sim \mathcal{N}(0, \sigma^2) \text{ without the canary}, \qquad x_t \sim \mathcal{N}(1, \sigma^2) \text{ with it}, \tag{47.12}$$

and each step is exactly μ-GDP with $\mu = 1/\sigma$. The audit's μ_{lo} from Equation 47.9 with Clopper–Pearson rates is a rigorous lower bound on the per-step μ. If $\mu_{\text{lo}} > 1/\sigma$, the implementation does not add the noise it claims.

An **end-to-end audit** with the many-trial protocol of Section 47.5 tests everything at once, sampling and accounting included, but needs many runs.

47.8.3. Derivation

1. **One step with the canary always present is a Gaussian mechanism.** With $q_c = 1$ there is no sampling coin for the canary, so Fact 4 gives Equation 47.12: a shift of 1 in noise of standard deviation σ. By Fact 3 the best test thresholds x_t itself, and its trade-off curve is Equation 47.2 with $\mu = 1/\sigma$.
2. **The steps are independent trials.** The noise is fresh at every step and the canary's gradient is fixed, so the T projections of each run are independent, and the counts at a fixed threshold are binomial.
3. **The bound on μ.** For any threshold, a μ-GDP step has $\text{TPR} \le 1 - \Phi(\Phi^{-1}(1-\text{FPR}) - \mu)$, which rearranges to Equation 47.9. Replacing the rates by their Clopper–Pearson bounds can only lower the right-hand side (it grows with the TPR and shrinks with the FPR), so with probability $1-\beta$ the true per-step μ is at least μ_{lo}.
4. **A refutation.** A correct implementation has $\mu = 1/\sigma$, so $\mu_{\text{lo}} > 1/\sigma$ happens with probability at most β. Observing it rejects the hypothesis that the code adds noise σC to a sum with sensitivity C.

47.8.4. Interpretation

Per-step audits test the noise and the clipping; they cannot see the sampling or the accountant. With the canary in every step, the audit never exercises the sampling code, and it compares the measured noise with the claimed σ, not with the claimed ε. A bug in how batches are drawn, or in what the accountant is told, passes it. Nasr et al. (2023) audit one step for this reason and say so; they caught clipping applied after averaging, noise drawn from a seed with only 100 possible values (a similar error appeared in a canonical JAX example of DP-SGD), and a wrong noise scale.

End-to-end audits see everything, but only large bugs. An end-to-end audit tests the claimed ε directly, so it catches an accounting bug as readily as a noise bug, provided the true ε exceeds the claim by more than the audit's shortfall. From Section 47.5, that shortfall is about three units at 100,000 runs for the running example. Tramèr, Terzis, Steinke, Song, Jagielski & Carlini (2022) used such an audit to show that an open-source implementation of a differentially private deep-learning algorithm violated its claimed guarantee, at a confidence they report as $1 - 10^{-10}$.

What no canary audit catches. An audit tests one dataset, one canary and one attack. A bug that only shows on datasets or records the audit did not try, or that raises ε by less than the audit's shortfall, passes. Sampling bugs are the instructive case. Batches drawn by shuffling but accounted as Poisson can have an ε several times the reported one (Amplification by subsampling derives a lower bound that shows it), yet a per-step audit with the canary in every step never exercises the sampling, and an end-to-end audit sees the gap only where it exceeds the audit's shortfall. Passing an audit is evidence, never a certificate.

47.8.5. Example: three implementations and an accounting bug

Table 47.6 audits three implementations of the running example's noise, each with two runs of 10,000 steps, and an accounting bug.

Table 47.6.: Per-step audits of three implementations of the running example's DP-SGD step, from 10,000 steps with and 10,000 without a Dirac canary, at 95% confidence. The last column is what the RDP accountant would report for the noise the audit measured.

Implementation	Noise on the sum	Claimed per-step μ	Audited μ_{lo}	Accountant at $\sigma = 1/\mu_{\text{lo}}$	Verdict
Correct	σC	1	0.886	5.38	consistent
Variance passed as a standard deviation	$\sigma^2 C^2 = 0.5\,C$	1	1.745	29.27	refuted
Noise scaled for the mean, added to the sum	$\sigma C/B = 0.01\,C$	1	6.359	over 4,700	refuted

The correct implementation passes: 0.886 is below its claimed 1, and plugged into the accountant it gives 5.38, close to but below 6.71. The two noise bugs fail decisively. Passing $\sigma^2 C^2 = 0.25$ where the code expects a standard deviation halves the noise when $C = 0.5$, and the audit measures $\mu_{\text{lo}} = 1.745$ against the claimed 1. Scaling the noise for the averaged gradient, whose sensitivity is C/B, and then adding it to the sum, whose sensitivity is C, makes it $B = 100$ times too small, and 10,000 steps separate the two hypotheses perfectly: 6.359 is the most Equation 47.9 can certify from 5,000 error-free trials per hypothesis, the evaluation half. The same bug also fails an end-to-end audit with the sum of projections: with 10,000 runs per hypothesis, the threshold catches all 5,000 canaries of the evaluation half with one false positive, and $\varepsilon_{\text{lo}} = 7.21 > 6.71$.

The accounting bug: the code is correct, but the accountant is told the dataset has 20,000 records instead of 10,000, as can happen when augmented copies are counted, so it computes $q = 0.005$ and reports $\varepsilon = 3.06$. The per-step audit measures the noise, which is right, and composing its μ_{lo} at the claimed $q = 0.005$ gives 2.47, which does not contradict 3.06. The end-to-end audit of Table 47.3 does: its 3.63 with 50,000 trials per hypothesis exceeds 3.06, so the claim is false with 95% confidence. Figure 47.4 shows why the two noise bugs are easy to see.

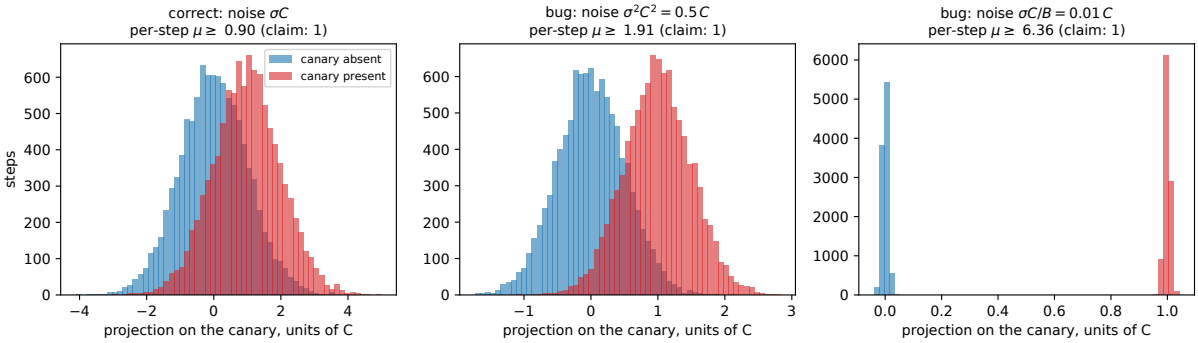

Figure 47.4.: Per-step audits of three implementations: the projections of 10,000 steps on a Dirac canary, without it (blue) and with it at every step (red), in units of C. A correct implementation has noise of standard deviation σC; the two bugs shrink it by a factor of 2 and of 100. The titles give the certified lower bound on the per-step μ; the claim is 1.

47.8.6. Check yourself

- A per-step audit of your implementation gives $\mu_{\text{lo}} = 0.97$ for a claimed $\sigma = 1$. Can you conclude the implementation is correct? *(No. A lower bound on μ can show that μ is too large, never that it is small enough: 0.97 is consistent with the claimed $\mu = 1$, and also with noise a little too small. And the audit says nothing about the sampling, the accountant or bugs that do not affect a Dirac canary.)*
- The opposite mistake adds noise σC to the averaged gradient instead of to the sum. Would an audit flag it? *(No. Noise σC on the mean is noise σCB on the sum, B times more than claimed: the implementation is more private than its claim and every audit passes. It is still a bug, since it wastes accuracy, but audits only catch errors in the unsafe direction.)*

47.9. Code: run every audit

The script code/auditing.py implements the Clopper–Pearson bounds from the incomplete beta function, the bound of Equation 47.4 with thresholds chosen on half the trials, the white-box simulation of Equation 47.3 with both statistics, the one-run bound of Equation 47.11, the black-box audit of the running example's network (importing the model and DP-SGD from code/dp_sgd.py) and the per-step audits. From the repository root:

```
uv run python code/part05-dp-ml/auditing.py
```

It takes a few minutes, most of it simulating 100,000 white-box trials of 10,000 steps each and training three networks.

Output (seed 0), summarized in Table 47.7:

Table 47.7.: The script's output with the default seed.

Experiment	Result
Clopper–Pearson, $k = 10$ of 10,000	$[0.00048, 0.00184]$, as in Part 1
One-run bound, the paper's examples	0.702, 0.699 and 0.673, as published
Ceiling of a perfect attack	5.60 with 1,000 trials, 7.90 with 10,000; 3,038 needed for 6.71
White-box Dirac audit, likelihood ratio	$\varepsilon_{\text{lo}} = 3.63$ with 50,000 trials per hypothesis
Same, Gaussian-shape estimate	5.33, against the CLT's 6.01
One run, 1,000 white-box Dirac canaries	2.22
One run, black box, mislabeled canaries	0.13 with DP-SGD, 0.24 with clipping only, 2.96 non-private
Per-step audits	Correct 0.886 against a claim of 1; bugs 1.745 and 6.359

tests/test_auditing.py checks that the output still matches.

What to take from it. The bounds are valid but conservative, and they grow only like the logarithm of the effort. An audit is most useful as a test: the strongest attack you can mount, white-box with a gradient canary, aimed at the claim you want to check. A correct implementation passes it with room to spare, and the two noise bugs fail it with margins no amount of bad luck explains.

47.11. Cheat sheet

Canary in (D') or out (D); FPR and TPR of the attack's threshold test; n trials per hypothesis; Clopper–Pearson bounds $\overline{\text{FPR}}$ and $\underline{\text{TPR}}$ at $\beta/2$. Table 47.8 collects the results.

Table 47.8.: Every result of the chapter.

Result	Formula	Conditions
DP caps every test	$\text{TPR} \le e^{\varepsilon}\text{FPR} + \delta$, $1 - \text{FPR} \le e^{\varepsilon}(1 - \text{TPR}) + \delta$	Any test, any neighbours
Certified bound	$\max\{\ln \frac{\underline{\text{TPR}} - \delta}{\overline{\text{FPR}}}, \ln \frac{1 - \overline{\text{FPR}} - \delta}{1 - \underline{\text{TPR}}}\}$	Independent trials; threshold chosen on other trials
Ceiling	$\approx \ln(n/\ln(2/\beta))$: 5.60 at $n = 1{,}000$, 7.90 at 10,000	Perfect attack
Best statistic, Dirac canary	$\Lambda = \sum_t \ln(1 - q + qe^{(x_t - 1/2)/\sigma^2})$	White box, untouched coordinate
Gaussian approximations	$\mu = q\sqrt{T(e^{1/\sigma^2} - 1)}$; sum of projections $q\sqrt{T}/\sigma$	CLT regime
Where ε lives	FPR $\Phi(-\varepsilon/\mu - \mu/2)$: 8.1×10^{-8} for the running example	μ-GDP
GDP bound from one test	$\mu \ge \Phi^{-1}(\text{TPR}) - \Phi^{-1}(\text{FPR})$	Rigorous for μ; for ε only if the curve is Gaussian
One run	$W \preceq \text{Bin}(r, \frac{e^{\varepsilon}}{1+e^{\varepsilon}})$, plus $2m\delta$-type correction	Canaries included by independent fair coins

Result	Formula	Conditions
Per-step audit	$x_t \sim \mathcal{N}(0, \sigma^2)$ vs $\mathcal{N}(1, \sigma^2)$; claim $\mu = 1/\sigma$	Canary at every step; tests noise and clipping only

Rules of thumb

- An audit can refute a claim, never prove one. Report its threat model with its number.
- Budget trials before you start: certifying ε needs at least $e^{\varepsilon} \ln(2/\beta)$ trials per hypothesis, and in practice far more, because ε at small δ lives at false positive rates you cannot measure.
- To test an implementation, use the strongest attack: white box, Dirac gradient canary, likelihood ratio. Audit the noise per step and the claim end to end.
- Choose thresholds and list lengths on separate data, or pay for the choice with a Bonferroni correction.
- Read a small black-box bound as a statement about the attacker, not as the model's privacy.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

48. Adaptive data analysis

48.1. Why this matters

Every chapter so far has used differential privacy (DP) to protect the people in a dataset. This chapter uses it for a different purpose: to keep a data analysis honest. Machine learning reuses its evaluation data all the time. You tune hyperparameters on a validation set, look at the scores, and try new settings. Likewise, a competition shows a leaderboard score after every submission and teams adjust to it, while a benchmark test set is used by a whole field for a decade. In each case the next question asked of the data depends on the answers to the previous ones. **How many such questions can one holdout set answer before its answers stop telling you anything about new data?**

The answer depends on how the questions are answered. If you report exact averages on the holdout set, answers break quickly. When the holdout labels are coin flips, so that no model can beat 50% on new data, a thousand random submissions to a leaderboard of 1,000 records are enough to make one look 72% accurate. If you split the holdout set and answer each question on its own fresh part, the answers stay valid, but the data you need grows linearly with the number of questions. A DP mechanism does much better: adding Gaussian noise to each answer makes the data you need grow only like the square root of the number of questions. When there is also a training set to explore freely, the **reusable holdout** does better still: it adds noise, and pays privacy, only for the questions whose answers on the holdout set disagree with the training set.

48.1.1. The one idea: an answer that reveals little about any one record cannot be overfitted

Overfitting a holdout set means choosing questions that fit its particular records. To do that, the analyst must learn something about those records from the earlier answers. A DP mechanism limits what any answer, and any sequence of answers, reveals about a single record, so it stops the overfitting. The proof reuses the main identity of Algorithmic stability and generalization in Part 1, which Section 48.5 restates. There, the expected gap between a chosen question's value on the sample and on the population is an average, over records, of how much the chosen question's value on a record changes when that record is replaced by a fresh one. Part 1 bounded each such term by the uniform stability of one fixed algorithm. DP bounds each term whatever the analyst does with the answers, because DP survives post-processing and adaptive composition, while uniform stability survives neither (Section 48.5 explains why).

Table 48.1 lists the results and where each is used.

Table 48.1.: The results of this chapter and where each is used.

Result	Where it is used
Fixed questions need records growing like $\ln k$; one adaptive question can break exact answers	Recognizing when a reused holdout set is invalid
Sample splitting costs k	The baseline every method must beat; final test sets
DP implies generalization (transfer lemma and theorem)	Turning any DP mechanism into a valid answering procedure
Gaussian noise answers k adaptive questions to accuracy α with about $\sqrt{k}/\alpha^2$ records	Sizing a holdout set for an interactive analysis
The reusable holdout (Thresholdout)	Confirming findings from a training set on a holdout set
What it means for practice	Hyperparameter search, leaderboards, benchmark reuse

Notation. The data are a sample of n records, the dataset $D = (x_1, \dots, x_n)$. The records are drawn independently from a distribution $\mathcal{D}$, the population, and each record x_i holds features and label together. A **statistical query** is a function q from one record to $[0, 1]$, such as "does this classifier get this record right?". Its **empirical value** is its average over the sample, $q(D) = \frac{1}{n}\sum_i q(x_i)$, and its **population value** is its average over the distribution, $q(\mathcal{D}) = \mathbb{E}_{x\sim\mathcal{D}}\, q(x)$.

An **analyst** asks k queries, q_1 to q_k, one at a time. A mechanism M answers each of them, giving the number a_j for query q_j. Because the analyst may choose each query from the earlier answers, the analysis is **adaptive**. Write $D^{(i)}$ for the sample with x_i replaced by an independent fresh draw x_i'. Samples that differ in one record, such as D and $D^{(i)}$, are neighbours under the **replace-one relation**. Under this relation, every statistical query has sensitivity $1/n$, since one record moves an average of n values in $[0, 1]$ by at most $1/n$. The goal is **accuracy against the population**. The largest error $\max_j |a_j - q_j(\mathcal{D})|$ should be at most a target accuracy α, either on average or with probability at least $1 - \beta$ for a small failure probability β.

How to read this chapter. Section 48.3 shows the problem and Section 48.4 the simple fix. Section 48.5 is the key result, and its proof is short. Section 48.6 turns it into a rate, Section 48.7 into the reusable holdout, and Section 48.8 into advice for machine-learning practice.

48.2. Toolkit: four facts every derivation uses

48.2.1. Fact 1 — The largest of many averages: the maximal inequality

Each empirical value is an average of n independent values in $[0, 1]$, so its error, written $Z = q(D) - q(\mathcal{D})$, is rarely large. Hoeffding's lemma (Concentration inequalities) makes this precise through the moment generating function. For a query fixed before the sample is drawn, and for every real λ,

$$\mathbb{E}\, e^{\lambda Z} \le e^{\lambda^2 v/2}, \qquad v = \frac{1}{4n}. \tag{48.1}$$

The value of v comes from applying the lemma to each of the n centred terms, each scaled by $1/n$ and so lying in a range of length $1/n$, which gives $e^{\lambda^2/(8n^2)}$ per term. Independence multiplies the n bounds to $e^{\lambda^2/(8n)}$. A variable with this property is called **sub-Gaussian with variance proxy** v, because a Gaussian variable with variance σ^2 has the property with $v = \sigma^2$, as an equality.

The fact this chapter uses is about the largest of many such variables. If $Z_1, \dots, Z_m$ are each sub-Gaussian with variance proxy v, whatever their dependence, then

$$\mathbb{E}\Big[\max_{j \le m} Z_j\Big] \le \sqrt{2v \ln m}. \tag{48.2}$$

The reason is that the exponential of a maximum is at most the sum of the exponentials. For $\lambda > 0$, Jensen's inequality for the convex function e^x gives $e^{\lambda\, \mathbb{E} \max_j Z_j} \le \mathbb{E}\, e^{\lambda \max_j Z_j}$. The exponential of the maximum is at most the sum of all m exponentials, and each has expectation at most $e^{\lambda^2 v/2}$, so the right side is at most $m\, e^{\lambda^2 v/2}$. Taking logarithms and dividing by λ gives $\mathbb{E} \max_j Z_j \le \ln m/\lambda + \lambda v/2$, and the choice $\lambda = \sqrt{2 \ln m / v}$ gives Equation 48.2. For k queries, write $Z_j = q_j(D) - q_j(\mathcal{D})$ for the error of query j. Applied to the $2k$ variables $\pm Z_j$, the inequality bounds the largest error in absolute value, with $m = 2k$.

48.2.2. Fact 2 — Renaming a record and a fresh draw

The stability chapter's main identity rests on one observation. Suppose x_i and the fresh draw x_i' are independent and have the same distribution, and both are independent of the other records and of an algorithm's own coins. Then swapping them does not change the joint distribution of all these random quantities. So any expectation computed from (D, x_i') equals the same expectation computed after the swap, from $(D^{(i)}, x_i)$. Write $q_{W(D)}$ for the query that a randomized algorithm W outputs on the dataset D (the chapter shortens it to q_W when the sample is clear). Then

$$\mathbb{E}[q_{W(D)}(x_i')] = \mathbb{E}[q_{W(D^{(i)})}(x_i)]. \tag{48.3}$$

The left side is the population value of the chosen query, because x_i' is a new record that W never saw. Averaging over x_i' alone, with D and W's coins fixed, gives $q_{W(D)}(\mathcal{D})$. The right side is the value of a query chosen *without* x_i on the record x_i. The stability chapter walks through the swap on a table of every outcome.

48.2.3. Fact 3 — DP bounds the average of any bounded function of the output

Differential privacy has two parameters, a privacy level ε and a slack δ. A mechanism M is (ε, δ)-DP when replacing a dataset D by a neighbour D' multiplies the probability of every set of outputs S by at most e^{ε}, up to the slack δ (The definition):

$$\Pr[M(D) \in S] \le e^{\varepsilon} \Pr[M(D') \in S] + \delta. \tag{48.4}$$

The derivations need the same bound for averages. For every function f of the output with values in $[0, 1]$,

$$\mathbb{E}\big[f(M(D))\big] \le e^{\varepsilon}\, \mathbb{E}\big[f(M(D'))\big] + \delta. \tag{48.5}$$

To see this, write the average of a quantity between 0 and 1 as the integral of its tail. For a random output Y, the average of $f(Y)$ is the integral, over thresholds t from 0 to 1, of the chance that $f(Y)$ exceeds t:

$$\mathbb{E}[f(Y)] = \int_0^1 \Pr[f(Y) > t]\, dt. \tag{48.6}$$

Each tail is the probability of an event, so DP bounds it by e^{ε} times the tail for D', plus δ. Integrating over t from 0 to 1 gives Equation 48.5, because the δ integrates to δ.

Two properties of DP make this useful against an analyst (Post-processing, group privacy and composition). **Post-processing**: any computation on the output that does not touch the data is as private as the output. **Adaptive composition**: a sequence of mechanisms, each chosen from the earlier outputs, is private with parameters that add up, or that grow more slowly under the accountants of Composition. The analyst's choice of each query is post-processing of the earlier answers, and the answers to those chosen queries compose adaptively. So the whole transcript of queries and answers inherits the guarantee of the answering mechanism, however clever the analyst. The derivations swap one record for a fresh one, so the guarantees here are for the replace-one relation. A mechanism that is ε-DP for adding or removing a record is 2ε-DP for replacing one. An (ε, δ)-DP mechanism becomes $(2\varepsilon, (1 + e^{\varepsilon})\delta)$-DP.

48.2.4. Fact 4 — The Gaussian mechanism in zero-concentrated DP

Zero-concentrated differential privacy (zCDP) measures privacy by one number ρ, which bounds the Rényi divergence between the outputs on neighbours by ρ times the order. Adding Gaussian noise of standard deviation σ to a query of sensitivity Δ satisfies zCDP with $\rho = \Delta^2/(2\sigma^2)$. Under adaptive composition the values of ρ add, and a ρ-zCDP mechanism is (ε, δ)-DP for every $\delta > 0$ with

$$\varepsilon = \rho + 2\sqrt{\rho \ln(1/\delta)} \tag{48.7}$$

(Concentrated differential privacy). For k statistical queries, with $\Delta = 1/n$, the total is $\rho = k/(2n^2\sigma^2)$. Because ε grows like $\sqrt{\rho}$ when ρ is small, at a fixed noise level and sample size it grows like $\sqrt{k}$ in the number of queries. That $\sqrt{k}$ is the one this chapter's rate inherits.

48.3. Reusing a holdout set overfits

48.3.1. Context

A holdout set gives an unbiased verdict on a model that was fixed before the holdout set was drawn. The trouble starts on the second question. In a hyperparameter search, a competition or a benchmark, the analyst sees an answer and lets it shape the next question. How quickly does that go wrong, and how many questions does it take?

48.3.2. Statement

Fixed queries. If the k queries are chosen before the sample is drawn, their empirical values are accurate, and the number of queries enters only through its logarithm. On average,

$$\mathbb{E}\Big[\max_{j\le k}\big|q_j(D)-q_j(\mathcal{D})\big|\Big]\le\sqrt{\frac{\ln(2k)}{2n}},\tag{48.8}$$

and all k errors are below α with probability at least $1-\beta$ once

$$n\ge\frac{\ln(2k/\beta)}{2\alpha^2}.\tag{48.9}$$

At $\alpha=\beta=0.05$, ten queries need 1,199 records. A thousand queries need 2,120, and a million need only 3,501.

One adaptive query, after many fixed ones, is enough to break this. Let the records be uniform on N values, labelled $1,\dots,N$. The analyst asks the N point queries $q_v(x)=\mathbf{1}[x=v]$, one per value, which are fixed in advance. Their empirical values say exactly which values occur in the sample. Then the analyst asks one more query, chosen from those answers: "is this record's value one of those that occur in the sample?". Its empirical value is 1, while its population value is the fraction of the N values that the sample covers, at most n/N. So with $k=N+1$ queries the largest error is

$$\max_j\big|q_j(D)-q_j(\mathcal{D})\big|\ge 1-\frac{n}{N}=1-\frac{n}{k-1}.\tag{48.10}$$

With exact empirical answers, n must therefore grow linearly in k to keep the error below $\frac{1}{2}$, against $\ln k$ for fixed queries.

48.3.3. Derivation

1. **Fixed queries, on average.** For a query fixed in advance, Fact 1 says the error $q_j(D)-q_j(\mathcal{D})$ is sub-Gaussian with variance proxy $1/(4n)$, and so is its negative. The maximal inequality Equation 48.2 over these $2k$ variables, with $v=1/(4n)$, gives $\sqrt{2\ln(2k)/(4n)}$, which is Equation 48.8.
2. **Fixed queries, with high probability.** Hoeffding's inequality bounds the chance that one error exceeds α by $2e^{-2n\alpha^2}$, so the union bound over k queries bounds the chance that any of them does by $2ke^{-2n\alpha^2}$. Setting this equal to β and solving for n gives the sample size of the statement.
3. **Where adaptivity enters.** Step 1 needs q_j fixed while the records are drawn, so that $q_j(x_1),\dots,q_j(x_n)$ are independent draws with mean $q_j(\mathcal{D})$. The final query of the attack is built from the sample, so its values on the sample's records are all 1, whatever $\mathcal{D}$ is.
4. **The attack's population value.** The final query is 1 exactly on the distinct values in the sample, of which there are at most n. Each value has probability $1/N$, so the population value is at most n/N. Averaged over samples, the population value is exactly $1-(1-1/N)^n$, because a given value is missed by all n draws with probability $(1-1/N)^n$.

48.3.4. Interpretation

The point queries are harmless one at a time: each of their errors is tiny. Together they reveal the sample, and the damage is done by one query that the revealed sample makes possible. That is the general shape of adaptive overfitting. Earlier answers carry information about individual records, and a later query exploits it.

Real analysts leak more slowly than this attack, but they leak. **Freedman's paradox** (Freedman 1983) is the statistical version. Screen many candidate variables on a sample, keep those that look related to the outcome, and test the kept ones on the same sample, and the test looks significant even when every variable is noise. Part 1's stability chapter runs this experiment on a holdout set (Choosing what to measure after looking). The **boosting attack** of Blum & Hardt (2015) is the leaderboard version. Its queries are random submissions, and it combines the ones that happened to score above chance by a majority vote.

48.3.5. Example: the point-query attack and a leaderboard

With $n = 1{,}000$ records on $N = 2{,}000$ values, the 2,000 point queries are all within 0.0035 of their population values in one run of the chapter's script. The final query has empirical value 1 and population value 0.3905, against an expected $1-(1-1/2{,}000)^{1{,}000} = 0.3935$. So its error is about 0.61, while Equation 48.8 would bound the average largest error of 2,001 fixed queries by 0.0644. With $N = 10{,}000$ values the error is about 0.90.

The boosting attack is closer to practice. The holdout labels are n fair coins, so no submission can beat 50% on new data. The attacker submits k random labellings and reads each one's exact accuracy. Then it submits the majority vote of those that scored above 50%. Table 48.2 averages 20 runs.

Table 48.2.: The boosting attack against a leaderboard that reports exact holdout accuracy, averaged over 20 runs. The final submission's true accuracy is exactly 0.5.

Holdout n	Submissions k	Reported accuracy of the final submission	Overfitting	Approximation $\sqrt{k/(2n)}/\pi$	Bound Equation 48.8 for $k+1$ fixed queries
1,000	10	0.5224	0.0224	0.0225	0.0393
1,000	100	0.5739	0.0739	0.0712	0.0515
1,000	1,000	0.7182	0.2182	0.2251	0.0617
10,000	100	0.5227	0.0227	0.0225	0.0163
10,000	1,000	0.5712	0.0712	0.0712	0.0195
10,000	10,000	0.7142	0.2142	0.2251	0.0223

The overfitting grows like $\sqrt{k/n}$, and a short argument predicts its constant. A random submission's accuracy is $\frac{1}{2}$ plus an error of standard deviation $1/(2\sqrt{n})$, approximately normal. Given that the error is positive, its average is $\frac{1}{2\sqrt{n}}\sqrt{2/\pi}$, the mean of a half-normal. The accuracy is the average agreement over the records, and the records are interchangeable, so a kept submission agrees with each holdout label with probability $\frac{1}{2} + \frac{1}{2\sqrt{n}}\sqrt{2/\pi}$. About $k/2$ submissions are kept.

On each record the vote is then a sum of $k/2$ terms of ± 1. Each term has mean twice the excess agreement, $\frac{1}{\sqrt{n}}\sqrt{2/\pi}$, so the sum has mean $k\sqrt{2/\pi}/(2\sqrt{n})$, and its standard deviation is about $\sqrt{k/2}$. Their ratio is $\sqrt{k/n}/\sqrt{\pi}$. A normal sum with a small mean-to-spread ratio z is positive with probability $\Phi(z) \approx \frac{1}{2} + z/\sqrt{2\pi}$, the first-order expansion of the normal distribution function. So the vote is right with probability about $\frac{1}{2} + z/\sqrt{2\pi}$, which gives

$$\text{overfitting} \approx \frac{1}{\sqrt{2\pi}} \cdot \frac{\sqrt{k/n}}{\sqrt{\pi}} = \frac{\sqrt{k/(2n)}}{\pi}. \tag{48.11}$$

The approximation matches the simulation until the overfitting is large, where the first-order expansion of Φ overstates it, since an accuracy cannot pass 1 (Figure 48.1). Once k is a few dozen, the attack beats the bound for fixed queries, and with $k = n$ submissions it reports 71% to 72% for a coin.

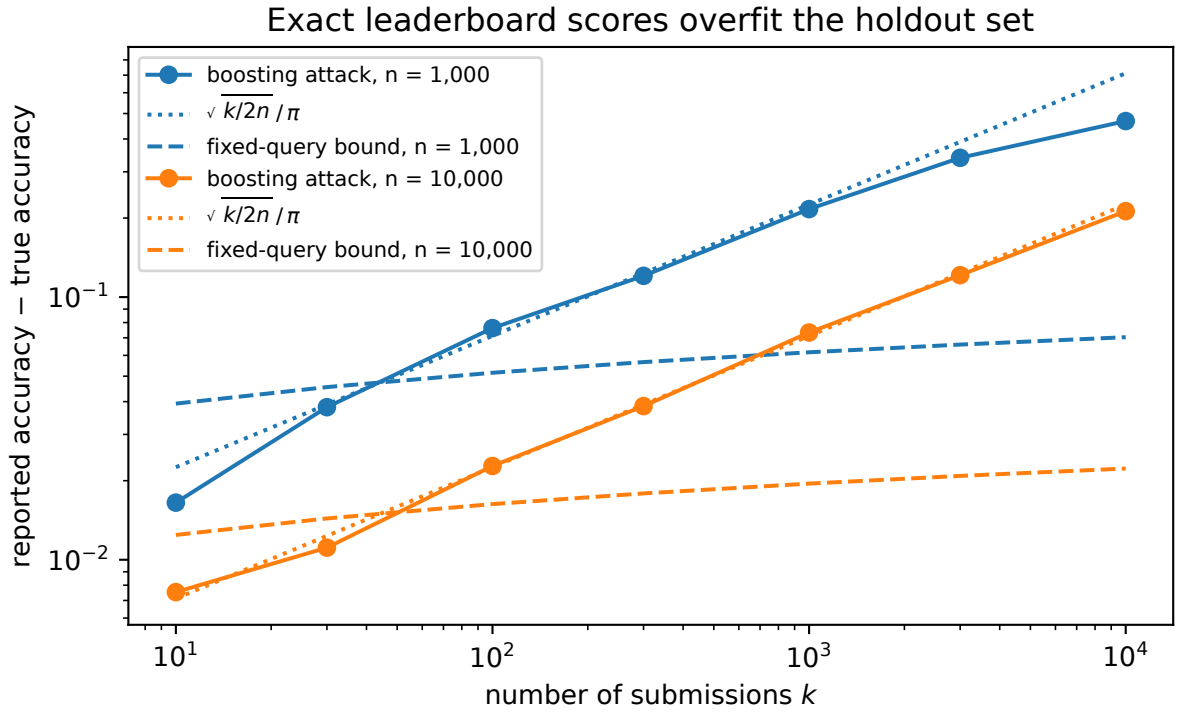

Figure 48.1.: Overfitting of the boosting attack (reported minus true accuracy) against the number of submissions, for holdout sets of 1,000 and 10,000 records, with the approximation $\sqrt{k/(2n)}/\pi$ (dotted) and the bound for fixed queries (dashed). The attack grows like $\sqrt{k}$, the bound like $\sqrt{\ln k}$.

48.3.6. Check yourself

- In the point-query attack, which queries are adaptive? *(Only the last one. The N point queries are fixed in advance and accurate. The attack needs only one adaptive round.)*
- A leaderboard rounds every score to the nearest 0.01. Does the boosting attack still work? *(Yes, more slowly. Rounding hides small differences, but submissions that land above 0.5*

after rounding still lean towards the labels. Blum & Hardt's Ladder, in Section 48.8, goes further and releases a new score only when it beats the previous best by a margin.)

48.4. Sample splitting and its cost

48.4.1. Context

The attack works because a query can depend on the records that answer it. The obvious fix is to make that impossible: never let a record answer a query it helped to choose. How much data does this cost?

48.4.2. Statement

Split the sample into k parts $D_1, \dots, D_k$ of n/k records each, and answer query j with its empirical value on part j only, $a_j = q_j(D_j)$. Then, however the queries are chosen,

$$\mathbb{E}\Big[\max_{j \le k} \big|q_j(D_j) - q_j(\mathcal{D})\big|\Big] \le \sqrt{\frac{k \ln(2k)}{2n}}, \tag{48.12}$$

and all errors are below α with probability $1 - \beta$ once $n \ge k \ln(2k/\beta)/(2\alpha^2)$. The data needed grows linearly in k.

48.4.3. Derivation

1. **Condition on the past.** Fix the parts $D_1, \dots, D_{j-1}$ and the analyst's own randomness. Query q_j depends only on the answers from those parts, so it is now fixed. Part D_j is independent of them, so its n/k records are fresh draws from $\mathcal{D}$ as far as q_j is concerned.
2. **One query.** Given the past, Fact 1 applies to $q_j(D_j) - q_j(\mathcal{D})$ with n/k records, so its moment generating function is at most $e^{\lambda^2 k/(8n)}$. A bound that holds for every value of the past also holds on average over it, so the same bound holds without conditioning.
3. **All queries.** The maximal inequality Equation 48.2 needs only the bound of step 2 for each variable, not independence between them. With $v = k/(4n)$ and $m = 2k$ it gives Equation 48.12. The high-probability version follows in the same way from Hoeffding's inequality and the union bound.

48.4.4. Interpretation

Splitting buys validity by using each record once, which is the same as collecting fresh data for every query. It is the right tool when the analysis has few rounds of adaptivity. If the queries come in r rounds, and each round is fixed before its answers are seen, one part per round suffices, and k becomes r in the factor in front of $\ln(2k)$. A final test set, used once after all decisions are made, is the extreme case $r = 1$.

When every query is adaptive, though, the cost is steep. At $\alpha = 0.05$ and $k = 1{,}000$ the expected-error bound Equation 48.12 needs 1,520,181 records, against 1,521 for the expected-error bound

Equation 48.8 if the queries were fixed in advance (Table 48.5). The 2,120 records quoted earlier for 1,000 fixed queries are larger because they make every error small with probability 0.95, not just on average.

48.4.5. Example: a hyperparameter search

A team tries 1,000 configurations one after another, each chosen from the validation scores of the earlier ones, on a validation set of 10,000 records. If each score were a query fixed in advance, Equation 48.8 would bound the average largest error by 0.0195. The search is adaptive, so that bound does not apply. Splitting the validation set into 1,000 parts of 10 records restores validity but leaves Equation 48.12 at $\sqrt{1{,}000 \ln 2{,}000/20{,}000} = 0.6165$, which is useless for scores between 0 and 1.

48.4.6. Check yourself

- Why does step 3 not need the parts to give independent answers? *(The maximal inequality bounds the expected maximum through a sum of moment generating functions. A sum of expectations needs no independence.)*
- An analysis has 3 rounds of 100 queries each, each round fixed before its answers are seen. How many parts does it need? *(Three, one per round. Within a round the queries are fixed with respect to that round's part.)*

48.5. Differential privacy implies generalization

48.5.1. Context

The attack learns individual records from the answers and then asks a query that fits them. A mechanism that hides individual records should therefore stop it, without throwing away any data. This section proves that it does. The proof is the replace-one argument of Part 1's stability chapter, with the stability of the algorithm replaced by the privacy of the answers. The first result, the **transfer lemma**, says that a query chosen privately has nearly the same expected value on the sample as on the population. The second, the **transfer theorem**, turns this into accuracy against the population for every answer of a private mechanism. It follows Dwork, Feldman, Hardt, Pitassi, Reingold & Roth (2015) and the lecture notes of Kamath's course (2020).

48.5.2. Statement

Transfer lemma. Let W be an (ε, δ)-DP algorithm, under the replace-one relation, that takes a sample and outputs a statistical query q_W. Then the chosen query's empirical value and its population value have nearly the same expectation:

$$\left| \mathbb{E}[q_W(D)] - \mathbb{E}[q_W(\mathcal{D})] \right| \le e^{\varepsilon} - 1 + \delta. \tag{48.13}$$

The proof gives two one-sided bounds, which are sharper than Equation 48.13 when the expectations are small:

$$\mathbb{E}[q_W(D)] \le e^{\varepsilon}\,\mathbb{E}[q_W(\mathcal{D})] + \delta, \qquad \mathbb{E}[q_W(\mathcal{D})] \le e^{\varepsilon}\,\mathbb{E}[q_W(D)] + \delta. \tag{48.14}$$

Transfer theorem. Let M answer k adaptively chosen statistical queries, and let the whole interaction be (ε, δ)-DP in the sample. Suppose its answers are accurate on the sample on average, $\mathbb{E}[\max_j |a_j - q_j(D)|] \le \alpha$. Then they are accurate on the population, up to the lemma's term:

$$\mathbb{E}\Big[\max_{j \le k} \big|a_j - q_j(\mathcal{D})\big|\Big] \le \alpha + e^{\varepsilon} - 1 + \delta. \tag{48.15}$$

For small ε, $e^{\varepsilon} - 1 \approx \varepsilon$, so privacy at level ε costs about ε in accuracy.

48.5.3. Derivation

The lemma first, in five steps.

1. **The empirical value is an average over records.** By definition, $q_W(D) = \frac{1}{n}\sum_i q_W(x_i)$, so $\mathbb{E}[q_W(D)] = \frac{1}{n}\sum_i \mathbb{E}[q_{W(D)}(x_i)]$, by linearity of expectation.
2. **The population value is the same average after a swap.** By Fact 2, $\mathbb{E}[q_{W(D)}(\mathcal{D})] = \mathbb{E}[q_{W(D)}(x'_i)] = \mathbb{E}[q_{W(D^{(i)})}(x_i)]$ for every i. In words, the population value of a query chosen from D equals the value on x_i of a query chosen without x_i.
3. **DP compares the two choices.** Hold D and x'_i fixed. Then D and $D^{(i)}$ are neighbours, and $f(q) = q(x_i)$ is a function of W's output with values in $[0, 1]$. Fact 3 gives $\mathbb{E}_W[q_{W(D)}(x_i)] \le e^{\varepsilon}\,\mathbb{E}_W[q_{W(D^{(i)})}(x_i)] + \delta$, where $\mathbb{E}_W$ averages over W's coins. Averaging over D and x'_i keeps the inequality.
4. **Combine.** Average step 3 over i, then use step 1 on the left and step 2 on the right: $\mathbb{E}[q_W(D)] \le e^{\varepsilon}\,\mathbb{E}[q_W(\mathcal{D})] + \delta$. Subtracting $\mathbb{E}[q_W(\mathcal{D})]$ from both sides leaves $(e^{\varepsilon} - 1)\,\mathbb{E}[q_W(\mathcal{D})] + \delta$, which is at most $e^{\varepsilon} - 1 + \delta$ because a query's value is at most 1.
5. **The other direction.** The replace-one relation is symmetric, so step 3 also holds from $D^{(i)}$ to D: $\mathbb{E}_W[q_{W(D^{(i)})}(x_i)] \le e^{\varepsilon}\,\mathbb{E}_W[q_{W(D)}(x_i)] + \delta$. The same averaging gives $\mathbb{E}[q_W(\mathcal{D})] \le e^{\varepsilon}\,\mathbb{E}[q_W(D)] + \delta$, and the two directions together give Equation 48.13.

The theorem then follows by choosing the worst query privately.

1. **Add the complements.** For each query q_j, also consider $1 - q_j$, answered by $1 - a_j$. These answers are computed from the original ones, so they cost nothing (post-processing, Fact 3). Their errors are the original errors with the sign flipped, $(1 - q_j(\mathcal{D})) - (1 - a_j) = -(q_j(\mathcal{D}) - a_j)$. Over the $2k$ queries, the largest signed error $q(\mathcal{D}) - a$ is therefore the largest absolute error of the original k.
2. **Pick the worst query privately.** Let W read the transcript of queries and answers and output the query, among the $2k$, with the largest $q(\mathcal{D}) - a$. W uses the distribution $\mathcal{D}$, which is fixed and is not data, and the transcript, which is (ε, δ)-DP. So W is post-processing, and it is (ε, δ)-DP.
3. **Split the worst error.** Writing a_W for the answer to the chosen query, add and subtract its empirical value:

$$\mathbb{E}\Big[\max_j \big|a_j - q_j(\mathcal{D})\big|\Big] = \mathbb{E}[q_W(\mathcal{D}) - a_W] = \mathbb{E}[q_W(\mathcal{D}) - q_W(D)] + \mathbb{E}[q_W(D) - a_W]. \tag{48.16}$$

4. **Bound each part.** The first part is at most $e^{\varepsilon} - 1 + \delta$ by the lemma, since W is DP. The second is at most $\mathbb{E}[\max_j |q_j(D) - a_j|] \le \alpha$, by the assumed accuracy on the sample. Adding them gives Equation 48.15.

Step 1 on a small case. The complements turn a largest absolute error into a largest signed one, so that a single query W can carry it. Table 48.3 takes two queries, one answered too high and one too low.

Table 48.3.: Two queries and their complements. The largest signed error over all four, 0.12, equals the largest absolute error of the original two.

Query	Answer a	Population value $q(\mathcal{D})$	Signed error $q(\mathcal{D}) - a$
q_1	0.62	0.50	-0.12
q_2	0.40	0.45	$+0.05$
$1 - q_1$	0.38	0.50	$+0.12$
$1 - q_2$	0.60	0.55	-0.05

The largest absolute error is 0.12, on q_1, whose answer is too high. Its signed error is negative, so the largest signed error among q_1 and q_2 alone would be 0.05. The complement $1 - q_1$ has the same error with the opposite sign, $+0.12$, and W picks it.

48.5.4. Interpretation

It is Part 1's identity with a different bound on each term. Steps 1 and 2 of the lemma together say that

$$\mathbb{E}[q_W(D)] - \mathbb{E}[q_W(\mathcal{D})] = \frac{1}{n} \sum_{i=1}^{n} \mathbb{E}\Big[q_{W(D)}(x_i) - q_{W(D^{(i)})}(x_i)\Big]. \tag{48.17}$$

This is the stability chapter's identity for the expected gap (Algorithmic stability and generalization), with the chosen query as the model and $q(x)$ as the loss. That chapter bounded each term by the uniform stability of a fixed algorithm, the largest change in the loss when one record is replaced. Here each term's expectation is bounded through the distribution of W's output. Step 3 bounds one expectation by e^{ε} times the other plus δ, and since the values lie in $[0, 1]$ their difference is at most $e^{\varepsilon} - 1 + \delta$. DP is a form of stability: a bound on how much one record can change the *distribution* of an output.

Why this form of stability survives the analyst. Uniform stability is a property of one algorithm, and it does not survive what the analyst does next. Keeping the query with the largest of several values is a discontinuous choice. When two values are nearly tied, one record can change which query wins, and the chosen query's value on that record can jump by a large amount. Part 1 showed the same instability in the 1-nearest-neighbour rule. DP survives post-processing and adaptive composition (Fact 3), so every query the analyst can build from private answers is chosen privately. That is the property the lemma needs.

How good the bound is. For small ε the lemma costs about ε. A cost linear in ε is the right order in general. For example, take a single record that is a fair bit, keep it with probability $e^{\varepsilon}/(1 + e^{\varepsilon})$ and flip it otherwise, and choose the query "equals the result". This choice already has a bias of

about $\varepsilon/4$ (Exercise 2 in the exercise book). The sharper form in step 4, $(e^{\varepsilon}-1)\,\mathbb{E}[q_W(\mathcal{D})]+\delta$, is smaller when the chosen query has a small population value. The bound becomes useless once ε is near the accuracy you want, which ties the privacy level to the target accuracy: answering to within 0.05 needs ε around 0.05 or below. The theorem holds only on average. High-probability versions exist, with different proofs, and Section 48.6 states them.

48.5.5. Example: picking the best-looking query

Take $k = 1{,}000$ queries that are all pure noise, each the rate at which a random feature agrees with a random label on $n = 1{,}000$ records. Every population value is $\frac{1}{2}$, and the empirical values are independent with standard deviation $1/(2\sqrt{n}) = 0.0158$. Choosing the query with the largest empirical value, with no privacy, overstates it by 0.0509 on average over 2,000 runs. That is close to the maximal inequality's bound, 0.0616, which Equation 48.8 gives for 1,000 queries.

Now choose with the exponential mechanism of Selection, which picks query j with probability proportional to $e^{\varepsilon n q_j(D)/2}$. Its score has sensitivity $1/n$, so it is ε-DP. The script computes its selection bias exactly for each sample, as the probability-weighted average of the empirical values, and Table 48.4 compares it with the lemma.

Table 48.4.: Selection bias of the exponential mechanism over 1,000 null queries on 1,000 records, averaged over 2,000 runs, against the transfer lemma.

ε	Measured bias $\mathbb{E}[q_W(D)] - \frac{1}{2}$	Lemma $e^{\varepsilon}-1$	Sharper $(e^{\varepsilon}-1)\cdot\frac{1}{2}$
0.01	0.00124	0.01005	0.00503
0.1	0.01245	0.10517	0.05259
1	0.04991	1.71828	0.85914
No privacy (argmax)	0.0509		

For small ε the measured bias is $\varepsilon/8$, a quarter of the sharper bound and half the $\varepsilon/4$ of the one-record example above. A short calculation explains it. The mechanism weights the empirical values by $e^{t q_j(D)}$ with $t = \varepsilon n/2$. The derivative in t of an average with these weights is the weighted variance of the values, so for small t the weighted average exceeds the plain average by about t times their variance, which is about $1/(4n)$. The product is $\varepsilon n/2 \cdot 1/(4n) = \varepsilon/8$. At $\varepsilon = 1$ the mechanism behaves like the argmax, and the lemma's bound, 1.72, says nothing (Figure 48.2).

48.5.6. Check yourself

- In step 2 of the theorem, W uses $\mathcal{D}$, which nobody knows. Is that a problem? *(No. The selector W exists only inside the proof, so no one has to run it. It only has to be a DP function of the transcript, and using $\mathcal{D}$ costs no privacy because the distribution is fixed, not data.)*
- Why does the lemma need the replace-one relation rather than add or remove? *(The swap in step 2 replaces x_i by x_i' and keeps n records, so step 3 compares two samples that differ by one replacement. An add-or-remove guarantee at (ε, δ) gives $(2\varepsilon, (1+e^{\varepsilon})\delta)$ for a replacement.)*

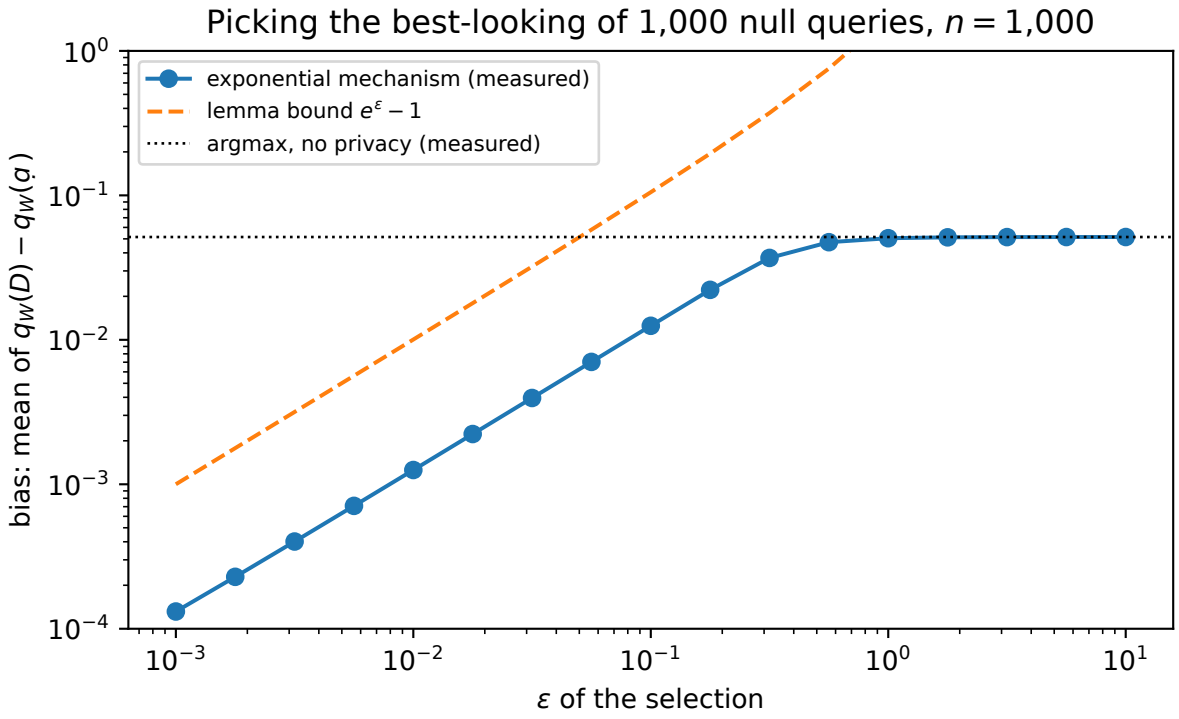

Figure 48.2.: Selection bias of the exponential mechanism choosing among 1,000 noise queries on 1,000 records, against the ε of the choice, with the transfer lemma's bound $e^{\varepsilon} - 1$ and the bias of the non-private argmax.

48.6. Answering with Gaussian noise: the $\sqrt{k}$ rate

48.6.1. Context

The transfer theorem turns any private mechanism that is accurate on the sample into one that is accurate on the population. The simplest choice is to add Gaussian noise to each empirical value. How many records does it need for k adaptive queries, and how does that compare with splitting?

48.6.2. Statement

Answer each query with $a_j = q_j(D) + \xi_j$, where the ξ_j are independent Gaussian noises of standard deviation σ. For every $\delta > 0$,

$$\mathbb{E}\Big[\max_j \big|a_j - q_j(\mathcal{D})\big|\Big] \le \sigma\sqrt{2\ln(2k)} + e^{\varepsilon} - 1 + \delta, \qquad \varepsilon = \rho + 2\sqrt{\rho\ln(1/\delta)}, \quad \rho = \frac{k}{2n^2\sigma^2}. \tag{48.18}$$

Choosing σ and δ to minimize the bound makes the error at most α. Step 4 below explains why δ should then be of order α. With that choice, the number of records grows like the square root of k:

$$n = O\Big(\frac{\sqrt{k\,\ln k\,\ln(1/\alpha)}}{\alpha^2}\Big). \tag{48.19}$$

Three results go further, and this chapter states them with citations rather than proofs. The first is a **high-probability** version of the transfer theorem (Bassily, Nissim, Smith, Steinke, Stemmer & Ullman 2016). Suppose a mechanism is (ε, δ)-DP, and with probability $1 - \beta$ all its answers are within α of the empirical values. Suppose also that ε is at most a constant times α, and δ at most a constant times $\alpha\beta$. Then its answers are within a constant times α of the population values, with probability at least $1 - c\beta$ for a constant c. Jung, Ligett, Neel, Roth, Sharifi-Malvajerdi & Shenfeld (2020) give a shorter proof with explicit constants. Section N.2 in the appendices derives it step by step, in a form that divides the sample's failure probability by a free constant, which for Gaussian noise costs only a logarithm. With Gaussian noise this gives $n = \tilde{O}(\sqrt{k}/\alpha^2)$ records with high probability, where $\tilde{O}$ means "of this order, up to factors logarithmic in k, $1/\alpha$ and $1/\beta$".

The second result helps when the number of queries is huge. Suppose the records take at most $|\mathcal{X}|$ distinct values, a finite domain. Then private multiplicative weights (Query release) answers k adaptive queries with a number of records that grows only with $\ln k$ (Bassily et al. 2016):

$$n = \tilde{O}\Big(\frac{\sqrt{\ln|\mathcal{X}|}\,\ln k}{\alpha^3}\Big). \tag{48.20}$$

It beats the Gaussian mechanism once k is large compared with $\ln|\mathcal{X}|/\alpha^2$.

The third result is a lower bound. Once the records have enough dimensions, and assuming that one-way functions exist, no computationally efficient mechanism can answer more than about n^2 adaptive queries accurately (Hardt & Ullman 2014; Steinke & Ullman 2015). Under that assumption, the $\sqrt{k}$ rate is the best an efficient mechanism can reach in general.

48.6.3. Derivation

1. **Privacy.** Each answer is the Gaussian mechanism on a query of sensitivity $1/n$, so by Fact 4 it is ρ_1-zCDP with $\rho_1 = 1/(2n^2\sigma^2)$. The analyst chooses each query from earlier answers, and adaptive composition adds the ρ values to $\rho = k\rho_1$. Equation 48.7 converts it to (ε, δ).
2. **Accuracy on the sample.** The errors on the sample are the noises ξ_j, Gaussian with variance σ^2, so they are sub-Gaussian with $v = \sigma^2$. The maximal inequality over the $2k$ values $\pm\xi_j$ gives $\mathbb{E}\max_j |\xi_j| \le \sigma\sqrt{2\ln(2k)}$.
3. **Transfer.** The transfer theorem with $\alpha = \sigma\sqrt{2\ln(2k)}$ from step 2 and (ε, δ) from step 1 gives Equation 48.18.
4. **The rate.** For small ε the transfer term is about ε, and for small ρ the conversion is dominated by its square-root term, so

$$e^\varepsilon - 1 \approx \varepsilon \approx 2\sqrt{\rho\ln(1/\delta)} = \frac{\sqrt{2k\ln(1/\delta)}}{n\sigma}. \tag{48.21}$$

   More noise lowers this term but raises the noise term of step 2. Write the bound as $\sigma A + B/\sigma$, where the constant $A = \sqrt{2\ln(2k)}$ comes from step 2 and the constant $B = \sqrt{2k\ln(1/\delta)}/n$ from the display above. Setting the derivative $A - B/\sigma^2$ to zero gives the best noise level $\sigma = \sqrt{B/A}$, and there the bound equals $2\sqrt{AB}$. Setting $2\sqrt{AB}$ equal to α, leaving the small δ term aside for now, and solving for n gives the approximate size below. It slightly understates the exact optimum of Table 48.5, because $e^\varepsilon - 1$ exceeds ε and the conversion's ρ term was dropped.

$$n \approx \frac{8\sqrt{k\ln(2k)\ln(1/\delta)}}{\alpha^2}. \tag{48.22}$$

   Taking δ of order α, so that the δ term stays below α, gives Equation 48.19.

48.6.4. Interpretation

The $\sqrt{k}$ is the $\sqrt{k}$ of composition. To hide each record across k answers, the total privacy loss must stay small, and under zCDP it grows like $\sqrt{k}$ times the loss of one answer. Balancing the two terms, as in step 4, puts the best noise per answer at $\sigma = \sqrt{B/A}$, which grows like $k^{1/4}/\sqrt{n}$ up to logarithms. The error, the noise plus the transfer term, then grows like $k^{1/4}$ and falls like $1/\sqrt{n}$. Splitting pays $\sqrt{k/n}$ instead. Answering empirically pays nothing for privacy, but it loses validity quickly. The boosting attack's overfitting, about $\sqrt{k/(2n)}/\pi$, reaches 0.05 after about $0.05n$ adaptive queries, and the point-query attack pushes the error past $\frac{1}{2}$ after about $2n$.

The constants are large. Table 48.5 solves each expected-error bound for the smallest n that reaches $\alpha = 0.05$. For one query the Gaussian bound needs 7,300 records, against 139 for the other two expected-error bounds, because the transfer term must itself be below 0.05. Splitting stays cheaper up to a few hundred adaptive queries. Beyond that, the square root wins by a growing factor: at a million queries, 33 million records against 2.9 billion. Neither is close to the 2,902 records that a million fixed queries need.

Table 48.5.: Records needed to bring each bound on the expected largest error down to 0.05. The fixed-query column is valid only for queries chosen in advance; the other two hold for adaptive queries.

Queries k	Fixed in advance Equation 48.8	Sample splitting Equation 48.12	Gaussian noise Equation 48.18
1	139	139	7,300
10	600	5,992	47,985
100	1,060	105,967	201,800
1,000	1,521	1,520,181	764,337
10,000	1,981	19,806,976	2,758,964
1,000,000	2,902	2,901,731,548	33,393,779

At the optimum, the Gaussian bound splits the error almost equally between the noise, 0.0242, and the transfer term, 0.0258. The privacy parameters there are $\varepsilon = 0.0236$ and $\delta = 0.0019$, the same for every k. They do not depend on k because, once the noise term $\sigma\sqrt{2\ln(2k)}$ is fixed, k and n enter the transfer term only through $k\ln(2k)/n^2$, and the n that reaches the target fixes that combination. Here δ protects no one, because the goal is valid answers. It is only a parameter of the bound, where it adds to the error, so the optimizer sets it to whatever minimizes the total, here 0.0019. Figure 48.3 shows the three slopes.

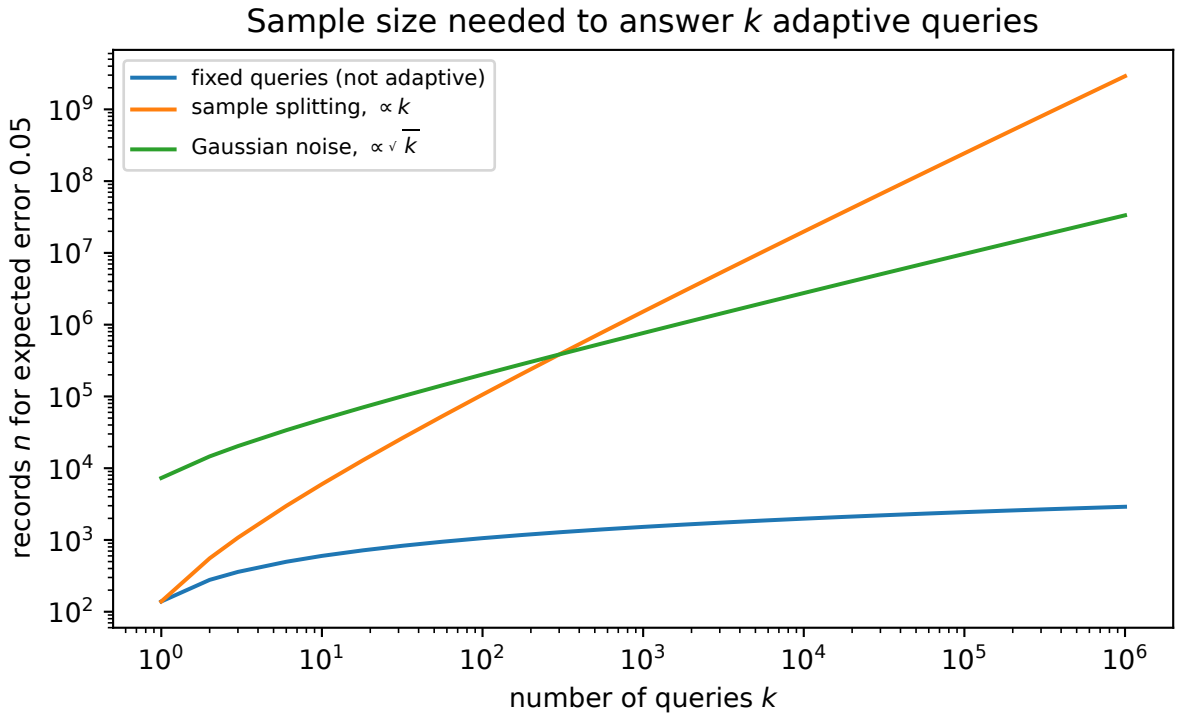

Figure 48.3.: Records needed for an expected largest error of 0.05 against the number of queries, for queries fixed in advance, sample splitting and Gaussian noise with the transfer theorem. The slopes on this log-log scale are about 0, 1 and $\frac{1}{2}$.

48.6.5. Example: 1,000 queries on 10,000 records

With $n = 10{,}000$ and $k = 1{,}000$ adaptive queries, the best Gaussian bound is 0.4095. It uses $\sigma = 0.0513$, so that the noise contributes 0.2001 and the transfer term 0.2093, with $\varepsilon = 0.1674$. Splitting gives 0.6165, and fixed queries would give 0.0195. So at this size the guarantee for adaptive queries is weak whichever method you use. The theorem is a worst-case statement, against an analyst who attacks the holdout set on purpose. Section 48.7 shows that a typical analyst is much easier to defend against.

48.6.6. Check yourself

- Why does the noise per answer grow like $k^{1/4}$ rather than $\sqrt{k}$? *(Composition in zCDP makes ε grow like $\sqrt{k}/(n\sigma)$, so keeping ε fixed needs $\sigma \propto \sqrt{k}$. But the optimum balances ε against the noise, and the balance point is $\sigma \propto k^{1/4}/\sqrt{n}$, up to logarithms.)*
- At $k = 1$ the Gaussian bound needs 7,300 records, against 139 for the plain empirical answer. Why use it at all? *(For one query you would not. The method pays a fixed overhead for a guarantee whose cost grows like $\sqrt{k}$, which only pays off for many adaptive queries.)*

48.7. The reusable holdout: Thresholdout

48.7.1. Context

In machine learning the analyst usually has two sets: a training set to explore freely, and a holdout set only for confirming what the training set suggests. Most of the time the two agree, and then the holdout set's answer adds nothing that the training set did not already say. Only disagreements, the sign of overfitting to the training set, carry information about the holdout set. The **reusable holdout** of Dwork, Feldman, Hardt, Pitassi, Reingold & Roth (2015), built on an algorithm called **Thresholdout**, answers from the training set when the two agree and pays privacy only when they do not. That is the pattern of the sparse vector technique of Selection.

48.7.2. Statement

Thresholdout holds a training set D_t and a holdout set D_h of n records, a threshold τ and a noise scale b. It starts with a noisy threshold $\hat{\tau} = \tau + \zeta$, where ζ is Laplace noise of scale $2b$, and answers each query q in two steps.

1. Draw Laplace noise ν of scale $4b$, and compare the gap between the two sets with the noisy threshold: is $|q(D_h) - q(D_t)| + \nu > \hat{\tau}$?
2. If not, answer with the training value $q(D_t)$. If so, count one **overfitting detection**, answer with $q(D_h) + \xi$, where ξ is Laplace noise of scale b, and redraw the threshold noise ζ.

The holdout set is protected by the detections alone. If a query changes by at most Δ when one holdout record is replaced, then a run that stops at its B-th detection is ε-DP in the holdout records with

$$\varepsilon = \frac{2B\Delta}{b}, \tag{48.23}$$

however many queries were answered below the threshold. For statistical queries $\Delta = 1/n$. Every answer is close to the holdout value, within the threshold plus noise for an answer below and within the noise ξ for an answer above. So the transfer theorem applies with the holdout set as the sample. The answers are accurate on the population to within their accuracy on the holdout set, about τ plus noise, plus $e^{\varepsilon} - 1$.

48.7.3. Derivation

1. **One detection is one run of AboveThreshold.** Between two detections, Thresholdout compares a stream of queries $|q(D_h) - q(D_t)|$ with one noisy threshold and stops at the first that exceeds it. That is AboveThreshold from Selection. It is $(\varepsilon_1 + \varepsilon_2)$-DP when its threshold noise has scale Δ/ε_1 and its query noise scale $2\Delta/\varepsilon_2$, for any number of answers below the threshold. The reason is that all the answers below are explained by one shift of the threshold noise.
2. **The sensitivity of the compared quantity.** The training set does not depend on the holdout set, so hold it fixed. Replacing one holdout record moves $q(D_h)$ by at most Δ, so it moves $|q(D_h) - q(D_t)|$ by at most Δ too.
3. **The cost of one detection.** The threshold noise has scale $2b = \Delta/\varepsilon_1$, so $\varepsilon_1 = \Delta/(2b)$. The query noise has scale $4b = 2\Delta/\varepsilon_2$, so $\varepsilon_2 = \Delta/(2b)$. The noisy answer is the Laplace mechanism with scale b, which costs Δ/b. The total is $\Delta/(2b) + \Delta/(2b) + \Delta/b = 2\Delta/b$.
4. **The answers below the threshold.** They are training values, which do not depend on the holdout set. Their only link to it is the comparison, which step 1 already paid for.
5. **All detections.** Each detection closes one run, and the next run starts with fresh threshold noise. Basic composition over the B closed runs gives Equation 48.23. Queries after the last detection would form an unfinished run, which costs the threshold term $\Delta/(2b)$ of step 3. That is why the holdout set stops at the B-th detection. If the analysis ends earlier, the unfinished run fits within the unused budget. Advanced composition would make the cost grow like $\sqrt{B}$ rather than B, at the price of a δ.

48.7.4. Interpretation

Only overfitting is charged. A query whose training and holdout values agree costs nothing, however many such queries there are. An analyst who overfits the training set triggers detections, and each detection spends a fixed amount of privacy. When the budget is spent, the holdout set must stop answering. This is the right accounting for confirmatory analysis, where most hypotheses either hold on both sets or fail on the training set first.

Accuracy means accuracy to within the threshold. Below the threshold, the answer is the training value, which can differ from the holdout value by about τ. So τ sets the resolution of every answer. A smaller τ gives sharper answers but more detections. Dwork et al. (2015) prove a high-probability guarantee for Thresholdout directly, in which the number of queries can grow exponentially with n as long as the number of detections stays small.

The formal guarantee needs large holdout sets. For the transfer term to be below the accuracy α you want, $\varepsilon = 2B/(nb)$ must be at most about α, so B detections need n of order $B/(b\alpha)$ records. The experiment below runs far outside that regime and still works, because its analyst is not trying to attack the holdout set.

48.7.5. Example: selecting features on a training set and confirming them on a holdout set

This is the experiment of Dwork et al. (2015), scaled down. A training set and a holdout set each have $n = 2{,}000$ records with $d = 5{,}000$ features, each $+1$ or -1, and a label ± 1. In the first setting, every feature is independent of the label, so no classifier can beat 50%. In the second, 20 features agree with the label with probability $\frac{1}{2} + 1.5/\sqrt{n}$, a **correlation** of $3/\sqrt{n} = 0.067$. The correlation of a ± 1 feature with a ± 1 label is the average of their product, twice the agreement rate minus 1. It lies between -1 and 1, and one record moves it by at most $2/n$. The analyst works as follows.

1. Compute each feature's correlation with the label on the training set, and keep the features where it exceeds $1/\sqrt{n}$ in size.
2. Ask the holdout set for the correlations of those features, and keep the ones whose holdout correlation also exceeds $1/\sqrt{n}$ in size, with the same sign.
3. Rank them by training correlation. For each m from 10 to 200, build the classifier $\text{sign}(\sum_j s_j x_j)$ over the top m, where s_j is the sign of feature j's correlation, and ask the holdout set for its accuracy.

The holdout queries are answered in three ways: exactly, with Gaussian noise of standard deviation $1/\sqrt{n}$ (the sampling error of one correlation), or by Thresholdout with $\tau = 4/\sqrt{n}$ and $b = 1/\sqrt{n}$. The script computes each classifier's true accuracy exactly, from the distribution of the features. Table 48.6 averages 10 repetitions for $m = 200$.

Table 48.6.: The reusable-holdout experiment with 200 selected features, averaged over 10 repetitions. The true accuracy is computed exactly.

Setting	Holdout answered	Training accuracy	Reported holdout accuracy	True accuracy
No signal	Exactly	0.6980	0.6842	0.5000
No signal	With Gaussian noise	0.7172	0.6135	0.5000
No signal	By Thresholdout	0.7664	0.5217	0.5000
20 informative features	Exactly	0.7146	0.7039	0.5355
20 informative features	With Gaussian noise	0.7322	0.6386	0.5347
20 informative features	By Thresholdout	0.7759	0.5471	0.5312

Answered exactly, the holdout set reports 68% for a classifier that cannot beat 50%. Gaussian noise of the size of the sampling error removes only part of the bias, because the selection still sees the holdout correlations through modest noise. Thresholdout reports 52%, within its threshold of the truth. That threshold is $\tau = 4/\sqrt{n}$ on a correlation, and since an accuracy is (1 + correlation)/2, it is $2/\sqrt{n} = 0.045$ on an accuracy. Thresholdout works in two ways. Most holdout correlations in step 2 come back as training values, so nearly every feature that passed on the training set is confirmed, and the selection barely depends on the holdout set. Then the accuracy queries of step 3 have training accuracies far above their holdout accuracies, so they trigger detections

and come back as noisy holdout values. The training accuracy differs between the three rows because each way of answering confirms a different set of features. With 20 informative features, Thresholdout's report, 0.5471, is close to the true accuracy of 0.5312, and its selection is about as good as the others (Figure 48.4).

The privacy accounting tells the other half of the story. Each repetition asks about 1,587 holdout queries, and Thresholdout records 325.8 detections on average. A correlation moves by at most $\Delta = 2/n$ when one record changes, and each detection costs $2\Delta/b = 0.0894$ by Equation 48.23. The 325.8 detections of an average repetition therefore cost $\varepsilon = 29.1$, plus $\Delta/(2b) = 0.022$ for the run left open at the end. The Gaussian answers, of standard deviation $\sigma = 1/\sqrt{n}$, cost $\rho = \Delta^2/(2\sigma^2) = 2/n$ each, so all of them together have $\rho = 1.59$, which is $\varepsilon = 10.1$ at $\delta = 10^{-5}$. Neither is anywhere near the small ε the transfer theorem needs. The guarantee is a worst case. This analyst only screens features, and does not attack the holdout set the way the boosting attack does.

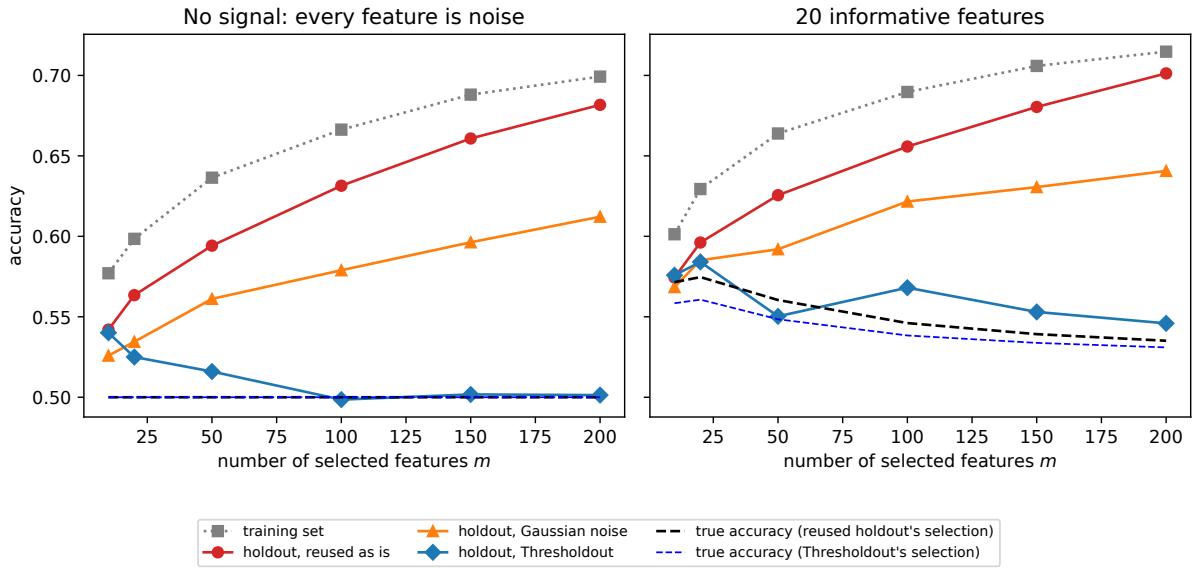

Figure 48.4.: Accuracy of a classifier built from the top m features against m: on the training set, as reported by a holdout set reused as is, with Gaussian noise and through Thresholdout, and the true accuracy. Left: every feature is noise. Right: 20 features carry signal.

48.7.6. Check yourself

- Why may Thresholdout use the training set without any noise? *(The guarantee protects the holdout records. The training set is independent of them, so answering from it reveals nothing about the holdout set.)*
- What happens if an analyst keeps asking queries after the budget of detections is spent? *(The holdout set must stop answering, or answer only from the training set. Every further detection would add $2\Delta/b$ to ε.)*

48.8. What it means for machine-learning practice

48.8.1. Context

Few machine-learning projects call their workflow "adaptive data analysis", but most are. Hyperparameter search, early stopping on a validation loss, choosing an architecture after looking at errors, competition leaderboards and benchmark test sets all ask a fixed set of records many questions chosen from earlier answers. What should you do differently?

48.8.2. Statement

Five rules follow from the earlier sections.

1. **Count adaptive rounds, not queries.** Questions chosen before any answer was seen are cheap: k of them cost $\ln k$ (Equation 48.8). Choosing the best of k models trained without the validation set is in this class. The bias of its validation score is at most $\sqrt{\ln(2k)/(2n)}$. The cost grows with every round in which answers shape the next questions.
2. **Keep a final test set and use it once.** One query is never adaptive. If the analysis has a few rounds, give each round its own part of the data (Section 48.4).
3. **Answer through noise when the rounds are many.** Gaussian noise with the transfer theorem (Section 48.6), or Thresholdout when there is a training set to compare with (Section 48.7), lets one holdout set answer many more adaptive queries than splitting.
4. **Private tuning generalizes for free.** A hyperparameter search that is (ε, δ)-DP in the validation set, as in Hyperparameter tuning and private selection, chooses its winner privately. By the transfer lemma, the winner's validation score overstates its true score by at most $e^{\varepsilon} - 1 + \delta$ on average.
5. **For leaderboards, release less.** Blum & Hardt's (2015) **Ladder** reports a new score only when a submission beats the best so far by a margin, rounded to that margin. Its error against the population is of order $n^{-1/3}$, times a factor that grows only like the cube root of $\ln(kn)$, and it stops the boosting attack.

48.8.3. Derivation

Rules 1 and 2 are Equation 48.8 and Equation 48.12. A score of a model trained elsewhere is a query fixed before the validation set was drawn, and the winner's overstatement is at most the largest error among the k scores, which Equation 48.8 bounds. Rule 3 is Equation 48.18 and Equation 48.23. Rule 4 is the transfer lemma Equation 48.13 applied to the search, whose output, the winning configuration, is a DP choice of a query: "is this record classified correctly by the winner?". Rule 5 is the Ladder paper's theorem. Section N.3 in the appendices proves it with Hoeffding's inequality and a union bound over the leaderboard's possible histories. Its idea is that a leaderboard that changes rarely reveals few bits, and few bits cannot encode much about individual records.

48.8.4. Interpretation

Worst case against typical case. The theory guards against an analyst who attacks the holdout set. Real practice is usually milder, and the evidence agrees. Recht, Roelofs, Schmidt & Shankar (2019) collected new test sets for CIFAR-10 and ImageNet after years of reuse of the old ones. Accuracy dropped, by 3 to 15 points on CIFAR-10 and 11 to 14 points on ImageNet, but the ranking of models was largely preserved. The authors attribute the drop to small differences between the old and new test images rather than to adaptive overfitting. Roelofs et al. (2019) found little adaptive overfitting across more than a hundred Kaggle competitions. One proposed reason is that similar models ask similar questions, and a question close to an earlier one reveals little new about the records (Mania et al. 2019). The theory still explains when reuse is dangerous: few records, many truly adaptive rounds, and an incentive to climb the leaderboard.

Splitting is often the practical answer. A training, validation and test split is splitting with three rounds. It is cheap because a typical project has few true rounds. Noise-based reuse earns its keep when the rounds are many and the data are scarce, such as in a long interactive analysis of a fixed medical cohort.

The same mechanism serves both goals. A DP mechanism used for adaptive data analysis also protects the people in the holdout set. Thresholdout's guarantee is a privacy guarantee. A team that already pays for privacy in its validation set gets protection against adaptive overfitting at no extra cost.

48.8.5. Example: what a search on 10,000 validation records can claim

A team on a validation set of 10,000 records reports the best of 1,000 configurations. If the configurations were all trained and fixed before the validation set was opened, rule 1 bounds the expected optimism of the winner's score by 0.0195. If the search was sequential, with each configuration chosen from the earlier scores, that bound no longer holds, and the adaptive bounds of Table 48.5 show that 10,000 records are far too few to certify 1,000 adaptive scores to within 0.05. The honest options are a fresh test set for the final model, or a private search whose ε bounds the optimism by rule 4. With $\varepsilon = 0.05$ and a negligible δ, that bound is $e^{0.05} - 1 = 0.051$.

48.8.6. Check yourself

- A team uses early stopping on a validation set, checking the loss after every epoch for 100 epochs. Is that adaptive? *(Yes, mildly. Each decision to continue depends on earlier validation losses. Here the questions are few and similar, so the bias is small, but the validation loss at the stopping point is still optimistic.)*
- Why does rule 4 not make every private search's reported score trustworthy to within ε? *(The lemma bounds the bias on average, not for one search, and it assumes the reported score was computed on the same records the search was private in. A score on other data is a different question.)*

48.9. Code: check every number by simulation

The script code/part05-dp-ml/adaptive_data_analysis.py computes every number in this chapter and draws its figures. It runs the point-query attack, the boosting attack against an exact leaderboard, and the selection-bias experiment. It solves the three expected-error bounds for the sample size each needs, and runs the reusable-holdout experiment with exact population accuracies. From the repository root:

```
uv run python code/part05-dp-ml/adaptive_data_analysis.py
```

It takes about three minutes, most of it in the boosting attack and the holdout experiment.

Output (seed 0), summarized in Table 48.7:

Table 48.7.: Summary of the script's output.

Experiment	Result
Fixed queries, $\alpha = \beta = 0.05$	1,199 records for 10 queries, 3,501 for a million
Point-query attack, $n = 1{,}000$	Error 0.61 with 2,001 queries, 0.90 with 10,001
Boosting attack	Overfitting 0.2182 at $k = n = 1{,}000$; approximation $\sqrt{k/(2n)}/\pi$ within 0.01 below saturation
Selection bias, 1,000 null queries	Argmax 0.0509; exponential mechanism 0.00124 at $\varepsilon = 0.01$, against $e^{\varepsilon} - 1 = 0.01005$
Records for error 0.05, $k = 1{,}000$	Fixed 1,521; splitting 1,520,181; Gaussian 764,337
Reusable holdout, no signal, $m = 200$	Reported 0.6842 exactly, 0.6135 with Gaussian noise, 0.5217 with Thresholdout; true 0.5

tests/test_adaptive_data_analysis.py checks that the output still matches the numbers in this chapter.

What to take from it. Exact answers break quickly under adaptive queries: the boosting attack grows like $\sqrt{k}$, as the short argument predicts. The transfer lemma is valid but loose by a factor of about 8 for small ε and useless for ε near 1. The rates are real but carry large constants, so splitting wins for small numbers of queries. Finally, a typical analyst is much easier to defend against than the worst case, and Thresholdout removes most of the overfitting at privacy levels far outside its theorem.

48.11. Cheat sheet

Table 48.8 collects the results. Each query maps a record to $[0, 1]$, the sample has n records, and k queries are asked.

Table 48.8.: Every result of the chapter.

Result	Statement	Conditions
Maximal inequality	$\mathbb{E}\max_{j\le m} Z_j \le \sqrt{2v\ln m}$	Each Z_j sub-Gaussian with proxy v
Fixed queries	$\mathbb{E}\max_j \lvert q_j(D) - q_j(\mathcal{D})\rvert \le \sqrt{\ln(2k)/(2n)}$	Queries chosen before the sample is drawn
Point-query attack	Error $\ge 1 - n/(k-1)$ with k queries	Exact empirical answers, one adaptive query

Result	Statement	Conditions
Boosting attack	Overfitting $\approx \sqrt{k/(2n)}/\pi$	Exact leaderboard, random submissions
Sample splitting	$\mathbb{E}\max_j \lvert q_j(D_j) - q_j(\mathcal{D})\rvert \le \sqrt{k\ln(2k)/(2n)}$	Query j answered on its own part
Transfer lemma	$\lvert\mathbb{E}q_W(D) - \mathbb{E}q_W(\mathcal{D})\rvert \le e^{\varepsilon} - 1 + \delta$	W is (ε, δ)-DP under replace-one
Transfer theorem	Population error $\le \alpha + e^{\varepsilon} - 1 + \delta$	Sample error $\le \alpha$ on average; interaction DP
Gaussian noise	$\sigma\sqrt{2\ln 2k} + e^{\varepsilon} - 1 + \delta$, $\rho = k/(2n^2\sigma^2)$; $n = \tilde{O}(\sqrt{k}/\alpha^2)$	Noise of standard deviation σ per answer
High probability (Bassily et al.)	(α, β) on the sample gives $(O(\alpha), O(\beta))$ on the population	$\varepsilon = O(\alpha)$, $\delta = O(\alpha\beta)$
Thresholdout	$\varepsilon = 2B\Delta/b$ for B detections	Answers below the threshold are free
Lower bound (Hardt–Ullman, Steinke–Ullman)	About n^2 adaptive queries at most	Efficient mechanisms, high-dimensional records, one-way functions exist

Rules of thumb

- Count adaptive rounds, not queries. The records needed grow like $\ln k$ for queries fixed in advance, and for adaptive ones like k with splitting and $\sqrt{k}$ with noise.
- An answer that reveals little about any record cannot be overfitted. Privacy at level ε costs about ε in accuracy.
- Keep a test set that is used once, at the end.
- On a leaderboard, release improvements, not scores.

Practice. Exercises for this chapter, each with a worked solution, are in the exercise book.

A. How much noise to add

Every differentially private release in this book answers the same practical question. You have a number, or a list of numbers, computed from people's data, and you want to publish it with random noise added. How much noise is enough? This appendix answers that question from scratch for the mechanisms the book uses most. They are Laplace noise for pure differential privacy (DP), Gaussian noise for approximate DP, which allows a small failure probability, randomized response for a single bit, and the exponential mechanism for choosing among candidates. It assumes only that you know what a probability density, an average, a logarithm and an exponential are. Everything else, including the definition of differential privacy itself, is built up on the page.

The results sit together because they all rest on one quantity, the **privacy loss**. It measures how much more likely an output is when one person's record is in the data than when it is changed. Each mechanism is calibrated by bounding the privacy loss, everywhere for pure DP and except on outputs of small total probability for approximate DP. The chapters derive the same formulas with more general tools. Table A.1 shows where each one is stated and used, and its symbols are defined in the sections it points to.

Table A.1.: The calibration formulas derived in this appendix and the chapter sections that state or use them.

Section of this appendix	What it derives	Where the chapters state or use it
Section A.1	The definition, the privacy loss and the exact δ	Section 18.1, Section 18.2, Section 18.4
Section A.2	Sensitivity of counts, sums, means and histograms	Section 20.1
Section A.3	Laplace noise of scale Δ_1/ε gives ε-DP	Section 20.2
Section A.4	Randomized response and its unbiased estimate	Section 18.3
Section A.5	The exponential mechanism and its utility	Section 22.1, Section 22.2
Section A.6	The classic Gaussian formula $\sigma = \Delta_2\sqrt{2\ln(1.25/\delta)}/\varepsilon$	Section 20.3
Section A.7	The exact Gaussian $\delta(\varepsilon)$ and the smallest σ	Section 20.4, Section 20.5
Section A.8	Computing δ in code, and how ε, δ, σ and Δ_2 trade off	Section 20.4, Section 46.7

A.1. What differential privacy promises, and the privacy loss

A.1.1. The question

Before you can ask how much noise is enough, you need to know what "enough" means. What exactly must the noisy output satisfy, and how do you check it for one mechanism?

A.1.2. The answer

A dataset is a collection of records, one per person. Two datasets D and D' are **neighbours** if they differ in one person's record. The book uses two versions of this. Under **add/remove**, D' is D with one record added or removed, so the two have different numbers of records. The size n is then itself protected, because the output must not reveal which size is true. Under **replace-one**, D' is D with one record changed, so n is the same on both and treated as public. This appendix uses add/remove unless it says otherwise, as the chapters do for counts and histograms.

A **mechanism** M is a randomized algorithm: run on a dataset D, it returns a random output $M(D)$. Write $p_D(y)$ for the probability (or density) that $M(D)$ outputs y, and $p_{D'}(y)$ for the same on the neighbour. An **event** S is any set of outputs, such as "the released count is above 1240". The privacy parameter $\varepsilon \geq 0$ says how much one record may change the probability of an event: by at most a factor e^{ε}, so a small ε means a factor close to 1. Formally, M is **ε-differentially private** (ε-DP) if for every pair of neighbours and every event S,

$$\Pr[M(D) \in S] \leq e^{\varepsilon} \Pr[M(D') \in S]. \tag{A.1}$$

The weaker version allows a small slack δ on top of the factor. A mechanism is **(ε, δ)-differentially private** if, for every pair of neighbours and every event S,

$$\Pr[M(D) \in S] \leq e^{\varepsilon} \Pr[M(D') \in S] + \delta. \tag{A.2}$$

Read it as "the factor e^{ε} holds, except for a δ of probability". Both definitions must hold with D and D' swapped too, since a neighbour of D' is D.

The quantity that decides both is the **privacy loss** of an output y. It is the log of how much more likely y is on D than on D':

$$L(y) = \ln \frac{p_D(y)}{p_{D'}(y)}. \tag{A.3}$$

A loss of 0 means y is equally likely on both datasets and says nothing about which one was used. A loss of ε means y is e^{ε} times more likely on D. Two facts, proved below, turn the definitions into statements about L. First, if $L(y) \leq \varepsilon$ for every output y and every ordered pair of neighbours, the mechanism is ε-DP. Second, call the outputs where the loss exceeds ε the **bad set**, $B = \{y : L(y) > \varepsilon\}$. The smallest δ that works for one pair at a given ε is the probability of the bad set on D, minus e^{ε} times its probability on D':

$$\delta(\varepsilon) = \Pr[M(D) \in B] - e^{\varepsilon} \Pr[M(D') \in B]. \tag{A.4}$$

A.1.3. A worked example

Take a mechanism with three possible outputs, and the probabilities in Table A.2 on a dataset D and its neighbour D'.

Table A.2.: A mechanism with three outputs on two neighbouring datasets. The last row uses $e^{\varepsilon} = 2$.

Output y	1	2	3
$p_D(y)$	0.5	0.3	0.2
$p_{D'}(y)$	0.2	0.3	0.5
Ratio $p_D(y)/p_{D'}(y)$	2.5	1	0.4
Privacy loss $L(y)$	0.9163	0	-0.9163
$p_D(y) - 2\,p_{D'}(y)$	0.1	-0.3	-0.8

The largest ratio is 2.5, at output 1, so this pair is ε-DP with $\varepsilon = \ln 2.5 = 0.9163$ and with nothing smaller. The script that comes with this appendix (see the Code section at the end) checks all 7 non-empty events, and none has a larger ratio of probabilities than 2.5.

Now ask for a smaller ε, so that the factor e^{ε} is 2 instead of 2.5. Output 1 then breaks the factor, because its ratio is 2.5. It is the only output in the bad set, because only there is the ratio above 2. So Equation A.4 gives $\delta = 0.5 - 2 \times 0.2 = 0.1$. As a check, the script computes $\Pr[M(D) \in S] - 2\Pr[M(D') \in S]$ for every event S. The largest value is indeed 0.1000, reached by the event that holds output 1 alone. Figure A.1 draws it: δ is the red part of the first bar, the probability that sticks out above e^{ε} times the neighbour's.

Note that δ is not the probability of the bad set, which here is 0.5. Most of that probability is allowed by the factor e^{ε}, and only the excess counts.

A.1.4. Why it works

1. **A pointwise bound gives the event bound.** Suppose $L(y) \le \varepsilon$ at every output, that is $p_D(y) \le e^{\varepsilon} p_{D'}(y)$. The probability of an event is the sum of the probabilities of its outputs, so summing this inequality over the outputs in S gives $\Pr[M(D) \in S] \le e^{\varepsilon} \Pr[M(D') \in S]$. For a density, the sum is an integral, and the same step works. So bounding the loss at every output is enough for ε-DP.
2. **The slack for one event is a sum over its outputs.** Moving the e^{ε} term to the left in Equation A.2, the event S needs $\delta \ge \Pr[M(D) \in S] - e^{\varepsilon} \Pr[M(D') \in S]$. The right side is the sum, over the outputs y in S, of $p_D(y) - e^{\varepsilon} p_{D'}(y)$.
3. **The worst event takes exactly the outputs with a positive term.** To make that sum as large as possible, include every output whose term is positive and leave out every other one. A term is positive exactly when $p_D(y) > e^{\varepsilon} p_{D'}(y)$, that is when $L(y) > \varepsilon$. So the worst event is the bad set B, and the smallest δ that covers every event is its sum, Equation A.4.
4. **The probability of the bad set is always a valid δ.** Dropping the term $e^{\varepsilon} \Pr[M(D') \in B]$, which is never negative, gives $\delta(\varepsilon) \le \Pr[M(D) \in B] = \Pr[L > \varepsilon]$, where the loss is computed at an output drawn from $M(D)$. This simpler bound is what the classic Gaussian formula of Section A.6 uses.

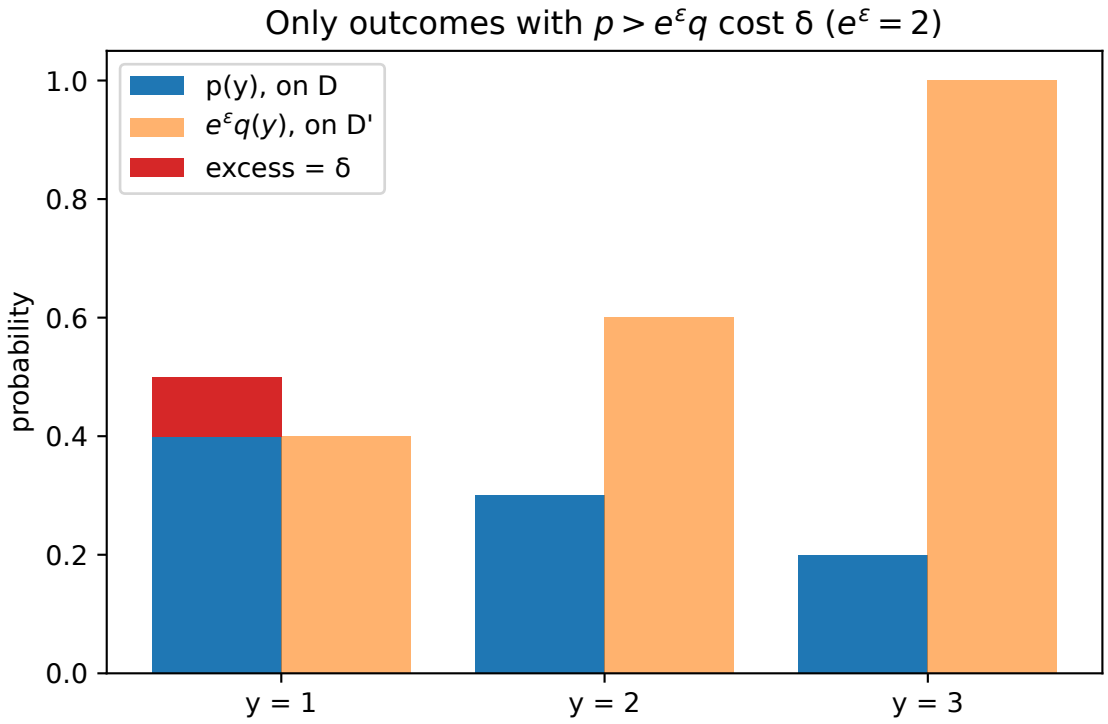

Figure A.1.: The three-output example. Blue bars are the probabilities on D, orange bars are $e^{\varepsilon} = 2$ times the probabilities on D'. Only output 1 has more probability on D than the orange bar allows, and the excess, in red, is the exact $\delta = 0.1$.

A.1.5. Checking it

The script lists every event of the three-output example and confirms both numbers by brute force. The largest ratio over events is 2.5000, the same as the largest ratio over single outputs. The largest excess at $e^{\varepsilon} = 2$ is 0.1000, the same as the sum over the bad set. The probability of the bad set, 0.5000, is five times larger than the exact δ, which shows how loose step 4 can be.

A.1.6. Recipe and pitfalls

To check a mechanism, write down its privacy loss for a pair of neighbours. If the loss never exceeds ε, you have ε-DP. If it does, the exact δ is the excess mass of Equation A.4, maximized over pairs of neighbours.

The most common mistake is to apply δ to each output instead of each event. "Every output has $p_D(y) \le e^{\varepsilon} p_{D'}(y) + \delta$" pays the slack once per output, and with many outputs that allows a mechanism that reveals everything (Section 18.2 gives the example). The second mistake is to forget the neighbouring relation. A replacement is a removal followed by an addition, so a guarantee under replace-one can cost up to twice the ε of one under add/remove. Every guarantee should therefore say which relation it uses. Section 18.4 writes the same exact δ as a divergence, and Section D.1 explains what ε means for an attacker.

A.2. Sensitivity: how much one person can move the answer

A.2.1. The question

Noise has to hide the effect of any one person. So before choosing the noise you need to know how far one person can move the answer. How do you compute that for the queries you actually run?

A.2.2. The answer

Let f be the query, a function that takes a dataset and returns d numbers. The **sensitivity** of f is the largest change that one person can cause, over all pairs of neighbours. Because the answer is a list of numbers, the change $v = f(D) - f(D')$ is a list too, and its size can be measured in two ways. The ℓ_1 **norm** $\|v\|_1 = |v_1| + \cdots + |v_d|$ adds up the absolute changes, and Laplace noise is calibrated to it. The ℓ_2 **norm** $\|v\|_2 = \sqrt{v_1^2 + \cdots + v_d^2}$ is the straight-line length of the change, and Gaussian noise is calibrated to it. So there are two sensitivities, one for each norm:

$$\Delta_1 = \max_{D \sim D'} \|f(D) - f(D')\|_1, \qquad \Delta_2 = \max_{D \sim D'} \|f(D) - f(D')\|_2. \tag{A.5}$$

Table A.3 gives them for the standard queries. Values are **clipped** to a range $[0, C]$: any value above C is replaced by C before the query runs, so no record can contribute more than C.

Table A.3.: Sensitivities of the standard queries under the two neighbouring relations.

Query	Add/remove Δ_1	Add/remove Δ_2	Replace-one Δ_1	Replace-one Δ_2
Count of records	1	1	0	0
Sum of values clipped to $[0, C]$	C	C	C	C
Mean of n clipped values, n public	no useful bound	no useful bound	C/n	C/n
Histogram, each record in one bin	1	1	2	$\sqrt{2}$
d counts that one record can all change by 1	d	$\sqrt{d}$	d	$\sqrt{d}$

A.2.3. A worked example

A study releases the mean age of $n = 1000$ patients, with ages clipped to $[0, 100]$, under replace-one. One patient's age can change from 0 to 100 at most, so the sum moves by at most $C = 100$. The mean is the sum divided by the fixed n, so it moves by at most $100/1000 = 0.1$ years. That is the sensitivity, $\Delta_1 = \Delta_2 = 0.1$, however old the patients actually are.

A.2.4. Why it works

Each row asks what the single worst record can do.

1. **Count.** Adding or removing a person changes the count by exactly 1. Replacing a person leaves it unchanged, which is why under replace-one the count of all records is public anyway.
2. **Sum of clipped values.** Adding a person with value x in $[0, C]$ changes the sum by x, at most C. Replacing x by x' changes it by $|x - x'|$, again at most C. Both bounds are reached with $x = C$ and $x' = 0$.
3. **Mean.** Under replace-one, the mean is the sum divided by the public n, so its sensitivity is the sum's divided by n, which is C/n. Under add/remove the divisor changes too, and the change depends on n, which is private. The script finds that for datasets of 1 to 3 values in $[0, 3]$ one record can move the mean by 1.5, from the mean of $\{0\}$ to the mean of $\{0, 3\}$. The usual fix is to release a noisy sum and a noisy count separately and divide them.
4. **Histogram.** Under add/remove the person lands in one bin, so one bin changes by 1. Both norms of the change are 1. Under replace-one one bin loses 1 and another gains 1, so the ℓ_1 norm is $1 + 1 = 2$ and the ℓ_2 norm is $\sqrt{1^2 + 1^2} = \sqrt{2}$.
5. **Counts that one person can all touch.** Suppose each person answers d yes/no questions and you release the number of "yes" answers to each. One person who says yes to all d moves every count by 1, so the ℓ_1 norm of the change is d and the ℓ_2 norm is $\sqrt{d \cdot 1^2} = \sqrt{d}$.

The last row shows why the two norms matter. When one person spreads their effect over many coordinates, Δ_1 grows like d but Δ_2 only like $\sqrt{d}$. Since the noise is scaled to the sensitivity, as the next sections show, this is why Gaussian noise wins for long vectors (Section 20.5).

A.2.5. Checking it

The script lists every dataset of 1 to 3 records and every neighbour under both relations, and takes the largest change. Values are in $\{0, 1, 2, 3\}$, so $C = 3$ and the histogram has 4 bins, and the vector query uses $d = 3$ questions. It reproduces every row of Table A.3. For example, the histogram has ℓ_1 sensitivity 1 under add/remove and 2 under replace-one, with ℓ_2 sensitivity 1.4142 under replace-one. The three counts have 3 and 1.7321. For the mean of exactly 3 records under replace-one it finds $3/3 = 1.0000$.

A.2.6. Recipe and pitfalls

First fix the neighbouring relation, then ask what the worst single record can do to each coordinate, and add the changes up in the norm your noise needs. Compute the sensitivity before you look at the data, because it is a worst case over everything the domain allows, not over the data you hold.

Unbounded data has infinite sensitivity. If ages, incomes or gradients can be as large as anyone likes, one record can move a sum by any amount, and no finite noise hides it. Clip every value to a fixed range first, and calibrate to the clipping norm. A second pitfall is a person who contributes many records: if one person can add 5 ratings, a count of ratings has sensitivity 5 per person, not 1. Section C.1 applies the same reasoning to clipped gradients.

A.3. Laplace noise: scale Δ_1/ε gives ε-DP

A.3.1. The question

You want to publish a count, or a few numbers, with pure ε-DP. How wide must the Laplace noise be, and how far will the published answer be from the truth?

A.3.2. The answer

The **Laplace distribution** is a two-sided exponential, peaked at 0. With scale b, its typical size, it puts density $\frac{1}{2b}e^{-|z|/b}$ at each value z. The **Laplace mechanism** adds independent Laplace noise to each of the d numbers, with the scale set to the ℓ_1 sensitivity divided by ε:

$$M(D) = f(D) + (Z_1, \dots, Z_d), \qquad Z_i \sim \mathrm{Lap}(b), \qquad b = \frac{\Delta_1}{\varepsilon}. \tag{A.6}$$

It is ε-DP. For one number, the error is the noise itself, and it exceeds a threshold τ with probability exactly $e^{-\tau/b}$. So with probability 0.95 the error is at most $b \ln 20$.

A.3.3. A worked example

A hospital has 1,234 patients with diabetes. On the neighbouring dataset D' there is one more, so the two true counts are 1234 and 1235, and $\Delta_1 = 1$. With $\varepsilon = 0.5$, the scale is $b = 1/0.5 = 2$.

The privacy loss at an output y is the log of the ratio of the two Laplace densities. The factors $\frac{1}{2b}$ cancel, and the log of a ratio of exponentials is the difference of the exponents, so

$$L(y) = \frac{|y - 1235| - |y - 1234|}{b}. \tag{A.7}$$

Table A.4 evaluates it at five outputs.

Table A.4.: The Laplace mechanism for a count with $b = 2$: the two densities and the privacy loss at five outputs.

Output y	1230	1234	1234.5	1235	1240
$p_D(y)$	0.0338	0.2500	0.1947	0.1516	0.0124
$p_{D'}(y)$	0.0205	0.1516	0.1947	0.2500	0.0205
Ratio	1.6487	1.6487	1.0000	0.6065	0.6065
$L(y)$	0.5	0.5	0	-0.5	-0.5

At $y = 1230$ the loss is $(5 - 4)/2 = 0.5$, and at $y = 1240$ it is $(5 - 6)/2 = -0.5$. Below both true counts the ratio is stuck at $e^{0.5} = 1.6487$, above both it is stuck at $e^{-0.5} = 0.6065$, and between them it moves from one to the other. It never goes further, however far out the output lands.

For accuracy, the 95% error bound is $b \ln 20 = 2 \times 2.9957 = 5.99$. So the published count is within about 6 of 1234 in 95% of releases. The bound scales with $1/\varepsilon$, so it is 29.96 at $\varepsilon = 0.1$, where the scale is 10, and 3.00 at $\varepsilon = 1$.

A.3.4. Why it works

1. **Only the shift matters.** Write $a = f(D)$ and $a' = f(D')$ for the two true answers. For one number, the privacy loss at y is $(|y - a'| - |y - a|)/b$, as in the example.
2. **Bound it with the triangle inequality.** The distance from y to a' is at most the distance from y to a plus the distance from a to a', so $|y - a'| - |y - a| \le |a - a'|$. In the example, with $y = 1230$, this says $5 - 4 \le 1$.
3. **The shift is at most the sensitivity.** So $L(y) \le |a - a'|/b \le \Delta_1/b$, and with $b = \Delta_1/\varepsilon$ that is ε. This holds at every output y.
4. **Several numbers.** With d coordinates and independent noise, the density of the output is the product of the d coordinate densities. The log of a product is a sum, so the privacy loss is the sum of the coordinate losses. Each is at most $|a_i - a'_i|/b$ by step 2, and their sum is at most $\|a - a'\|_1/b \le \Delta_1/b = \varepsilon$.
5. **Conclude.** The loss is at most ε at every output, for every pair of neighbours in either order. So by step 1 of Section A.1 the mechanism is ε-DP.
6. **Accuracy.** The absolute error $|Z|$ has density $\frac{1}{b}e^{-z/b}$ for $z \ge 0$, twice the Laplace density on one side. Its integral from τ to infinity is $e^{-\tau/b}$. Setting $e^{-\tau/b} = 0.05$ and solving gives $\tau = b \ln 20$. The same density has average $\int_0^\infty z\frac{1}{b}e^{-z/b}\,\mathrm{d}z = b$, so the typical error is b.

The bound of step 2 is reached, with equality, at every output below both true answers. So with a smaller scale b the loss there would be $1/b > \varepsilon$, and those outputs would break the factor e^{ε}. For the count above, the event "the output is at most 1234" has probability 0.5 on D and $\frac{1}{2}e^{-1/b} = 0.3033$ on D', a ratio of exactly $e^{0.5}$.

A.3.5. Checking it

Figure A.2 draws the two densities and their ratio for the example. The ratio is flat at e^{ε} on the left and at $e^{-\varepsilon}$ on the right, and it never leaves that band. Figure A.3 draws the privacy loss itself. It is flat outside the two true answers and a straight line between them, and it stays between -0.5 and 0.5. On a grid of 70,001 outputs from 1200 to 1270, the script finds the loss in exactly $[-0.5000, 0.5000]$.

For several numbers, the script takes three yes/no counts that one person can all raise by 1, so $\Delta_1 = 3$ and $b = 3/0.5 = 6$. Over 100,000 random outputs, the largest privacy loss is 0.5000, the ε that step 4 promises.

For accuracy, a million draws of Lap(2) give a mean absolute error of 2.0026 against the exact 2. Their 95th percentile is 5.9938 against $b \ln 20 = 5.9915$. The error exceeds 5.9915 in a fraction 0.0501 of draws.

A.3.6. Recipe and pitfalls

1. Compute the ℓ_1 sensitivity Δ_1 under your neighbouring relation.
2. Set $b = \Delta_1/\varepsilon$ and add independent Lap(b) noise to every coordinate.
3. Quote the error: b on average, and $b \ln 20$ with probability 0.95 for each coordinate.

The noise does not depend on the number of people, so a count of a million people and a count of ten get the same noise. Small groups are therefore expensive. Use fresh noise for every release, because reusing the same noise draw lets an analyst subtract it out. Releasing the same count k times with fresh noise costs $k\varepsilon$, which Section B.1 derives. Section 20.2 adds the bound on the largest error over d coordinates.

A.4. Randomized response: one bit, ε-DP

A.4.1. The question

Each person holds one sensitive bit, such as "I have used a drug", and nobody is trusted to see the true bits. How often should each person tell the truth, and how do you estimate the fraction of ones from the noisy reports?

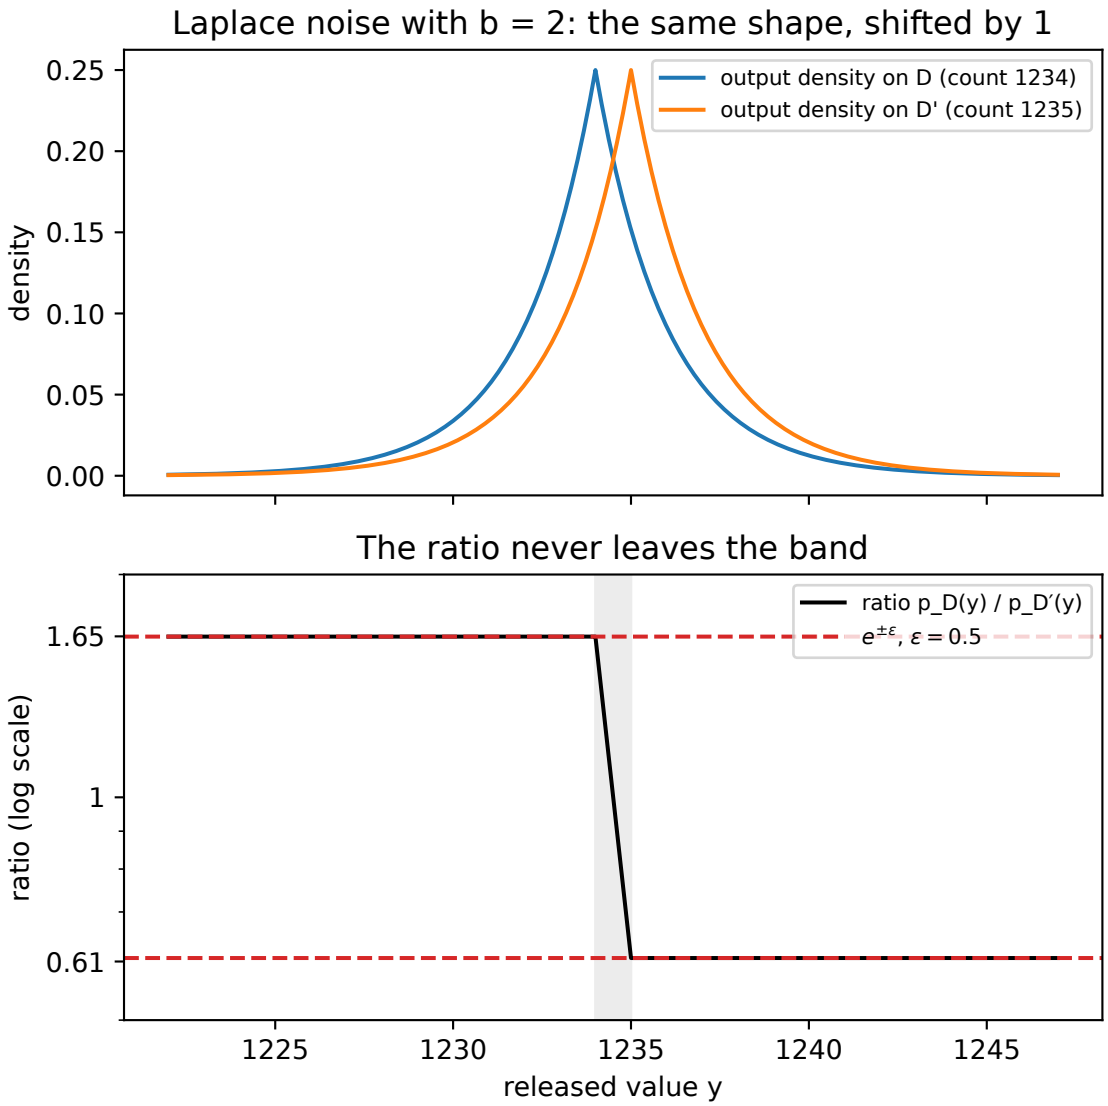

Figure A.2.: Top: the output densities of a count released with Laplace noise of scale 2, on a dataset with true count 1234 and on its neighbour with 1235. Bottom: their ratio on a log scale, which stays between $e^{-0.5}$ and $e^{0.5}$ at every output and reaches both ends.

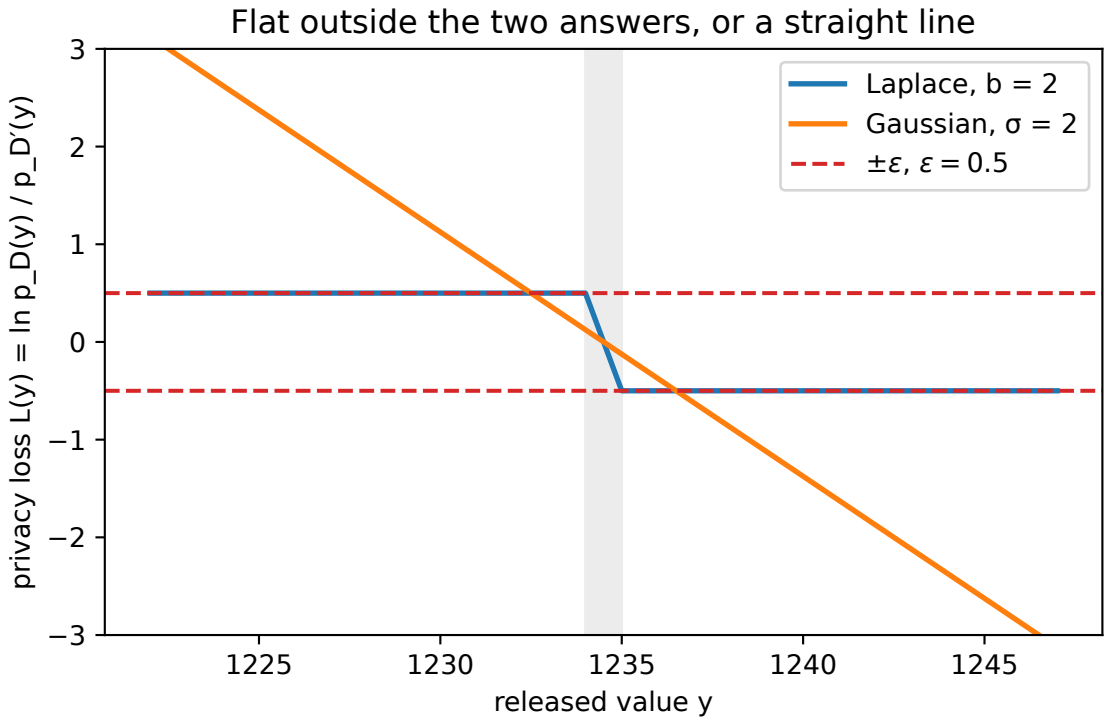

Figure A.3.: The privacy loss $L(y)$ of the same count against the released value, for Laplace noise of scale 2 and for Gaussian noise of standard deviation 2. The Laplace loss is flat outside the two true answers and never leaves $[-0.5, 0.5]$. The Gaussian loss is a straight line that leaves any band.

A.4.2. The answer

Each person reports their true bit with probability t and the flipped bit with probability $1 - t$, where

$$t = \frac{e^{\varepsilon}}{1 + e^{\varepsilon}}. \tag{A.8}$$

This is ε-DP under replace-one. If $\bar{y}$ is the fraction of reported ones among n people, an unbiased estimate of the true fraction π of ones is

$$\hat{\pi} = \frac{\bar{y} - (1 - t)}{2t - 1}, \qquad \mathrm{sd}(\hat{\pi}) = \frac{\sqrt{t(1 - t)}}{(2t - 1)\sqrt{n}}. \tag{A.9}$$

A.4.3. A worked example

At $\varepsilon = 0.5$, $t = e^{0.5}/(1 + e^{0.5}) = 0.6225$. A true 1 is reported as 1 with probability 0.6225, and a true 0 is reported as 1 with probability 0.3775. Their ratio is $0.6225/0.3775 = 1.6487 = e^{0.5}$.

Survey $n = 1000$ people, of whom a fraction $\pi = 0.3$ have the bit. The expected fraction of reported ones is $0.3 \times 0.6225 + 0.7 \times 0.3775 = 0.4510$. The estimate subtracts $1 - t = 0.3775$ and divides by $2t - 1 = 0.2449$, which turns this back into 0.3. Its standard deviation is $\sqrt{0.6225 \times 0.3775}/(0.2449\sqrt{1000}) = 0.0626$.

A.4.4. Why it works

1. **Privacy.** There are two inputs and two outputs. A report of 1 has probability t if the bit is 1 and $1 - t$ if it is 0, so its privacy loss is $\ln(t/(1 - t))$. With $t = e^{\varepsilon}/(1 + e^{\varepsilon})$, the ratio is $t/(1 - t) = e^{\varepsilon}$. A report of 0 has the inverse ratio, so $|L| \le \varepsilon$ at both outputs.
2. **Many people.** People flip their own coins independently, so the probability of all the reports is a product with one factor per person. Under replace-one, neighbours differ in one person's bit, so every other factor is the same on both datasets and cancels in the ratio. The loss is that one person's loss.
3. **The expected report.** A person with bit 1 reports 1 with probability t, and a person with bit 0 with probability $1 - t$. Averaging over the population gives $\mathbb{E}[\bar{y}] = \pi t + (1 - \pi)(1 - t) = (1 - t) + \pi(2t - 1)$.
4. **Unbias it.** Solving that equation for π gives $\hat{\pi}$. It is a linear function of $\bar{y}$, so its average is the true π.
5. **The spread.** Each report is a 0/1 variable with variance $t(1 - t)$, whatever the true bit, and the reports are independent. So $\bar{y}$ has variance $t(1 - t)/n$. Dividing by $2t - 1$ divides the standard deviation by $2t - 1$.

A.4.5. Checking it

Ten thousand simulated surveys give a mean estimate of 0.2996 and a standard deviation of 0.0629, against 0.3 and 0.0626 from the formulas.

A.4.6. Recipe and pitfalls

Set $t = e^{\varepsilon}/(1+e^{\varepsilon})$, collect the reports, and compute $\hat{\pi}$. Expect an error of about $1/(\varepsilon\sqrt{n})$ for small ε. The reason is that $e^{\varepsilon} \approx 1+\varepsilon$ there, so $t \approx (1+\varepsilon)/2$, which makes $2t-1 \approx \varepsilon/2$ and $t(1-t) \approx \frac{1}{4}$.

The price of trusting nobody is large. If one trusted party could see the true bits, it could add $\mathrm{Lap}(1/\varepsilon)$ noise to their count instead, and the error on the fraction would fall like $1/n$, not like $1/\sqrt{n}$. The guarantee also holds only under replace-one. Under add/remove the neighbour has one report more or fewer, and the number of reports, which is published, shows the difference at once. Section 18.3 compares the two designs, and Warner's original survey design is the same mechanism.

A.5. The exponential mechanism: choosing the best candidate

A.5.1. The question

Sometimes the output is not a number but a choice: the best model, the most common diagnosis, the winner of a vote. Adding noise to a name makes no sense. How do you choose privately, and how good is the choice?

A.5.2. The answer

Fix a list of candidates $\mathcal{R}$ in advance, and write $|\mathcal{R}|$ for their number. For each candidate r, a score $u(D, r)$ says how good it is on dataset D, where higher is better. Let Δu be the sensitivity of the score, the most that one person can change any one candidate's score.

The **exponential mechanism** gives each candidate a weight $\exp(\varepsilon u(D,r)/(2\Delta u))$, which grows with its score. It then picks a candidate with probability equal to its share of the total weight $W(D)$, the **normalizer**:

$$\Pr[M_E(D) = r] = \frac{\exp\left(\frac{\varepsilon\, u(D,r)}{2\Delta u}\right)}{W(D)}, \qquad W(D) = \sum_{s \in \mathcal{R}} \exp\left(\frac{\varepsilon\, u(D,s)}{2\Delta u}\right). \tag{A.10}$$

Dividing by the normalizer makes the probabilities add up to 1. The mechanism is ε-DP, and its choice is rarely far below the best score $\mathrm{OPT}(D)$. For every $t > 0$,

$$\Pr\left[u(D, M_E(D)) \le \mathrm{OPT}(D) - \frac{2\Delta u}{\varepsilon}(\ln|\mathcal{R}| + t)\right] \le e^{-t}. \tag{A.11}$$

A.5.3. A worked example

Six people vote among options A, B, C and D. On D the counts are $(3, 2, 1, 0)$, and on the neighbour D' one more person votes for B, so the counts are $(3, 3, 1, 0)$. The score is the count, so $\Delta u = 1$. Take $\varepsilon = 1$, so each weight is $e^{u/2}$.

On D the weights are $e^{1.5} = 4.4817$, $e^{1} = 2.7183$, $e^{0.5} = 1.6487$ and $e^{0} = 1$, which sum to $W(D) = 9.8487$. So A is chosen with probability $4.4817/9.8487 = 0.4551$. On D' B's weight rises to $e^{1.5}$ and the normalizer to $W(D') = 11.6121$. Table A.5 lists all four probabilities.

Table A.5.: The exponential mechanism with $\varepsilon = 1$ on a vote and its neighbour with one more vote for B.

Option	A	B	C	D
$\Pr[M_E(D) = r]$	0.4551	0.2760	0.1674	0.1015
$\Pr[M_E(D') = r]$	0.3859	0.3859	0.1420	0.0861
Ratio	1.1790	0.7151	1.1790	1.1790

For A, C and D the score did not change, so the ratio is just the change in the normalizer, $11.6121/9.8487 = 1.1790$. For B, its own weight is also $e^{1/2}$ times larger on D' than on D, so its ratio is $1.1790 \times e^{-1/2} = 1.1790 \times 0.6065 = 0.7151$. The largest privacy loss on this pair is $|\ln 0.7151| = 0.3353$, well below $\varepsilon = 1$.

A.5.4. Why it works

Privacy. The probability of r is a weight divided by a total, and one person can change both. So split the ratio of the probabilities on D and D' into two factors:

$$\frac{\Pr[M_E(D) = r]}{\Pr[M_E(D') = r]} = \exp\Big(\frac{\varepsilon\big(u(D, r) - u(D', r)\big)}{2\Delta u}\Big) \cdot \frac{W(D')}{W(D)}. \tag{A.12}$$

1. **The own-weight factor.** One person changes r's score by at most Δu, so the exponent is at most $\varepsilon\Delta u/(2\Delta u) = \varepsilon/2$. The factor is at most $e^{\varepsilon/2}$.
2. **The normalizer factor.** Every candidate's score on D' is at most Δu above its score on D, so every term of $W(D')$ is at most $e^{\varepsilon/2}$ times the matching term of $W(D)$. Adding up the terms, $W(D') \le e^{\varepsilon/2} W(D)$.
3. **Multiply.** The ratio is at most $e^{\varepsilon/2} \cdot e^{\varepsilon/2} = e^{\varepsilon}$. The candidate and the pair were arbitrary, and the same argument works with D and D' swapped, so by step 1 of Section A.1 the mechanism is ε-DP.

The 2 in the exponent is there because both factors can be large at once. One person can raise r's score and lower all the others, so each factor needs its own half of the budget.

Utility. Call a candidate poor if its score is at least c below the best.

1. **Poor candidates are light.** Each has weight at most $e^{\varepsilon(\mathrm{OPT}-c)/(2\Delta u)}$, since the weight grows with the score.
2. **The normalizer is heavy.** It contains the weight of a best candidate, so $W(D) \ge e^{\varepsilon\,\mathrm{OPT}/(2\Delta u)}$.
3. **Divide.** There are at most $|\mathcal{R}|$ poor candidates, so together they have probability at most $|\mathcal{R}|\, e^{\varepsilon(\mathrm{OPT}-c)/(2\Delta u)} / e^{\varepsilon\,\mathrm{OPT}/(2\Delta u)} = |\mathcal{R}|\, e^{-\varepsilon c/(2\Delta u)}$.
4. **Solve for c.** Setting $|\mathcal{R}|\, e^{-\varepsilon c/(2\Delta u)} = e^{-t}$ and taking logs gives $c = \frac{2\Delta u}{\varepsilon}(\ln|\mathcal{R}| + t)$.

A.5.5. Checking it

Figure A.4 shows the vote. On the right, each ratio is drawn as its two factors, and both stay below $e^{\varepsilon/2}$. Only B's score moved, so for A, C and D the own-weight factor is exactly 1.

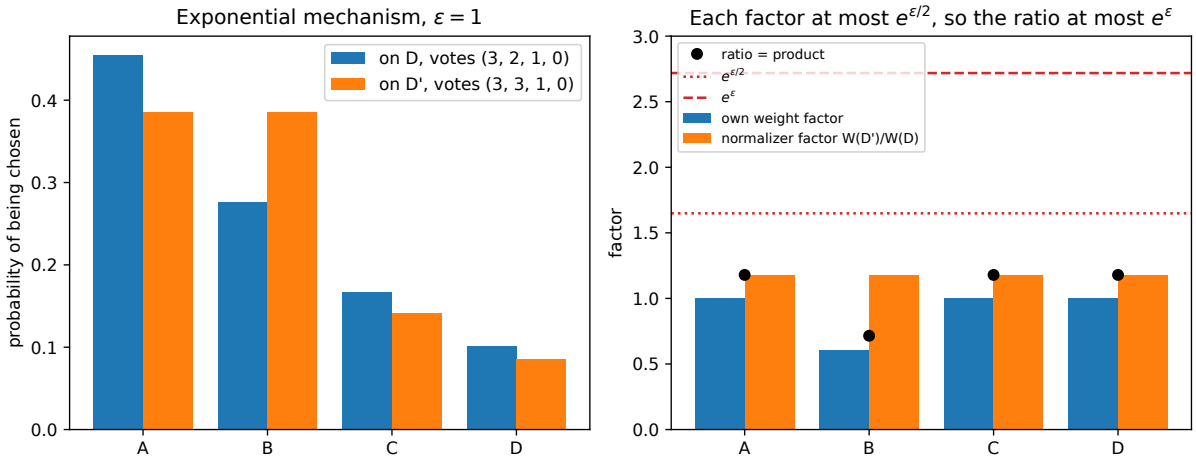

Figure A.4.: Left: the probability that the exponential mechanism with $\varepsilon = 1$ chooses each option, on a vote with counts (3, 2, 1, 0) and on its neighbour with one more vote for B. Right: each ratio of the two probabilities, split into the change of the option's own weight and the change of the normalizer. Each factor stays below $e^{\varepsilon/2}$, so the ratio stays below e^{ε}.

The utility bound is weak for so small an example. The probability of choosing C or D, at least $c = 2$ below A, is 0.2689. Step 3 with $|\mathcal{R}| = 4$ bounds it by $4e^{-1} = 1.4715$, which says nothing. It helps when there are many candidates. Take 50 models scored by their correct predictions, $900, 899, \dots, 851$, so that $\Delta u = 1$. With $\varepsilon = 1$ and $t = 3$, the bound says the gap exceeds $2(\ln 50 + 3) = 13.82$ with probability at most $e^{-3} = 0.0498$. The exact probability is 9.12×10^{-4}, much smaller, because most models are far below the best and much lighter than the bound assumes.

A.5.6. Recipe and pitfalls

1. Fix the list of candidates before looking at the data, and choose a score $u(D, r)$.
2. Find the score's sensitivity Δu.
3. Sample r with probability proportional to $\exp(\varepsilon u(D, r)/(2\Delta u))$.

The candidate list must not depend on the data, because the proof compares the same list on D and D'. Watch numerical overflow too: subtract the largest score before taking exponentials, which changes no probability. When every score moves the same way under each change of one person, as counts under add/remove do, the two factors cannot both be large, and the 2 can be dropped (Section 22.1). Section 22.2 adds the expected gap and the applications.

A.6. Gaussian noise, the classic formula

A.6.1. The question

Gaussian noise is calibrated to the ℓ_2 sensitivity, which is much smaller than the ℓ_1 sensitivity for long vectors such as gradients. But its privacy loss has no upper limit, so it can never give pure ε-DP. How much Gaussian noise gives (ε, δ)-DP, and where does the textbook formula come from?

A.6.2. The answer

Add independent normal noise with mean 0 and standard deviation σ to each coordinate. For $0 < \varepsilon < 1$ and $0 < \delta < 1$, the **Gaussian mechanism** with

$$\sigma = \frac{\Delta_2 \sqrt{2 \ln(1.25/\delta)}}{\varepsilon} \tag{A.13}$$

is (ε, δ)-DP. The proof below needs $\delta \leq 0.7448$, which every useful δ satisfies.

A.6.3. A worked example

Release the diabetes count with $\Delta_2 = 1$, $\varepsilon = 0.5$ and $\delta = 10^{-5}$. Then $\ln(1.25/10^{-5}) = \ln 125{,}000 = 11.7361$, and its double has square root $c = \sqrt{23.4722} = 4.8448$. So $\sigma = 4.8448/0.5 = 9.6896$. The 95% error of normal noise is 1.96 standard deviations, here 18.99, against 5.99 for Laplace noise at the same ε. For a single count Laplace noise is better, and Gaussian noise pays off only for long vectors.

A.6.4. Why it works

The plan is to find the privacy loss, which turns out to be a normal random variable. Then show that it exceeds ε with probability at most δ, and that this is enough. Write $\Phi(x)$ for the standard normal cumulative distribution function, the probability that a normal variable with mean 0 and standard deviation 1 is below x, and $\varphi(x) = e^{-x^2/2}/\sqrt{2\pi}$ for its density.

1. **The privacy loss is a straight line in the noise.** Take one number, with true answers a on D and $a + s$ on D', where s is the shift between them. An output from $M(D)$ is $y = a + z$, where z is the noise. Its density on D is proportional to $e^{-z^2/(2\sigma^2)}$ and on D' to $e^{-(z-s)^2/(2\sigma^2)}$, because y sits $z - s$ away from D''s answer. The log of the ratio is the difference of the exponents:

$$L = \frac{(z-s)^2 - z^2}{2\sigma^2} = \frac{s^2 - 2sz}{2\sigma^2}. \tag{A.14}$$

2. **So the loss is normal.** The noise z is normal with mean 0 and standard deviation σ, and L is a constant minus a multiple of z. So L is normal with mean $s^2/(2\sigma^2)$ and standard deviation $2s\sigma/(2\sigma^2) = s/\sigma$. Write $\mu = s/\sigma$ for the shift measured in noise standard deviations. Then L has mean $\mu^2/2$ and standard deviation μ. For a vector the same holds with $s = \|f(D) - f(D')\|_2$. The reason is that expanding the squared distances in the same way leaves only the noise's component along the direction of the shift, and that component is a single normal number with standard deviation σ.
3. **A small chance of a large loss is enough.** Let B be the bad set, the outputs with $L > \varepsilon$, and suppose its probability on D is at most δ. Split any event S into its part inside B and its part outside. The part inside has probability at most δ, because it is part of B. On the part outside, every output has $p_D(y) \le e^{\varepsilon} p_{D'}(y)$, so summing over it gives at most $e^{\varepsilon} \Pr[M(D') \in S]$. Adding the two parts gives

$$\Pr[M(D) \in S] \le e^{\varepsilon} \Pr[M(D') \in S] + \delta, \tag{A.15}$$

   which is Equation A.2. The pair in the other order has the same loss distribution, by the symmetry of the normal curve, so it needs nothing new.
4. **The bad event is a normal tail.** Standardize the loss by subtracting its mean $\mu^2/2$ and dividing by its standard deviation μ. The result is a standard normal variable, and $L > \varepsilon$ exactly when it exceeds the point $t = (\varepsilon - \mu^2/2)/\mu = \varepsilon/\mu - \mu/2$. By the symmetry of the normal curve, $\Pr[L > \varepsilon] = \Phi(-t)$. A larger shift makes t smaller and the tail heavier, so the worst pair has the largest shift, $s = \Delta_2$.
5. **Put in the formula.** Write $c = \sqrt{2\ln(1.25/\delta)}$, so Equation A.13 is $\sigma = c\Delta_2/\varepsilon$. Then $\mu = \Delta_2/\sigma = \varepsilon/c$, and

$$t = \frac{\varepsilon}{\mu} - \frac{\mu}{2} = c - \frac{\varepsilon}{2c}. \tag{A.16}$$

6. **Bound the normal tail.** For $t > 0$, every point z beyond t has $z/t \ge 1$, so the tail $\int_t^\infty \varphi(z)\,\mathrm{d}z$ is at most $\int_t^\infty \frac{z}{t}\varphi(z)\,\mathrm{d}z$. The derivative of $\varphi(z)$ is $-z\varphi(z)$, so the second integral equals $\varphi(t)/t$. This is the **Mills-ratio bound**:

$$\Phi(-t) \le \frac{e^{-t^2/2}}{t\sqrt{2\pi}}. \tag{A.17}$$

7. **Expand t^2.** Squaring step 5 gives $t^2 = c^2 - \varepsilon + \varepsilon^2/(4c^2)$, which is at least $c^2 - \varepsilon$. So $e^{-t^2/2} \le e^{-c^2/2} e^{\varepsilon/2}$. By the definition of c, $e^{-c^2/2} = \delta/1.25$. Together with step 6,

$$\Pr[L > \varepsilon] \le \delta \cdot \frac{e^{\varepsilon/2}}{1.25\sqrt{2\pi}\,t}. \tag{A.18}$$

8. **This is where 1.25 and $\varepsilon < 1$ come in.** The bound is at most δ when the fraction is at most 1, that is when $t \ge e^{\varepsilon/2}/(1.25\sqrt{2\pi})$. For $\varepsilon < 1$, the right side is below $e^{1/2}/(1.25\sqrt{2\pi}) = 0.5262$. It remains to show that t is that large. For $\varepsilon < 1$, step 5 gives $t = c - \varepsilon/(2c) \ge c - 1/(2c)$. This lower bound grows with c, and it equals 0.5262 at $c = 1.0176$, the positive root of $c^2 - 0.5262c - \frac{1}{2} = 0$. Since c grows as δ shrinks, $c \ge 1.0176$ holds whenever $\delta \le 1.25e^{-1.0176^2/2} = 0.7448$. So the constant 1.25 absorbs the factor $e^{\varepsilon/2}/(t\sqrt{2\pi})$, and the condition $\varepsilon < 1$ keeps $e^{\varepsilon/2}$ below $e^{1/2}$.

Step 3 is the reason a tail probability is enough. The rare outputs with a large loss are paid for by δ, and every other output keeps the factor e^{ε}.

A.6.5. Checking it

The proof made three approximations in a row. Step 4 replaced the exact δ by the bad-set probability, step 6 replaced that by the Mills bound, and step 7 loosened it further with the constants. Figure A.5 follows each of them for ε up to 1 at $\delta = 10^{-5}$. At $\varepsilon = 0.5$ the numbers are in Table A.6.

Table A.6.: Each step of the classic proof at $\varepsilon = 0.5$, $\delta = 10^{-5}$, $\Delta_2 = 1$, where $t = 4.7932$.

Quantity at the classic $\sigma = 9.6896$	Value
Target δ	10^{-5}
After expanding t^2, step 7	8.55×10^{-7}
Mills bound $\varphi(t)/t$, step 6	8.54×10^{-7}
Bad event $\Pr[L > \varepsilon] = \Phi(-t)$, step 4	8.21×10^{-7}
Exact $\delta(\varepsilon)$, from Section A.7	1.61×10^{-8}

So the classic σ delivers a δ 622 times smaller than asked for. The constants of step 8 cost a factor of 11.7, and dropping the correction term of Equation A.4 costs a factor of 51.0. The Mills ratio itself costs almost nothing.

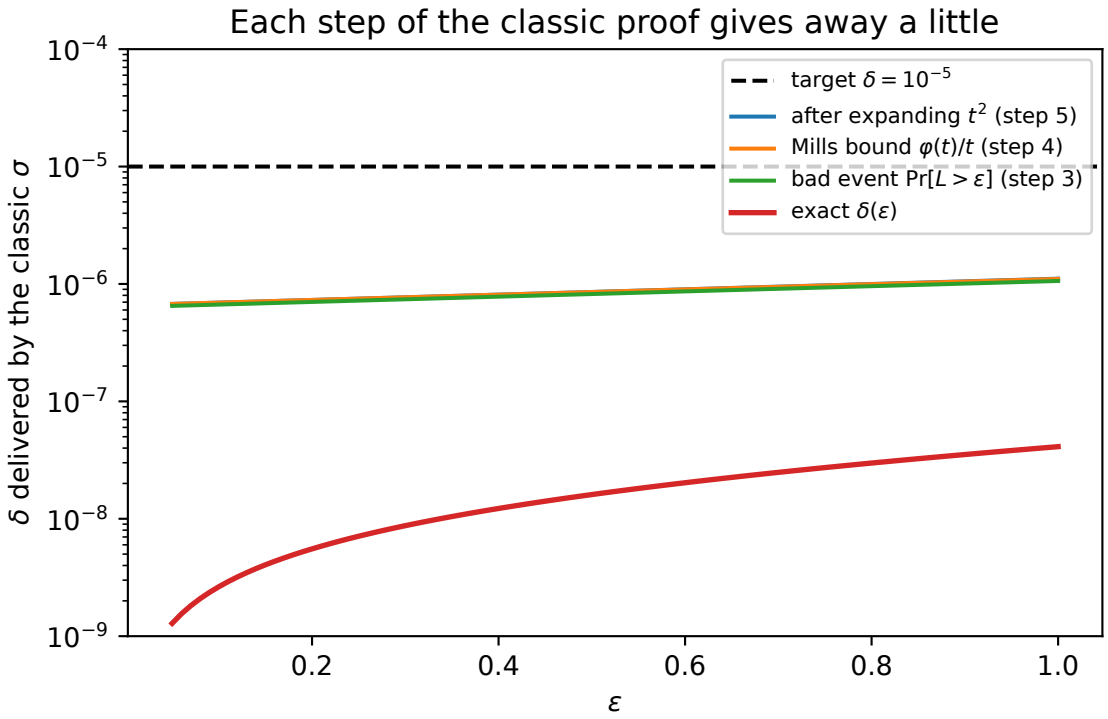

Figure A.5.: The δ that the classic σ delivers at each ε up to 1, for a target $\delta = 10^{-5}$, at each step of the proof. The bound after step 7, the Mills bound and the bad-event probability nearly coincide, about ten times below the target. The exact δ is a further 25.8 times smaller at $\varepsilon = 1$ and 505.9 times smaller at $\varepsilon = 0.05$.

A.6.6. Recipe and pitfalls

1. Compute the ℓ_2 sensitivity Δ_2.
2. For $\varepsilon < 1$, set $\sigma = \Delta_2\sqrt{2\ln(1.25/\delta)}/\varepsilon$.
3. Add independent normal noise with that σ to every coordinate.

The formula is valid but wasteful, as the table shows. The proof says nothing for $\varepsilon \geq 1$, and Section A.7 shows that the formula eventually becomes wrong there. Choose δ much smaller than $1/n$. A mechanism that publishes each person's record in full with probability δ satisfies the definition, and with n people and $\delta = 1/n$ it publishes about one person's record every time. Section 20.3 gives the same proof with the vector case in full.

A.7. Gaussian noise, the exact calibration

A.7.1. The question

The classic formula overshoots by a large factor, and it says nothing for $\varepsilon \geq 1$. What is the smallest σ that gives (ε, δ)-DP, for any ε?

A.7.2. The answer

Measure the sensitivity in units of the noise, $\mu = \Delta_2/\sigma$. The Gaussian mechanism is (ε, δ)-DP exactly when $\delta \geq \delta(\varepsilon)$, where

$$\delta(\varepsilon) = \Phi\Big(\frac{\Delta_2}{2\sigma} - \frac{\varepsilon\sigma}{\Delta_2}\Big) - e^{\varepsilon}\,\Phi\Big(-\frac{\Delta_2}{2\sigma} - \frac{\varepsilon\sigma}{\Delta_2}\Big) = \Phi\Big(\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) - e^{\varepsilon}\,\Phi\Big(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big). \tag{A.19}$$

This $\delta(\varepsilon)$ falls as σ grows. So the smallest σ for a target (ε, δ) is the one solution of $\delta(\varepsilon) = \delta$, which a computer finds by bisection.

A.7.3. A worked example

To see the two terms, take a case where both terms are large enough to see, $\mu = 1$ and $\varepsilon = 1$. The first term is $\Phi(0.5 - 1) = \Phi(-0.5) = 0.3085$, the probability of the bad set on D. The second is $e \cdot \Phi(-1.5) = 0.1816$, the correction. Their difference is the exact $\delta = 0.1269$.

Now the count again, with $\Delta_2 = 1$, $\varepsilon = 0.5$ and $\delta = 10^{-5}$. Bisection finds $\sigma = 7.0318$, and putting it back into Equation A.19 gives $\delta = 1.000 \times 10^{-5}$. The classic formula gave 9.6896, which is 1.378 times more noise than needed. At the classic σ the true δ is 1.61×10^{-8}. With the exact σ the 95% error is $1.96 \times 7.0318 = 13.78$, against 18.99 with the classic one.

A.7.4. Why it works

1. **Start from the exact δ.** By Equation A.4, the smallest δ for one pair of neighbours is $\Pr[M(D) \in B] - e^{\varepsilon} \Pr[M(D') \in B]$, where B is the set of outputs with $L > \varepsilon$.
2. **The first term.** Step 4 of Section A.6 found $\Pr[M(D) \in B] = \Phi(-t)$ with $t = \varepsilon/\mu - \mu/2$, which is $\Phi(\mu/2 - \varepsilon/\mu)$.
3. **The second term.** Measure the output in units of σ, starting from D's true answer. The bad set is the outputs below $\mu/2 - \varepsilon/\mu$, by step 4 of Section A.6. On D' the output is centred at μ instead of 0, so it falls below that point with probability $\Phi(\mu/2 - \varepsilon/\mu - \mu) = \Phi(-\mu/2 - \varepsilon/\mu)$.
4. **Combine.** Subtracting e^{ε} times the second term from the first gives Equation A.19 for this pair.
5. **The largest shift is the worst pair, and more noise always helps.** The plan is to show that δ grows with μ, by computing its derivative. Write $\alpha = \mu/2 - \varepsilon/\mu$ and $\beta = -\mu/2 - \varepsilon/\mu$ for the two arguments, so that $\delta = \Phi(\alpha) - e^{\varepsilon}\Phi(\beta)$. Their derivatives in μ are $\frac{1}{2} + \varepsilon/\mu^2$ and $-\frac{1}{2} + \varepsilon/\mu^2$, which differ by exactly 1. Also $\alpha^2 - \beta^2 = (\alpha - \beta)(\alpha + \beta) = \mu \cdot (-2\varepsilon/\mu) = -2\varepsilon$, so $\varphi(\beta) = e^{-\varepsilon}\varphi(\alpha)$. The derivative of δ in μ is therefore

$$\varphi(\alpha)\Big(\frac{1}{2} + \frac{\varepsilon}{\mu^2}\Big) - e^{\varepsilon}e^{-\varepsilon}\varphi(\alpha)\Big(-\frac{1}{2} + \frac{\varepsilon}{\mu^2}\Big) = \varphi(\alpha) > 0. \tag{A.20}$$

   So δ grows with the shift μ, and the worst pair of neighbours is the one with the largest shift, Δ_2. And since $\mu = \Delta_2/\sigma$, a larger σ means a smaller μ and a smaller δ.
6. **"Exactly when."** The worst pair needs $\delta \geq \delta(\varepsilon)$ by step 1, and every other pair needs less by step 5. So $\delta \geq \delta(\varepsilon)$ is both necessary and enough.
7. **Solve by bisection.** As σ grows from near 0 to very large, $\delta(\varepsilon)$ falls steadily from near 1 to near 0, so it crosses the target exactly once. Bisection keeps an interval of σ values with the crossing inside, evaluates δ at its midpoint, and keeps the half that still contains the crossing. Each step halves the interval, and the script takes its midpoints in $\ln \sigma$ because σ can range over many orders of magnitude.

Intuitively, step 5 says that adding more noise can only make the two datasets harder to tell apart. A Gaussian mechanism with a larger σ is the one with a smaller σ plus extra independent noise, and anything you can detect after adding that extra noise yourself, you could detect before.

A.7.5. Checking it

Figure A.6 draws the derivation at $\mu = 1$ and $\varepsilon = 1$. On the left, the bad set is the outputs left of -0.5σ, where the density on D rises above e^{ε} times the density on D'. The red area between the two curves is δ, and the orange area under it is the correction that the classic proof throws away. On the right, the same δ appears as the part of the privacy loss distribution beyond $L = \varepsilon$.

The script checks the closed form in three ways. First, it integrates the excess $p_D - e^{\varepsilon}p_{D'}$ over the bad set numerically (by Simpson's rule, on a fine grid), and at $\mu = 1$, $\varepsilon = 1$ this gives 0.1269. The same δ is also the average of $(1 - e^{\varepsilon - L})_+$ over losses drawn on D, where $(x)_+$ means $\max(x, 0)$ (Section 18.4 shows why). A Monte Carlo average of it over a million random draws gives 0.1270. Second, over 22 pairs of ε and μ, the largest relative difference between the closed form and the numerical integral is 3.1×10^{-6}. Third, a numerical derivative in μ agrees with $\varphi(\alpha)$ of step 5 to within 10^{-9} on a grid of 16 pairs.

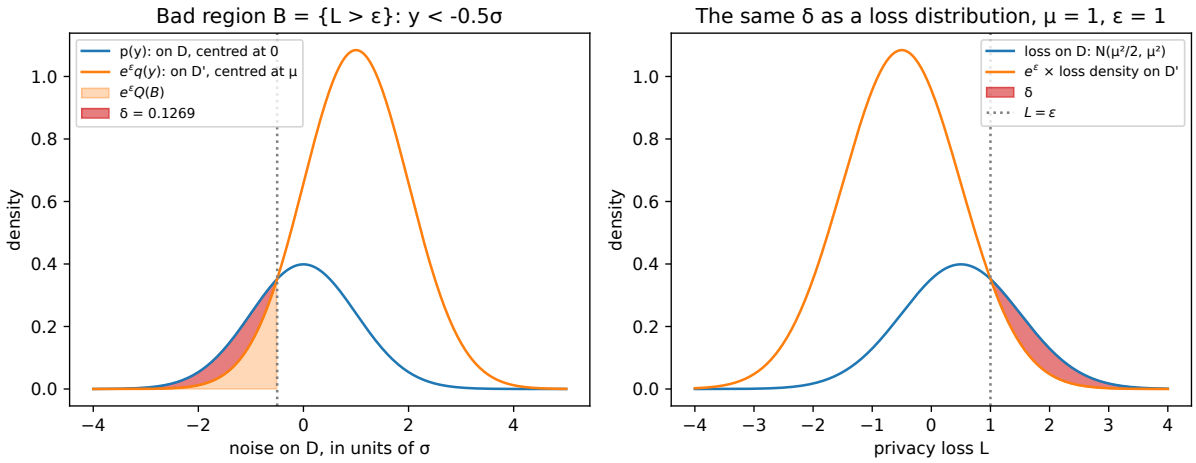

Figure A.6.: The exact δ of the Gaussian mechanism at $\mu = 1$, $\varepsilon = 1$. Left: the output density on D and e^ε times the density on D', with the output measured in units of σ. On the bad set, left of the dotted line, the red excess is $\delta = 0.1269$ and the orange area is the correction $e^\varepsilon \Pr[M(D') \in B] = 0.1816$. Right: the same excess in terms of the privacy loss, which is normal with mean $\mu^2/2$ and standard deviation μ on D.

Table A.7 compares the two calibrations at $\delta = 10^{-5}$, and Figure A.7 draws them over a wider range.

Table A.7.: The classic and the exact Gaussian noise at $\delta = 10^{-5}$.

ε	Classic σ/Δ_2	Exact σ/Δ_2	Classic / exact
0.1	48.4481	30.7496	1.576
0.25	19.3792	13.2855	1.459
0.5	9.6896	7.0318	1.378
1	4.8448	3.7306	1.299
2	2.4224	1.9938	1.215
4	1.2112	1.0812	1.120
8	0.6056	0.6002	1.009

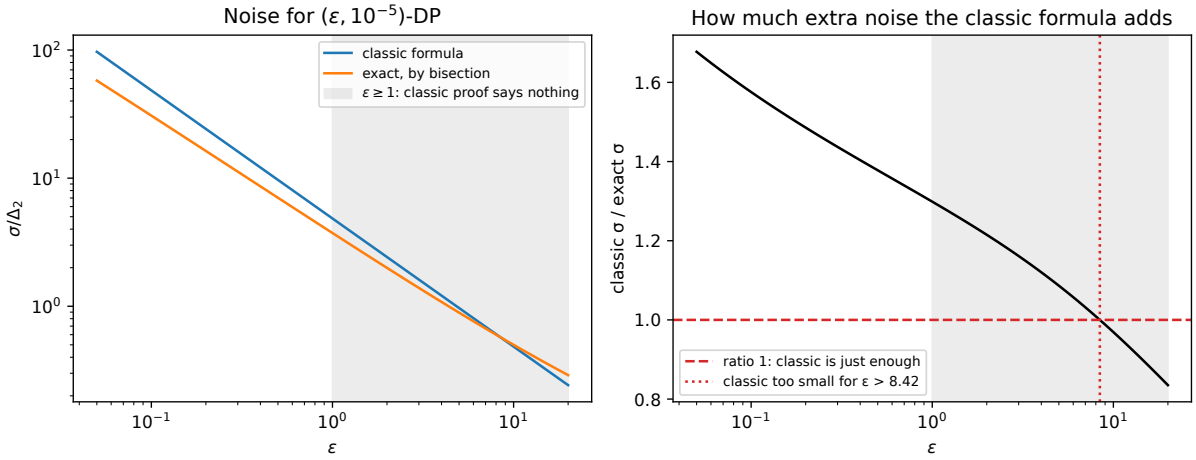

Figure A.7.: Left: the noise σ/Δ_2 needed for $(\varepsilon, 10^{-5})$-DP by the classic formula and by the exact calibration, on log axes. Right: their ratio. For ε from 0.05 to 1 the classic formula uses 1.30 to 1.68 times the necessary noise. Beyond $\varepsilon = 1$, in the shaded region, its proof says nothing, and beyond $\varepsilon = 8.42$ it adds too little noise.

For $\varepsilon < 1$ the classic formula is valid but loose, by a factor that grows as ε shrinks. Above 1 its proof no longer applies. The formula still happens to give enough noise at $\delta = 10^{-5}$ up to $\varepsilon = 8.42$, but beyond that point its true δ exceeds the target, so it is wrong there, not just unproved.

a whole curve of (ε, δ) pairs, so quote μ or the curve rather than one pair. Section 20.4 derives the same formula through a divergence between the two output distributions, and Section B.3 shows that many Gaussian releases combine into one. Section A.8 works through the formula by hand and in code, and shows how the noise changes when you move ε, δ or the number of releases.

A.8. How ε, δ, σ and the sensitivity trade off

A.8.1. The question

The last section gave a formula for the exact δ of the Gaussian mechanism and a way to solve it for σ. In practice you start from what you can give up, a privacy budget of ε and δ, or from the noise you can afford, and you want to know how the four quantities move together. They are the privacy parameter ε, the slack δ, the noise standard deviation σ and the ℓ_2 sensitivity Δ_2. How do you compute δ from normal probabilities, by hand and in code? And if you halve ε, make δ a thousand times smaller or release the answer ten times, how much more noise do you need?

A.8.2. The answer

Everything follows from the exact formula of Section A.7. Write $\Phi(x)$ for the probability that a standard normal variable is below x, and $\mu = \Delta_2/\sigma$ for the sensitivity measured in units of the noise. The mechanism is (ε, δ)-DP exactly when δ is at least

$$\delta(\varepsilon) = \Phi\Big(\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) - e^{\varepsilon}\,\Phi\Big(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big). \tag{A.21}$$

Six facts about it answer the questions.

1. **Only the ratio $\mu = \Delta_2/\sigma$ matters.** The formula sees Δ_2 and σ only through μ. Doubling the sensitivity and doubling σ therefore gives the same guarantee, and you can solve once for $\Delta_2 = 1$ and multiply the resulting σ by Δ_2.
2. **One σ gives a whole curve.** For a fixed μ, $\delta(\varepsilon)$ falls as ε grows. So a Gaussian mechanism is $(\varepsilon, \delta(\varepsilon))$-DP for every ε at once, not for one pair.
3. **The noise falls roughly like $1/\varepsilon$, then more slowly.** Write z_δ for the point a standard normal variable exceeds with probability δ, so that $\Phi(-z_\delta) = \delta$. The exact δ is never more than the probability of the bad set, a normal tail. So asking only that this tail be δ gives a simple **tail rule**, which always gives enough noise:

$$\sigma_{\text{tail}} = \Delta_2\,\frac{z_\delta + \sqrt{z_\delta^2 + 2\varepsilon}}{2\varepsilon}, \tag{A.22}$$

   The rule is about $\Delta_2 z_\delta/\varepsilon$ when ε is small compared with $z_\delta^2/2$, and about $\Delta_2/\sqrt{2\varepsilon}$ when it is large. At $\delta = 10^{-5}$ it uses 1.39 times the exact noise for $\varepsilon = 0.1$. The excess shrinks as ε grows, to 1.02 times at $\varepsilon = 32$.
4. **The noise grows only slowly as δ shrinks.** The point z_δ grows like $\sqrt{2\ln(1/\delta)}$, and by fact 3 the noise is roughly proportional to z_δ. Near $\delta = 10^{-5}$, each factor of 10 in δ adds only about 13% to 15% more noise at ε of 0.5 or 1.

5. **Repeating costs $\sqrt{k}$.** Releasing k answers, each with sensitivity Δ_2 and its own independent noise σ, gives exactly the guarantee of one release with $\mu\sqrt{k}$. Then k releases need $\sqrt{k}$ times the noise of one for the same (ε, δ).
6. **Choose δ from the number of people n.** Take δ well below $1/n$, for example $1/n^2$. The reason, shown in step 7 below, is that a mechanism that publishes each record with probability δ is $(0, \delta)$-DP, and with $\delta = 1/n$ it publishes someone's record with probability about 0.63.

A.8.3. A worked example

By hand. Take $\Delta_2 = 1$, $\sigma = 4$ and $\varepsilon = 1$. Table A.8 follows the formula one number at a time, for a dataset D and a neighbour D'. First compute μ, then the two arguments of Φ, which Section A.7 called α and β. Then look up Φ of each in a normal table or compute it, and finally combine them. The second term, $e^{\varepsilon}\Phi(\beta)$, is the **correction** that turns the probability of the bad set into the exact δ.

Table A.8.: The exact δ of the Gaussian mechanism with $\Delta_2 = 1$, $\sigma = 4$ and $\varepsilon = 1$, one step at a time.

Step	Formula	Value
Sensitivity in noise units	$\mu = \Delta_2/\sigma$	0.2500
First argument	$\alpha = \mu/2 - \varepsilon/\mu = 0.125 - 4$	-3.8750
Second argument	$\beta = -\mu/2 - \varepsilon/\mu = -0.125 - 4$	-4.1250
Probability of the bad set on D	$\Phi(\alpha)$	5.3312×10^{-5}
Same set on D'	$\Phi(\beta)$	1.8537×10^{-5}
Correction	$e^{\varepsilon}\,\Phi(\beta) =$ $2.7183 \times 1.8537 \times 10^{-5}$	5.0388×10^{-5}
Exact δ	$\Phi(\alpha) - e^{\varepsilon}\Phi(\beta)$	2.9243×10^{-6}

So noise of standard deviation 4 on a count, whose sensitivity is 1, gives $(1, 2.92 \times 10^{-6})$-DP. Notice how much the correction removes. The first term, the probability of the bad set, is 18.2 times the final δ, so using it alone would overstate δ eighteen-fold.

By computer. Most languages have no Φ built in, but they all have the **complementary error function** erfc, which Python calls `math.erfc`. In terms of it,

$$\Phi(x) = \tfrac{1}{2}\operatorname{erfc}\left(-x/\sqrt{2}\right), \qquad 1 - \Phi(x) = \tfrac{1}{2}\operatorname{erfc}\left(x/\sqrt{2}\right). \tag{A.23}$$

Use these forms, and never compute a small tail as 1 minus something close to 1. A double-precision number carries about 16 significant digits. So when $\Phi(x)$ is within 10^{-16} of 1, the subtraction $1 - \Phi(x)$ keeps none of the digits that matter. Table A.9 shows this at $x = 8$ and $x = 9$. The textbook form $\Phi(x) = \frac{1}{2}(1 + \operatorname{erf}(x/\sqrt{2}))$, with the plain error function erf, has the same problem for negative x, because erf is then close to -1.

Table A.9.: The probability that a standard normal variable exceeds x, computed three ways in double precision. Only the last is right.

Way of computing the upper tail at x	$x = 8$	$x = 9$
$1 - \Phi(x)$, by subtraction	6.6613×10^{-16}	0
$\Phi(-x)$ with the erf form	6.1062×10^{-16}	0
$\frac{1}{2}\operatorname{erfc}(x/\sqrt{2})$	6.2210×10^{-16}	1.1286×10^{-19}

The same cancellation spoils δ itself when δ is tiny. Then α and β are far out in the lower tail, where erf is close to -1 and the erf form adds 1 to it. The script that comes with this appendix calibrates σ at $\varepsilon = 1$ for four targets. It puts each σ back into the formula, computing Φ once with erfc and once with erf, and Table A.10 shows the result. With erfc, every target comes back correct to five digits. With erf, the target 10^{-12} is already off in the fifth digit. The error then grows fast, so that 10^{-15} comes back 4% too small and 10^{-18} comes back 55 times too large.

Table A.10.: The exact δ at $\varepsilon = 1$, recomputed at the calibrated σ with Φ from erfc and from erf. The last column is how much larger the first term is than the difference.

Target δ	σ/Δ_2	δ with erfc	δ with erf	First term / δ
10^{-9}	5.4953	1.0000×10^{-9}	1.0000×10^{-9}	32.5
10^{-12}	6.5578	1.0000×10^{-12}	9.9997×10^{-13}	45.4
10^{-15}	7.4870	1.0000×10^{-15}	9.6226×10^{-16}	58.5
10^{-18}	8.3220	1.0000×10^{-18}	5.5511×10^{-17}	71.7

Even with erfc, the formula subtracts two nearly equal terms, and a subtraction loses digits too. The last column says how many. When the first term is r times the difference, the subtraction loses about $\log_{10} r$ digits. Here r is at most 72, and $\log_{10} 72 = 1.86$, so the subtraction loses at most 2 of the 16 digits. To check this independently, the script also integrates the excess $p_D - e^{\varepsilon} p_{D'}$ over the bad set directly. Measure the noise in units of σ as y, so that its privacy loss is $L(y) = \mu^2/2 - \mu y$. The integrand is then $\varphi(y)\,(1 - e^{\varepsilon - L(y)})$, which is never a difference of two tails. That integral agrees with the erfc formula to about one part in 10^{12} at all four targets.

Scaling. Now take a sum of values clipped to $[0, 2]$, so that $\Delta_2 = 2$, with $\sigma = 8$. The ratio is still $\mu = 0.25$, so δ is again 2.9243×10^{-6}, and the same holds for $\Delta_2 = 0.5$ with $\sigma = 2$.

The curve. The same $\sigma = 4$ gives a whole curve of guarantees. It is $(1, 2.92 \times 10^{-6})$-DP, and also $(2, 5.09 \times 10^{-17})$-DP and $(0.9263, 10^{-5})$-DP. Figure A.8 draws the curve for four noise levels. Each falls steeply as ε grows, and each crosses $\delta = 10^{-5}$ at its own ε.

A.8.4. Why it works

1. **Only μ matters.** In the formula, Δ_2 and σ appear only in $\mu/2$ and ε/μ. So any sensitivity and noise with the same ratio give the same curve. In particular, the smallest σ for a target is Δ_2 times the smallest σ for a sensitivity of 1. The reason behind it is that measuring the output in units of σ turns every Gaussian mechanism into one with noise 1 and shift μ.

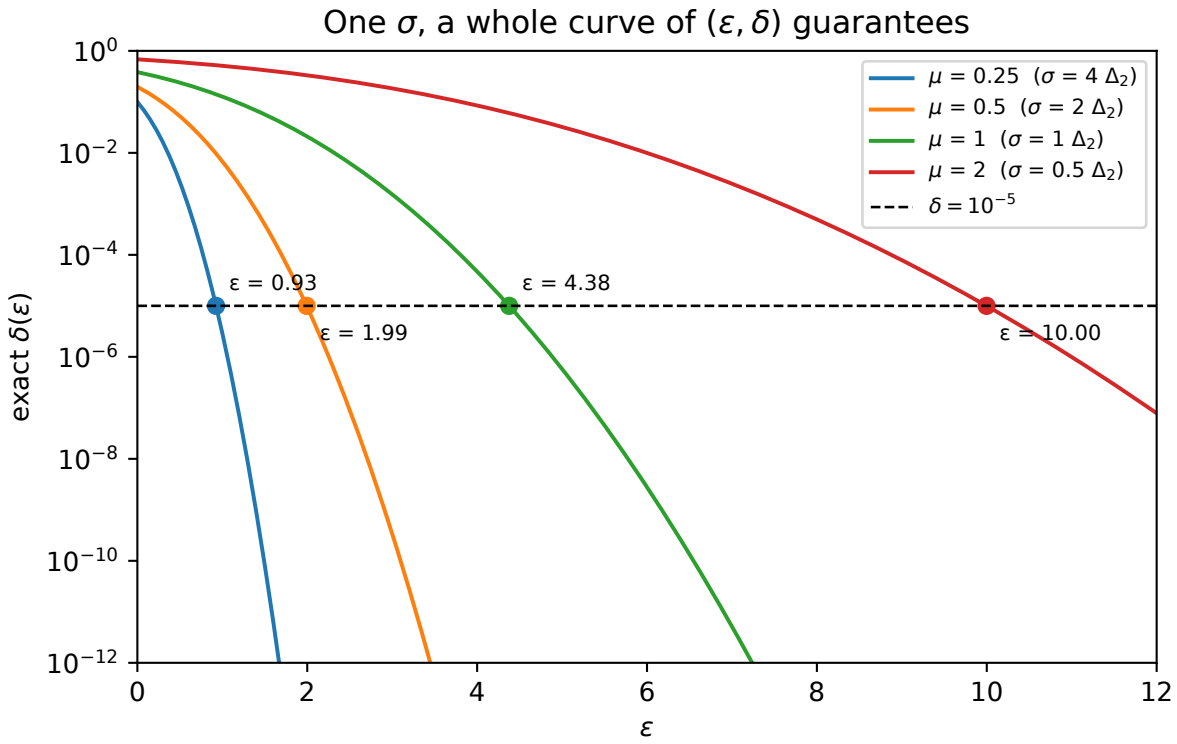

Figure A.8.: The exact $\delta(\varepsilon)$ of the Gaussian mechanism against ε, on a log scale, for four noise levels $\mu = \Delta_2/\sigma$. A single σ is $(\varepsilon, \delta(\varepsilon))$-DP for every ε on its curve. The dots mark the ε each one gives at $\delta = 10^{-5}$: 0.93 for $\sigma = 4\Delta_2$, 1.99 for $2\Delta_2$, 4.38 for Δ_2 and 10.00 for $\Delta_2/2$.

2. **The curve falls.** Write $\alpha = \mu/2 - \varepsilon/\mu$ and $\beta = -\mu/2 - \varepsilon/\mu$ as before, and φ for the standard normal density. Step 5 of Section A.7 showed that $e^{\varepsilon}\varphi(\beta) = \varphi(\alpha)$. Both arguments fall by $1/\mu$ for each unit of ε, so differentiating in ε gives

$$\frac{\mathrm{d}\delta}{\mathrm{d}\varepsilon} = -\frac{\varphi(\alpha)}{\mu} - e^{\varepsilon}\Phi(\beta) + \frac{e^{\varepsilon}\varphi(\beta)}{\mu} = -e^{\varepsilon}\,\Phi(\beta) < 0. \tag{A.24}$$

   The first and last terms cancel, and what is left is negative. So a larger ε always comes with a smaller δ, and one mechanism traces a curve. The same step 5 showed that δ grows with μ. More noise means a smaller μ, so it lowers the whole curve.
3. **A safe rule from the bad set alone.** Step 4 of Section A.1 showed that the exact δ is never more than the probability of the bad set, which step 4 of Section A.6 computed:

$$\Pr[L > \varepsilon] = \Phi(\alpha). \tag{A.25}$$

   So any σ that makes $\Phi(\alpha) = \delta$ is enough. Since $\Phi(-z_\delta) = \delta$, that means $\alpha = -z_\delta$, which is $\mu/2 - \varepsilon/\mu = -z_\delta$. Multiplying by 2μ gives the quadratic $\mu^2 + 2z_\delta\mu - 2\varepsilon = 0$, whose positive root is $\mu = \sqrt{z_\delta^2 + 2\varepsilon} - z_\delta$. Then $\sigma = \Delta_2/\mu$, and multiplying the top and bottom by $\sqrt{z_\delta^2 + 2\varepsilon} + z_\delta$ gives Equation A.22. Solving the same equation for ε instead gives the matching rule for the ε of a given σ:

$$\varepsilon_{\text{tail}} = z_\delta\mu + \frac{\mu^2}{2}. \tag{A.26}$$

4. **Its two regimes.** When 2ε is small compared with z_δ^2, the square root is close to z_δ, so $\sigma_{\text{tail}} \approx \Delta_2 z_\delta/\varepsilon$, which is proportional to $1/\varepsilon$. When 2ε is large compared with z_δ^2, the square root is close to $\sqrt{2\varepsilon}$ and dominates z_δ, so $\sigma_{\text{tail}} \approx \Delta_2/\sqrt{2\varepsilon}$. The bend between the two is near $\varepsilon = z_\delta^2/2$. At $\delta = 10^{-5}$, where $z_\delta = 4.2649$, that is $\varepsilon = 9.09$. The classic formula has the same $1/\varepsilon$ shape with $\sqrt{2\ln(1.25/\delta)}$ in place of z_δ, but it never bends, which is why it fails at large ε (Section A.7).
5. **Why δ costs little.** By the Mills-ratio bound of Section A.6, $\Phi(-z_\delta)$ is close to $e^{-z_\delta^2/2}/(z_\delta\sqrt{2\pi})$. So δ shrinks like $e^{-z_\delta^2/2}$, and z_δ grows only like $\sqrt{2\ln(1/\delta)}$. Dividing δ by 10 adds about $2\ln 10 = 4.61$ to z_δ^2. At $\delta = 10^{-5}$ this makes z_δ grow from 4.2649 to 4.7534, a factor of 1.115, and the tail rule's noise of about $\Delta_2 z_\delta/\varepsilon$ grows by the same factor. The exact noise grows a little faster, as the checks below show.
6. **Repeating adds the losses.** Suppose the k questions are fixed in advance, each answer has sensitivity Δ_2, and each gets independent noise σ. Together the k answers are one vector, with ℓ_2 sensitivity $\sqrt{k\Delta_2^2} = \sqrt{k}\,\Delta_2$. Step 2 of Section A.6 showed that a vector release behaves like one number shifted by the ℓ_2 length of the change. So the k releases have the exact curve of one release with $\mu\sqrt{k}$. To keep $\mu\sqrt{k}$ at the value one release needs, σ must grow by $\sqrt{k}$. When a question may depend on earlier answers, the k answers are no longer one fixed vector query, so this argument does not apply as it stands. Section B.3 proves the same result for that case.
7. **Why δ must be below $1/n$.** Take the mechanism that publishes each record in full with probability δ, independently. One record changes the output only when its own coin publishes it, so the two probabilities of any event differ by at most δ, and the mechanism is $(0, \delta)$-DP. Each of n records stays hidden with probability $1 - \delta$, so someone is exposed with probability $1 - (1 - \delta)^n$. With $\delta = 1/n$ this is about 0.63. The reason is that $n\ln(1 - 1/n)$ is close to -1 for large n, so

$$(1 - 1/n)^n = e^{n\ln(1-1/n)} \approx e^{-1}, \tag{A.27}$$

and $1 - e^{-1} = 0.63$. A guarantee that allows this mechanism promises little, so $n\delta$ must be far below 1.

A.8.5. Checking it

Table A.11 is the reference table of this section. It gives the exact σ/Δ_2 for five values of ε and four of δ, each found by bisection and checked by putting it back into the formula. Read along a row to see the cost of a smaller δ, and up a column to see the cost of a smaller ε.

Table A.11.: The smallest σ/Δ_2 for (ε, δ)-DP, from the exact calibration. Multiply by Δ_2 to get σ.

ε	$\delta = 10^{-3}$	$\delta = 10^{-5}$	$\delta = 10^{-7}$	$\delta = 10^{-9}$
0.1	17.4044	30.7496	41.3295	50.2098
0.5	4.6101	7.0318	8.9957	10.6739
1	2.5747	3.7306	4.6787	5.4953
2	1.4452	1.9938	2.4491	2.8445
4	0.8231	1.0812	1.2978	1.4878

Moving along a row, to a smaller δ, changes the noise much less than moving up a column, to a smaller ε. At $\varepsilon = 0.5$, for example, a δ ten thousand times smaller costs 1.518 times the noise. Halving ε instead, to 0.25, costs 1.889 times the noise (Table A.7 has the value at 0.25). Figure A.9 shows the whole plane. On the left each line is one noise level, and the lines are nearly vertical because σ depends mostly on ε. On the right, the product $\varepsilon\sigma/\Delta_2$ would be a flat line if σ were exactly proportional to $1/\varepsilon$.

Noise against ε. Table A.12 compares the tail rule with the exact calibration at $\delta = 10^{-5}$. The rule is always enough, as step 3 promises. Its excess over the exact noise is 39% at $\varepsilon = 0.1$, and it shrinks steadily as ε grows. The reason is the correction term that the rule ignores. At $\varepsilon = 0.1$ and the exact σ, the probability of the bad set is 111 times the final δ, so the correction removes almost all of it. At $\varepsilon = 8$ it is only 3.6 times the final δ, and the correction matters much less. In the exact calibration, the product $\varepsilon\sigma/\Delta_2$ grows by only a factor of 1.213 from $\varepsilon = 0.1$ to $\varepsilon = 1$. So "σ is proportional to $1/\varepsilon$" is a fair first guess below $\varepsilon = 1$. It fails at large ε, where the product keeps growing, up to 6.5579 at $\varepsilon = 32$.

Table A.12.: The noise for $(\varepsilon, 10^{-5})$-DP: the exact calibration, the tail rule of Equation A.22 and its two limits, with $z_\delta = 4.2649$.

ε	Exact σ/Δ_2	$\varepsilon\sigma/\Delta_2$	Tail rule	Tail / exact	z_δ/ε	$1/\sqrt{2\varepsilon}$
0.1	30.7496	3.0750	42.7658	1.391	42.6489	2.2361
0.5	7.0318	3.5159	8.6454	1.229	8.5298	1.0000
1	3.7306	3.7306	4.3791	1.174	4.2649	0.7071
2	1.9938	3.9876	2.2439	1.125	2.1324	0.5000
4	1.0812	4.3246	1.1728	1.085	1.0662	0.3536
8	0.6002	4.8018	0.6320	1.053	0.5331	0.2500

ε	Exact σ/Δ_2	$\varepsilon\sigma/\Delta_2$	Tail rule	Tail / exact	z_δ/ε	$1/\sqrt{2\varepsilon}$
32	0.2049	6.5579	0.2083	1.016	0.1333	0.1250

The last two columns show the two regimes of step 4. At $\varepsilon = 0.1$ the rule is almost exactly z_δ/ε. At $\varepsilon = 32$ the rule has moved well away from z_δ/ε and towards $1/\sqrt{2\varepsilon}$, but it is still above that limit, because z_δ is not yet small next to $\sqrt{2\varepsilon} = 8$.

Noise against δ. Starting from $\delta = 10^{-5}$, making δ ten times smaller raises the exact noise by a factor of 1.146 at $\varepsilon = 0.5$. There σ/Δ_2 goes from 7.0318 to 8.0576, while at $\varepsilon = 1$ the factor is 1.132. Both are a little above the 1.115 that step 5 predicted from z_δ alone, so the estimate from z_δ alone is slightly low.

The privacy a noise level buys. Turning the question around, Table A.13 gives the ε that a chosen σ buys at $\delta = 10^{-5}$, exactly and by the tail rule $\varepsilon_{\text{tail}} = z_\delta\mu + \mu^2/2$. For large σ the $z_\delta\mu$ term dominates, so ε falls like $1/\sigma$, the inverse of the noise rule. Again the rule is safe, because it never reports a smaller ε than the exact one.

Table A.13.: The ε that a given noise level buys at $\delta = 10^{-5}$.

σ/Δ_2	0.5	1	2	5	10	20
Exact ε	9.9973	4.3772	1.9931	0.7255	0.3407	0.1600
Tail rule $z_\delta\mu + \mu^2/2$	10.5298	4.7649	2.2574	0.8730	0.4315	0.2145

Repeating. Suppose ten releases must together be $(1, 10^{-5})$-DP. Then by step 6 each needs $\sqrt{10}$ times the noise of one release, so $\sigma = 11.7973$. As a check, putting $\mu = \sqrt{10}/11.7973$ back into the formula gives $\delta = 1.000 \times 10^{-5}$. The tempting alternative is to split the budget instead. Basic composition, which Section B.1 derives, says that the εs and the δs of separate releases add up, so ten $(0.1, 10^{-6})$-DP releases are together $(1, 10^{-5})$-DP. That needs $\sigma = 36.3047$, which is 3.08 times more noise. With 100 releases the gap grows to 9.70 times. Splitting gives each release only ε/k, and the noise grows roughly like $1/\varepsilon$, so it grows like k rather than $\sqrt{k}$.

Choosing δ from n. Table A.14 gives the noise at $\varepsilon = 1$ for four choices of δ, and how often the publish-a-record mechanism of step 7 would expose someone. A fixed $\delta = 10^{-5}$ is fine for a thousand people, with exposure 0.00995. For a million people it is ten times $1/n$, and the exposure is 0.99995. A rule sometimes used to get "a little below $1/n$", $\delta = 1/n^{1.1}$, is not far enough below, since its exposure is still 0.328 for ten thousand people. By contrast, $\delta = 1/n^2$ makes $n\delta = 1/n$, which keeps the exposure near $1/n$, and its noise is modest. For ten thousand people it needs only 1.367 times the noise of $\delta = 10^{-5}$.

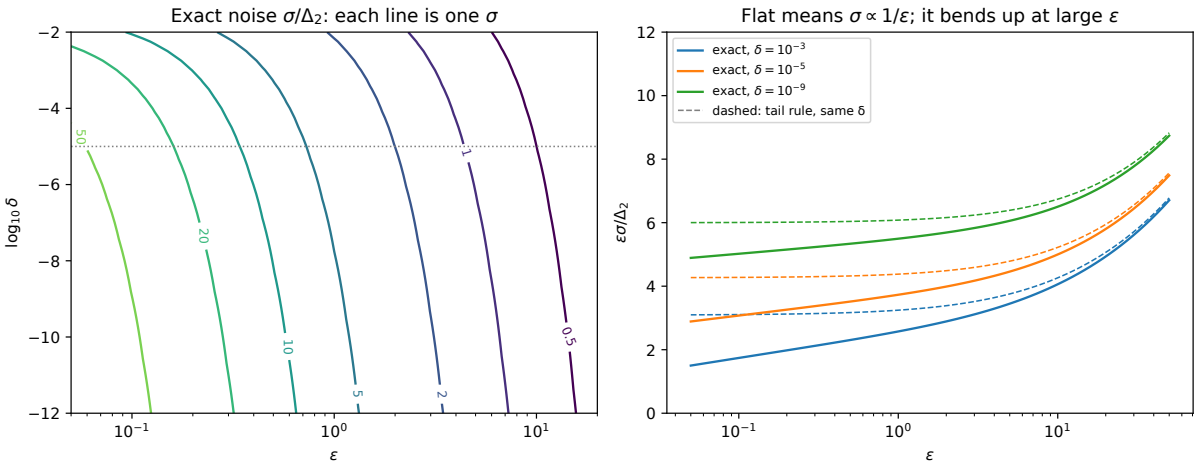

Figure A.9.: Left: contour lines of the exact σ/Δ_2 over ε (log scale) and $\log_{10}\delta$, with $\delta = 10^{-5}$ dotted. The lines are nearly vertical, so ε decides the noise far more than δ does. Right: the product $\varepsilon\sigma/\Delta_2$ against ε for three values of δ, exact (solid) and by the tail rule (dashed). The tail rule is nearly flat for small ε, where it is close to z_δ/ε, and the exact product sags below it there, because the correction term matters most at small ε. Both rise at large ε, where the noise falls more slowly than $1/\varepsilon$.

Table A.14.: The exact σ/Δ_2 at $\varepsilon = 1$ for four ways of choosing δ, and the probability $1-(1-\delta)^n$ that publishing each record with probability δ exposes someone. At $\delta = 1/n$ that probability is 0.632 for every n shown.

n	$\delta = 10^{-5}$	$\delta = 1/n$	$\delta = 1/n^{1.1}$	$\delta = 1/n^2$	Exposure at 10^{-5}	Exposure at $1/n^{1.1}$
1,000	3.7306	2.5747	2.7660	4.2247	0.00995	0.394
10,000	3.7306	3.1857	3.4106	5.1003	0.0952	0.328
100,000	3.7306	3.7306	3.9833	5.8678	0.632	0.271
1,000,000	3.7306	4.2247	4.5013	6.5578	0.99995	0.222

A.8.6. Recipe and pitfalls

Decide the quantities in this order, because the later steps use the earlier choices.

1. **Fix the neighbouring relation and compute** Δ_2, as in Section A.2. Clip first if the data are unbounded.
2. **Pick** δ **from the number of people** n, well below $1/n$. The choice $\delta = 1/n^2$ is cheap, as Table A.14 shows, and Section 46.7 discusses other rules.
3. **Pick** ε**.** It decides the noise far more than δ does, so spend your judgement here.
4. **Count the releases** k that must share the budget. If they are Gaussian releases of the same sensitivity, solve for one and multiply σ by $\sqrt{k}$.
5. **Solve for** σ **by bisection** on the exact formula with $\Delta_2 = 1$, computing Φ with erfc, and multiply by Δ_2. Table A.11 gives a first estimate, and Equation A.22 gives a safe closed form if you cannot run bisection.

6. **Check by plugging back.** Put $\mu = \Delta_2/\sigma$ into the formula and confirm that $\delta(\varepsilon)$ is at most your target.
7. **Report μ, or the curve,** not only one pair, so that a reader can find δ at any ε.

The common mistakes follow from the facts above. Quoting ε without δ says nothing, because one Gaussian mechanism has every ε on its curve. A δ of $1/n$ or more allows a mechanism that publishes a whole record. Computing $1-\Phi(x)$ by subtraction, or Φ with erf, silently loses accuracy from about $\delta = 10^{-12}$ and gives nonsense by 10^{-18}. The classic formula is unproved above $\varepsilon = 1$ and wrong above 8.42 at $\delta = 10^{-5}$. And forgetting composition is the most expensive mistake of all, because k releases at the σ of one are only (ε, δ)-DP for a much larger ε. Splitting the budget evenly fixes that, but at about k times the noise of one release instead of $\sqrt{k}$ times. Section B.3 and Section B.5 compare the ways to account for repeated releases.

A.9. All the recipes in one table

Table A.15 collects the calibrations of this appendix. Every row assumes you have fixed the neighbouring relation first, since the sensitivity depends on it.

Table A.15.: The calibration recipes of this appendix.

Mechanism	Sensitivity	Noise or rule	Guarantee
Laplace	Δ_1, the ℓ_1 norm	$\mathrm{Lap}(b)$ per coordinate, $b = \Delta_1/\varepsilon$	ε-DP; 95% error $b \ln 20$ per coordinate
Randomized response	one bit, under replace-one	truth with probability $e^\varepsilon/(1+e^\varepsilon)$	ε-DP; error about $1/(\varepsilon\sqrt{n})$
Exponential mechanism	Δu of the score	choose r with probability $\propto e^{\varepsilon u(D,r)/(2\Delta u)}$	ε-DP; gap $\le \frac{2\Delta u}{\varepsilon}(\ln\lvert\mathcal{R}\rvert + t)$ with probability $1 - e^{-t}$
Gaussian, classic	Δ_2, the ℓ_2 norm	$\sigma = \Delta_2\sqrt{2\ln(1.25/\delta)}/\varepsilon$	(ε, δ)-DP for $\varepsilon < 1$; loose
Gaussian, exact	Δ_2, the ℓ_2 norm	$\sigma = \Delta_2/\mu$ with $\delta(\varepsilon) = \delta$ by bisection	(ε, δ)-DP for every ε; tight
Gaussian, k releases	Δ_2 of each release	$\sqrt{k}$ times the exact σ of one, with δ well below $1/n$	(ε, δ)-DP for all k together

A.10. Code

The script computes every number on this page and draws every figure. It checks the three-output example against all events, finds every sensitivity by brute force over small datasets, and simulates the Laplace error and randomized response. For the Gaussian mechanism it compares the closed form with numerical integration and with Monte Carlo, checks the derivative of step 5, and solves the exact calibration by bisection. For the trade-offs it computes Φ three ways and checks tiny values of δ against an integral over the bad set. It also tabulates the noise as each quantity moves. From the repository root:

```
uv run python code/appendix-derivations/apx_core_calibration.py
```

Table A.16 summarizes its output with the default random seed, 0.

Table A.16.: The script's output with the default seed.

Check	Result
Three outputs, every event	Largest ratio 2.5000; largest excess at $e^{\varepsilon} = 2$ is 0.1000; bad set 0.5000
Sensitivities, every dataset of 1 to 3 records	Every row of Table A.3; mean under add/remove up to 1.5000
Laplace loss, count, $b = 2$	In exactly $[-0.5000, 0.5000]$; event ratio 1.6487
Laplace loss, three counts, $b = 6$	Largest over 100,000 outputs 0.5000
Laplace error, $b = 2$	Mean 2.0026 (exact 2); 95th percentile 5.9938 (formula 5.9915)
Randomized response, $\varepsilon = 0.5$, $n = 1000$	Mean 0.2996, standard deviation 0.0629 (formula 0.0626)
Exponential mechanism, vote	Largest privacy loss 0.3353 at $\varepsilon = 1$
Classic chain, $\varepsilon = 0.5$, $\delta = 10^{-5}$	8.55×10^{-7}, 8.54×10^{-7}, 8.21×10^{-7}, exact 1.61×10^{-8}
Exact δ, $\mu = 1$, $\varepsilon = 1$	0.1269 (Simpson 0.1269, Monte Carlo 0.1270)
Exact calibration, $\varepsilon = 0.5$, $\delta = 10^{-5}$	$\sigma = 7.0318$ against classic 9.6896
Classic formula fails at $\delta = 10^{-5}$	For $\varepsilon > 8.42$
Exact δ by hand, $\Delta_2 = 1$, $\sigma = 4$, $\varepsilon = 1$	2.9243×10^{-6} (bad-set integral the same)
Φ from erf at $\delta = 10^{-18}$	5.5511×10^{-17}, against 1.0000×10^{-18} from erfc
Tail rule against exact, $\delta = 10^{-5}$	1.391 times at $\varepsilon = 0.1$, 1.016 times at $\varepsilon = 32$
Ten releases at $(1, 10^{-5})$	$\sigma = 11.7973$ each, against 36.3047 when the budget is split

tests/test_appendix_core_calibration.py checks that the output still matches. Three things stand out. Every formula agrees with brute force or simulation to within sampling error. The Laplace and exponential mechanisms meet their bounds exactly on some outputs, so their noise cannot be reduced. And the classic Gaussian formula is safe but wasteful for small ε, and unsafe for very large ε, which is why the exact calibration should be the default.

B. Composing private releases

A private system almost never releases one number. A dashboard publishes a hundred counts, an analyst asks one query after another, and a training run takes thousands of noisy steps. Each release on its own may be private, but an attacker sees all of them together, so this appendix answers the practical questions that follow. What is the total privacy cost of a number k of releases? Why is that answer correct? How much noise must each release get so that the whole set stays within a budget? And which of the several ways to add up the cost should you use?

Everything here rests on one quantity, so here it is in three sentences. A mechanism M is **differentially private** if changing one person's record, which turns a dataset D into a **neighbouring** dataset D', barely changes the distribution of its output. The **privacy loss** of an output y is the logarithm of how much more likely y is under D than under D'. For a budget ε, pure ε-differential privacy (DP) says this loss is between $-\varepsilon$ and ε for every output. Approximate (ε, δ)-DP asks instead that every set S of outputs, for every pair of neighbours, satisfies

$$\Pr_{D}[S] \leq e^{\varepsilon} \Pr_{D'}[S] + \delta, \tag{B.1}$$

where $\Pr_D[S]$ is the chance that the output lands in S when the data are D. The small slack δ lets rare outputs break the factor e^{ε}. Section A.1 in the appendices states both definitions in full, with examples.

The one idea of this page is that **the privacy loss of several releases is the sum of their separate losses**. Basic composition bounds that sum by the largest value it can take. Advanced composition uses the fact that the terms partly cancel, like the steps of a random walk. For Gaussian noise the sum is again exactly Gaussian, and Rényi DP tracks a set of averages of the loss that add just as simply. A method that adds up the cost of many releases this way is called an **accountant**. Table B.1 lists the derivations and the chapter sections that use them.

Table B.1.: The derivations of this appendix and the chapter sections that state or use them.

Derivation	Where the chapters state or use it
Basic composition: budgets add (Section B.1)	Section 19.3; every accountant starts here
Advanced composition: $\sqrt{k}$ instead of k (Section B.2)	Section 21.1, Section 21.2
k Gaussian releases are one Gaussian release (Section B.3)	Section 19.3, Section 20.4, Section 32.6
Rényi DP of the Gaussian, and why it adds (Section B.4)	Section 29.4, Section 29.5, Section 29.8
Comparing the four ways to add up the cost (Section B.5)	Section 21.4, Section 37.2

Notation. The k mechanisms are $M_1, \dots, M_k$, run on the same dataset, and their outputs are $y_1, \dots, y_k$. For one mechanism, $p(y)$ is the probability (or density) of the output y when the data are D, and $q(y)$ is the same when the data are D'. The privacy loss is

$$L(y) = \ln \frac{p(y)}{q(y)}. \tag{B.2}$$

For Gaussian noise, σ is the standard deviation of the noise and Δ is the ℓ_2 sensitivity. That is the largest ordinary (Euclidean) distance by which one record can move the true answer, which may be a vector of numbers. Their ratio, the shift in units of the noise, is $\mu = \Delta/\sigma$. The accounting chapters take $\Delta = 1$ and call σ the noise multiplier, so their σ is this page's σ with $\Delta = 1$. The standard normal cumulative distribution function is Φ, and logarithms are natural.

Neighbours can be defined in two ways: by adding or removing one record, or by replacing one record with another. The choice changes the sensitivity of a query, but not any argument on this page, as long as every release uses the same relation.

B.1. Basic composition: the budgets add

B.1.1. The question

You release k answers computed from the same dataset, each with its own fresh noise, and each private on its own. What guarantee holds for all k answers together, including when you choose each query after reading the earlier answers?

B.1.2. The answer

If release i is $(\varepsilon_i, \delta_i)$-DP, then the k releases together are

$$\Big(\sum_{i=1}^{k} \varepsilon_i,\ \sum_{i=1}^{k} \delta_i\Big)\text{-DP}. \tag{B.3}$$

Here ε_i is the budget of release i, and δ_i its slack. The same holds when release i is chosen using the earlier outputs, as long as its budget is fixed in advance. The chapter states this as Equation 19.11 in Section 19.3.

B.1.3. A worked example

A dashboard publishes 10 counts, such as the number of patients in each of 10 clinics. One person changes each count by at most 1, so each count has sensitivity 1. Laplace noise of scale b makes a release with sensitivity Δ_1 private at $\varepsilon = \Delta_1/b$ (Section A.3). So each count gets Laplace noise of scale $b = 1/0.1 = 10$, which makes it 0.1-DP, and by Equation B.3 the 10 counts together are $10 \times 0.1 = 1$-DP.

It helps to see why one noisy count is 0.1-DP. Say the true count is 0 on D and 1 on D'. The Laplace density with scale b is $\frac{1}{2b}e^{-|z|/b}$, and the two densities centred at 0 and 1 have the same

constant $\frac{1}{2b}$ in front. So the constants cancel in the ratio, and the privacy loss of an output y is the difference of the two exponents,

$$L(y) = \frac{|y-1| - |y|}{b}. \tag{B.4}$$

For $y \le 0$ this is $((1-y)-(-y))/b = 1/b = 0.1$. For $y \ge 1$ it is -0.1, and in between it moves in a straight line from one to the other (Figure B.1, left). So the loss never leaves $[-0.1, 0.1]$.

The bound of 1 for the 10 counts is reached. Each count's loss is $+0.1$ exactly when its output is at most 0, its true value on D. Under D the noise is symmetric around 0, so this happens with probability $\frac{1}{2}$, and all 10 counts do it at once with probability $(\frac{1}{2})^{10} = 0.000977$. A simulation of a million dashboards finds the largest total loss to be exactly 1.0000, reached in a fraction 0.000997 of them. So for pure DP, basic composition is exact in the worst case. But that case is rare, and the average total loss on D is only 0.0484, as the checking section below shows. The gap between the worst and the typical loss is what the next section exploits.

B.1.4. Why it works

Pure DP, outputs with independent noise. The plan is to write the probability of all k outputs as a product, so that the ratio of two such probabilities becomes a product of ratios, and the log of the ratio becomes a sum.

1. **The joint probability is a product.** Each release uses its own fresh noise, so with the dataset held fixed the outputs are independent. The probability of seeing $y_1, \dots, y_k$ together is the product of the separate probabilities, $p(y_1, \dots, y_k) = p_1(y_1) \cdots p_k(y_k)$, and the same holds for q.
2. **The ratio is a product of ratios.** Dividing one product by the other, term by term,

$$\frac{p(y_1, \dots, y_k)}{q(y_1, \dots, y_k)} = \frac{p_1(y_1)}{q_1(y_1)} \cdots \frac{p_k(y_k)}{q_k(y_k)}. \tag{B.5}$$

3. **Each factor is bounded.** Release i is ε_i-DP, so its ratio lies between $e^{-\varepsilon_i}$ and e^{ε_i}.
4. **Multiply the bounds and take logs.** The product lies between $e^{-\sum \varepsilon_i}$ and $e^{\sum \varepsilon_i}$. The logarithm of a product is the sum of the logarithms, so the total loss is $L = L_1(y_1) + \cdots + L_k(y_k)$, and $|L| \le \sum_i \varepsilon_i$ at every output. That is pure $\sum_i \varepsilon_i$-DP.

Figure B.1 draws this for two counts. Each count's loss is flat at $+\varepsilon$ on one side, flat at $-\varepsilon$ on the other, with a ramp in between, and the loss of the pair is the sum of the two. It reaches 2ε only in the corner where both outputs favour D, that is, where both have the largest loss.

Adaptive releases. Now suppose you choose the second query after reading the first answer. The outputs are no longer independent, so step 1 needs a different reason. The **chain rule** of probability gives it. The chance of seeing y_1 and then y_2 is the chance of y_1, times the chance of y_2 given that the first output was y_1:

$$p(y_1, y_2) = p_1(y_1)\, p_2(y_2 \mid y_1). \tag{B.6}$$

The ratio is again a product of two ratios, and the second one, $p_2(y_2 \mid y_1)/q_2(y_2 \mid y_1)$, is the ratio of the mechanism you chose after seeing y_1. If every mechanism you might choose is ε_2-DP, that

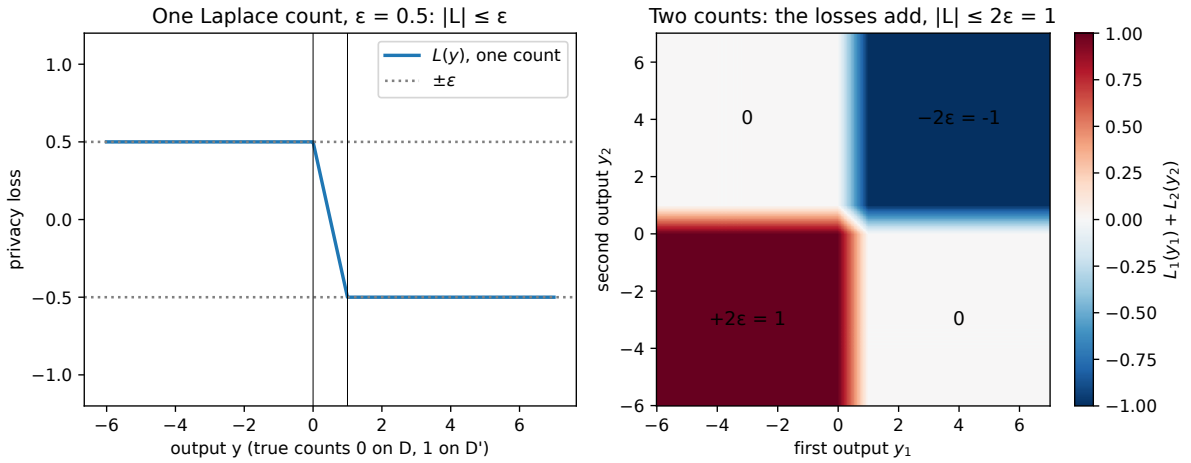

Figure B.1.: Left: the privacy loss of one count released with Laplace noise at $\varepsilon = 0.5$, as a function of the output, when the true count is 0 on D and 1 on D'. It is flat at $\pm\varepsilon$ outside $[0, 1]$. Right: the total loss of two such counts over the plane of the two outputs. It is the sum of two such steps, so it reaches 2ε only in the lower-left corner, where both outputs favour D. The figure uses $\varepsilon = 0.5$ rather than 0.1 so that the shading is visible.

ratio lies between $e^{-\varepsilon_2}$ and e^{ε_2}, whatever y_1 was. So steps 2 to 4 go through unchanged. With k releases the chain rule has k factors, one per release.

A tiny case makes this concrete. **Randomized response** at level ε reports a person's secret bit truthfully with probability $e^{\varepsilon}/(1 + e^{\varepsilon})$ and flips it otherwise. Ask once at level $\ln 3$, which tells the truth with probability $\frac{3}{4}$. If the answer is 1, ask again at $\ln 3$. If it is 0, ask again at $\ln 2$, which tells the truth with probability $\frac{2}{3}$. Take D to be the dataset where the person's bit is 1 and D' the one where it is 0. Table B.2 lists the four outcomes, as computed by this appendix's script (see the Code section).

Table B.2.: Two randomized-response answers about one bit, where the level of the second depends on the first answer. Each probability is a product of a first-step and a second-step factor, so each loss is a sum of two step losses.

Answers (y_1, y_2)	Probability on D	Probability on D'	Privacy loss L
$(1, 1)$	$\frac{3}{4} \cdot \frac{3}{4} = 0.5625$	$\frac{1}{4} \cdot \frac{1}{4} = 0.0625$	$\ln 3 + \ln 3 = 2.1972$
$(1, 0)$	$\frac{3}{4} \cdot \frac{1}{4} = 0.1875$	$\frac{1}{4} \cdot \frac{3}{4} = 0.1875$	$\ln 3 - \ln 3 = 0$
$(0, 1)$	$\frac{1}{4} \cdot \frac{2}{3} = 0.1667$	$\frac{3}{4} \cdot \frac{1}{3} = 0.2500$	$-\ln 3 + \ln 2 = -0.4055$
$(0, 0)$	$\frac{1}{4} \cdot \frac{1}{3} = 0.0833$	$\frac{3}{4} \cdot \frac{2}{3} = 0.5000$	$-\ln 3 - \ln 2 = -1.7918$

Each row's loss is the first answer's loss plus the second answer's loss, where the second loss belongs to whichever mechanism was chosen. The largest loss is $2.1972 = 2 \ln 3$. That equals the basic bound $\ln 3 + \ln 3$, in which the second budget is $\ln 3$, the larger of the two levels the second step could use.

Approximate DP. An (ε, δ)-DP mechanism may have outputs whose loss exceeds ε, or is even infinite, as long as they are rare. The Gaussian mechanism is an example: its loss is a straight line in the output, so it has no largest value. So the product argument fails, and a different one is needed. It rests on a fact that this page uses again later, the **bad-event fact**: for any threshold τ and any set S of outputs,

$$\Pr_{D}[S] \le e^{\tau} \Pr_{D'}[S] + \Pr_{D}[L > \tau]. \tag{B.7}$$

To see it, split S into the outputs whose loss is at most τ and the rest. On the first part $\ln(p/q) \le \tau$, so $p \le e^{\tau} q$ output by output. Adding up over that part gives at most e^{τ} times its probability under D', which is at most $e^{\tau} \Pr_{D'}[S]$. The second part lies inside the event $L > \tau$, so its probability is at most $\Pr_{D}[L > \tau]$. So if the loss exceeds τ with probability at most δ when the data are D, then $\Pr_{D}[S] \le e^{\tau} \Pr_{D'}[S] + \delta$ for every S. DP also asks for the same bound with D and D' swapped, and the same argument gives it.

Now suppose each release satisfies a **tail condition**: whatever the earlier outputs were, its loss exceeds ε_i with probability at most δ_i. Then the composition is $(\sum \varepsilon_i, \sum \delta_i)$-DP, in three steps.

1. **A large total needs a large term.** If every L_i is at most ε_i, the sum is at most $\sum_i \varepsilon_i$. So the total can exceed $\sum_i \varepsilon_i$ only if at least one term exceeds its own ε_i.
2. **Union bound.** The chance that at least one of several events happens is at most the sum of their chances. So

$$\Pr\left[L > \sum_i \varepsilon_i\right] \le \sum_i \Pr[L_i > \varepsilon_i] \le \sum_i \delta_i. \tag{B.8}$$

   In the adaptive case, the chance that term i exceeds ε_i is an average, over the earlier outputs, of a conditional chance that is at most δ_i. So it is at most δ_i too.
3. **Bad-event fact.** Equation B.7 with $\tau = \sum_i \varepsilon_i$ gives the result.

The tail condition is a **sufficient condition**: it is enough for (ε, δ)-DP, but it asks for more. The classic Gaussian calibration proves exactly this condition (Section 20.3), so the argument covers it. But some (ε, δ)-DP mechanisms do not satisfy it. For example, take a mechanism with two outputs. Output A has probability $\frac{1}{2}$ on D and $\frac{1}{2}e^{-1.1} = 0.1664$ on D', and output B takes the rest, $\frac{1}{2}$ and 0.8336. Output A has loss 1.1, above 1, and it happens half the time, so the tail condition at $\varepsilon = 1$ fails. Yet the only set that breaks the factor e is $\{A\}$, and it breaks it by just $\frac{1}{2} - e \times 0.1664 = 0.0476$. So the mechanism is $(1, 0.0476)$-DP. Basic composition still holds for releases that are only known to be $(\varepsilon_i, \delta_i)$-DP. Section 19.3 proves it with a two-step argument on events, and Section J.1 gives a second route through four-point randomized response.

B.1.5. Checking it

A simulation of a million runs of the 10-count dashboard backs up the worked example. The largest total loss is 1.0000, reached in a fraction 0.000997 of runs against the exact $(\frac{1}{2})^{10} = 0.000977$. The mean loss is 0.0484. That matches the exact value, which is 10 times the mean loss of one count, $\varepsilon + e^{-\varepsilon} - 1$ at $\varepsilon = 0.1$, a formula you get by integrating the loss of Figure B.1 against the Laplace density. The script also recomputes Table B.2 from the two randomized-response steps, and the two-output pair above. So the bound is exact for the worst output, and very loose for the typical one.

B.1.6. Recipe and pitfalls

To share a total budget (ε, δ) among k releases with basic composition, follow three steps.

1. Give release i a share ε_i and δ_i, so that the shares add up to ε and δ. Equal shares ε/k and δ/k are the simplest choice.
2. Calibrate each release to its share, for example with Laplace noise of scale Δ_1/ε_i, where Δ_1 is its ℓ_1 sensitivity, the largest total of the absolute changes one record can make to its answers.
3. Draw fresh, independent noise for every release.

Several things go wrong in practice. Reusing one noise draw for two different queries breaks step 1 of the derivation, because the outputs are no longer independent given the data. For example, subtracting two answers that share one noise draw cancels the noise exactly. Publishing the same noisy answer twice is fine, though, since the copy is computed from the output without touching the data. Choosing the budgets themselves from the answers, such as "stop when the answer looks good", is not covered, because each budget must be fixed in advance (Section 36.4 handles it). The δ_i add up, so k releases at $\delta_i = 10^{-5}$ give $k \times 10^{-5}$. And for many releases the bound is far too large, which is the subject of the next section.

B.2. Advanced composition: $\sqrt{k}$ instead of k

B.2.1. The question

You publish 100 counts, each 0.1-DP. Basic composition says the total is $\varepsilon = 10$. That is almost no guarantee, because it allows some output to be up to $e^{10} \approx 22{,}000$ times more likely on one dataset than on its neighbour. An attacker who sees that output can multiply their odds on which dataset it was by that much. If you accept a tiny slack δ', can you claim a much smaller ε?

B.2.2. The answer

Yes. Take k releases that are each ε-DP and any slack $\delta' > 0$. Together they are (ε', δ')-DP with

$$\varepsilon' = \varepsilon\sqrt{2k\ln(1/\delta')} + k\varepsilon(e^{\varepsilon} - 1). \tag{B.9}$$

The first term grows like $\sqrt{k}$, and the second is small when ε is small, because $e^{\varepsilon} - 1 \approx \varepsilon$. When each release is (ε, δ)-DP instead, the total slack becomes $k\delta + \delta'$. This is the theorem of Dwork, Rothblum and Vadhan, stated as Equation 21.9 in Section 21.2. The chapter also gives a sharper form whose second term is $k\varepsilon\tanh(\varepsilon/2)$. Here $\tanh(x) = (e^{2x} - 1)/(e^{2x} + 1)$ is the hyperbolic tangent, which is close to x for small x, so this term is about half the one above.

B.2.3. A worked example

Take $k = 100$, $\varepsilon = 0.1$ and $\delta' = 10^{-5}$. Then $\ln(1/\delta') = 11.5129$, so the first term is

$$0.1\sqrt{200 \times 11.5129} = 0.1\sqrt{2302.6} = 4.7985. \tag{B.10}$$

The second term is $100 \times 0.1 \times (e^{0.1} - 1) = 1.0517$. Their sum is $\varepsilon' = 5.8502$, against 10 for basic composition. The sharper tanh form gives 5.2981. The best bound that holds for every 0.1-DP release, the optimal composition of Section 21.4, gives 4.3068.

B.2.4. Why it works

The idea: a random walk. The total loss is a sum of k terms, one per release, and each lies between $-\varepsilon$ and ε. Basic composition assumes every term is $+\varepsilon$ at once. But the terms are random and partly cancel, like the steps of a walk that goes up or down at random. After k steps such a walk is typically about $\sqrt{k}$ steps from where it started, not k. The reason is that the variances of independent steps add, so the variance after k steps is k times that of one step, and the typical distance, its square root, grows like $\sqrt{k}$. The walk also drifts upward a little, because each term has a small positive average when the data are D, as step 2 shows. So the total loss is a small drift plus a fluctuation of order $\varepsilon\sqrt{k}$. A tail bound says how far above the drift the fluctuation can go except with probability δ', and the bad-event fact turns that into (ε', δ')-DP.

Randomized response shows the walk in its plainest form. At level ε each answer has loss exactly $+\varepsilon$ if it is truthful and $-\varepsilon$ if it is flipped. So the total loss of k answers is a walk with steps of $\pm\varepsilon$, which Figure B.2 draws. The chapter shows that randomized response is the worst case among all ε-DP mechanisms (Section 21.4). That is, no k releases that are each ε-DP need a larger δ, at any total ε, than k randomized responses do. So it is the right one to look at.

The derivation has seven steps.

1. **The loss is a sum of bounded terms.** By Section B.1 the total loss is $L = L_1 + \cdots + L_k$, where L_i is the loss of release i given the earlier outputs. Each release is ε-DP whatever the history, so $-\varepsilon \le L_i \le \varepsilon$.

2. **Each term has a small average.** Write m_i for the average of L_i on D, given the earlier outputs. The claim is that, for one ε-DP release with output probabilities p and q,

$$m = \sum_y p(y) \ln \frac{p(y)}{q(y)} \le \varepsilon(e^{\varepsilon} - 1). \tag{B.11}$$

   The proof uses one inequality about the logarithm of a positive number x,

$$\ln x \le x - 1. \tag{B.12}$$

   It holds because the line $x - 1$ touches the curve $\ln x$ at $x = 1$ and the curve bends down away from it. There are three sub-steps. The first one adds a term to m so that the positive and negative losses can be paired up, output by output.

- *Add a term that is never negative.* Apply $\ln x \le x - 1$ with $x = p/q$ and average under q. This gives $\sum_y q \ln(p/q) \le \sum_y q(p/q - 1) = \sum_y p - \sum_y q = 0$. Flipping the sign, and using $-\ln(p/q) = \ln(q/p)$, the sum $\sum_y q \ln(q/p)$ is never negative. Adding it to m can only make m larger, and the two sums combine term by term:

$$m \le \sum_y p \ln \frac{p}{q} + \sum_y q \ln \frac{q}{p} = \sum_y (p - q) \ln \frac{p}{q}. \tag{B.13}$$

- *Use the bound on the loss.* Each $|\ln(p/q)|$ is at most ε, so $m \le \varepsilon \sum_y |p - q|$.
- *Bound the total difference.* Write $|p - q| = q\,|p/q - 1|$. The ratio p/q lies between $e^{-\varepsilon}$ and e^{ε}, so $|p/q - 1|$ is at most $e^{\varepsilon} - 1$, its value at the upper end. At the lower end it is only $1 - e^{-\varepsilon}$, which is smaller. The $q(y)$ add up to 1, so $\sum_y |p - q| \le e^{\varepsilon} - 1$.

For randomized response, with two outputs, the average is easy to compute directly. Write $t = e^{\varepsilon}/(1 + e^{\varepsilon})$ for the chance of a truthful answer on D, whose loss is $+\varepsilon$, while a flipped answer has loss $-\varepsilon$. So $m = \varepsilon t - \varepsilon(1 - t) = \varepsilon(2t - 1)$. Substituting t gives $2t - 1 = (e^{\varepsilon} - 1)/(e^{\varepsilon} + 1)$, which is $\tanh(\varepsilon/2)$, so $m = \varepsilon \tanh(\varepsilon/2)$. At $\varepsilon = 0.1$ this is 0.0050, while the bound of Equation B.11 is 0.0105. At $\varepsilon = 1$ they are 0.4621 and 1.7183. So the bound holds and is about twice too large for small ε, which is where the chapter's sharper tanh form comes from.

3. **Centre the terms.** Write $X_i = L_i - m_i$. Given the earlier outputs, X_i has average zero, and it lies in an interval of length 2ε, from $-\varepsilon - m_i$ to $\varepsilon - m_i$. The total loss is the drift plus the sum of these centred terms, $L = \sum_i m_i + \sum_i X_i$, and the drift is at most $k\varepsilon(e^{\varepsilon} - 1)$ by step 2.

4. **One centred term has a small exponential average.** The next two steps bound the average of $e^{\lambda X}$ for a number $\lambda > 0$ of our choosing, because an exponential magnifies large values, and step 6 turns that into a tail bound. Hoeffding's lemma says that a variable X with average zero, which stays in an interval of length d, satisfies

$$\mathbb{E}\big[e^{\lambda X}\big] \le e^{\lambda^2 d^2/8} \qquad \text{for every real } \lambda. \tag{B.14}$$

The proof compares X with a variable that sits only at the two ends of the interval, which has the largest exponential average, and then bounds that average. Concentration inequalities gives the details. With $d = 2\varepsilon$ the right side is $e^{\lambda^2\varepsilon^2/2}$.

5. **The bounds multiply, even when releases adapt.** Write $W_j = X_1 + \cdots + X_j$ for the running sum, so that $e^{\lambda W_k} = e^{\lambda W_{k-1}} e^{\lambda X_k}$. Take the average of this product in two stages, first over the last output with the earlier ones fixed and then over the earlier ones. With the earlier outputs fixed, $e^{\lambda W_{k-1}}$ is a fixed number, and step 4 bounds the average of $e^{\lambda X_k}$ by $e^{\lambda^2\varepsilon^2/2}$ whatever the history was. So

$$\mathbb{E}\big[e^{\lambda W_k}\big] \le e^{\lambda^2\varepsilon^2/2}\,\mathbb{E}\big[e^{\lambda W_{k-1}}\big] \le \ldots \le e^{k\lambda^2\varepsilon^2/2}. \tag{B.15}$$

This is where adaptivity is handled. Each release may depend on the past, but the bound on its own term does not. This argument is Azuma's inequality.

6. **Turn the exponential average into a tail bound.** Markov's inequality says that a quantity that is never negative exceeds a level a with probability at most its average divided

by a. Apply it to $e^{\lambda W_k}$ at the level $a = e^{\lambda s}$, for a value s to be chosen. For $\lambda > 0$ the event $W_k \geq s$ is the event $e^{\lambda W_k} \geq e^{\lambda s}$, so

$$\Pr[W_k \geq s] \leq e^{-\lambda s + k\lambda^2\varepsilon^2/2}. \tag{B.16}$$

The exponent is a parabola in λ. Its derivative $-s + k\lambda\varepsilon^2$ is zero at $\lambda = s/(k\varepsilon^2)$, where the exponent equals $-s^2/(2k\varepsilon^2)$. Setting $e^{-s^2/(2k\varepsilon^2)} = \delta'$ and solving gives the level

$$s = \varepsilon\sqrt{2k\ln(1/\delta')}. \tag{B.17}$$

7. **Convert.** If $L > \varepsilon'$, then $\sum_i X_i = L - \sum_i m_i > \varepsilon' - k\varepsilon(e^\varepsilon - 1) = s$. So $\Pr[L > \varepsilon'] \leq \delta'$, and the bad-event fact Equation B.7 with $\tau = \varepsilon'$ gives (ε', δ')-DP. The same argument with D and D' swapped covers the other direction.

When each release is (ε, δ)-DP with $\delta > 0$, its loss can exceed ε on rare outputs, so step 1 fails. The fix uses a fact proved in the chapter: every such release behaves like a processed version of a simple mechanism that, with probability δ, announces which dataset it ran on, and otherwise runs ε-DP randomized response. Then the k announcements cost at most $k\delta$ by the union bound, and the rest is the argument above. Section 21.4 and Section J.1 carry this out.

B.2.5. Checking it

The script computes the loss of 100 randomized-response answers at $\varepsilon = 0.1$ exactly, from the binomial count of truthful answers. Its mean is 0.4996 and its standard deviation 0.9988, so the bound $\varepsilon' = 5.8502$ sits more than five standard deviations above the mean. The exact chance that the loss exceeds 5.8502 is 1.022×10^{-8}, far below the $\delta' = 10^{-5}$ the theorem promises. The exact δ at that ε', the smallest slack that works (Section B.3, step 4, shows how to compute it), is smaller still, 1.956×10^{-9}. So advanced composition is valid but conservative, for three reasons. Hoeffding's lemma allows for a larger spread than the walk has, and step 2 doubles the drift. Then the bad-event fact counts every output above ε' in full.

Figure B.2 draws 25 runs of the walk over 1000 answers. Basic composition is the straight line $i\varepsilon$, which leaves the plot at $i = 400$. The runs stay in a band around the drift whose width grows like $\sqrt{i}$. In 100,000 simulated runs of 1000 answers, the largest total loss was 18.4, while basic composition says 100 and advanced composition 25.6914.

B.2.6. Recipe and pitfalls

To spend a total budget $(\varepsilon_{\text{total}}, \delta')$ on k releases that are each ε-DP, set the leading term of Equation B.9 equal to the target. That gives each release roughly

$$\varepsilon \approx \frac{\varepsilon_{\text{total}}}{\sqrt{2k\ln(1/\delta')}}. \tag{B.18}$$

Then evaluate Equation B.9 with that ε, and lower it a little if the second term pushes the total over the target.

Advanced composition is worse than basic composition when k is small. Its first term is $\varepsilon\sqrt{k}$ times $\sqrt{2\ln(1/\delta')}$, which is 4.80 at $\delta' = 10^{-5}$, while basic composition is $\varepsilon k = \varepsilon\sqrt{k} \times \sqrt{k}$. So $\sqrt{k}$

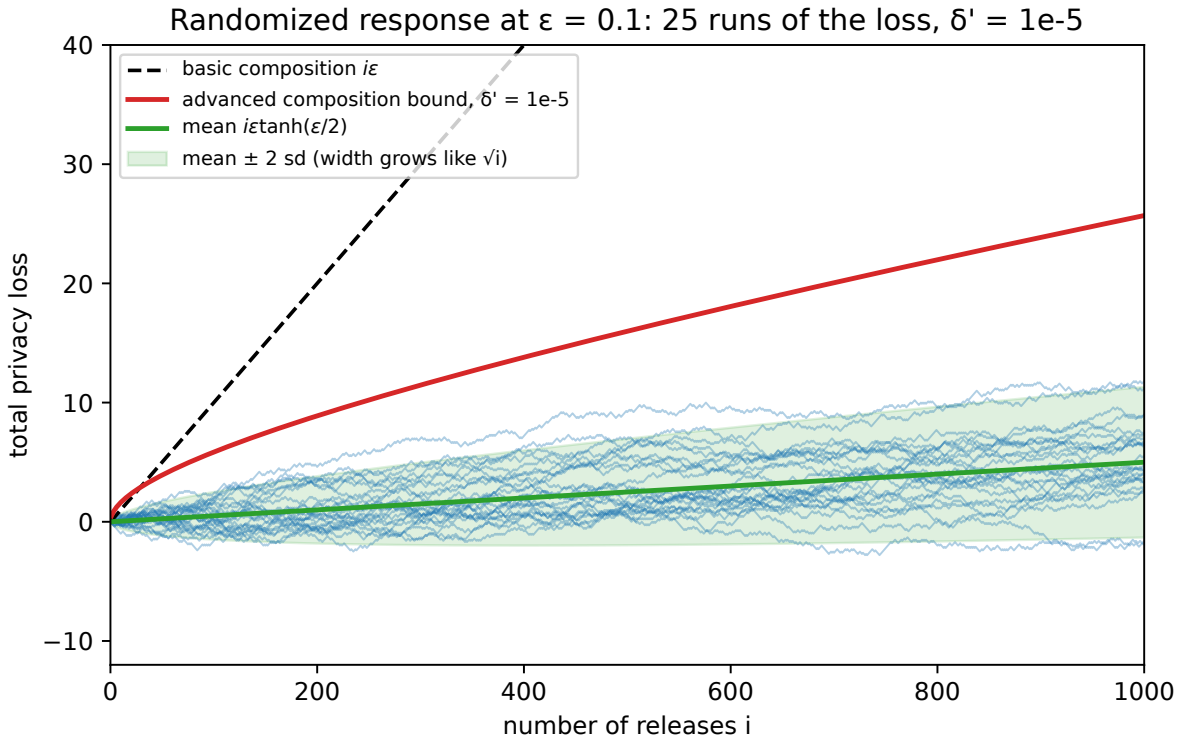

Figure B.2.: The total privacy loss of i randomized-response answers at $\varepsilon = 0.1$, for 25 simulated runs (thin lines). The green line is the mean loss and the shaded band the mean plus or minus two standard deviations, whose width grows like $\sqrt{i}$. The red curve is the advanced composition bound at $\delta' = 10^{-5}$, and the dashed line is the basic bound $i\varepsilon$.

must beat 4.80 and more. Setting the two bounds equal and solving for k shows that at $\varepsilon = 0.1$ advanced composition wins only once k exceeds $2\ln(1/\delta')/(2-e^{\varepsilon})^2 = 28.76$. So always compute both and keep the smaller. For $\varepsilon \geq \ln 2$ the second term alone is at least $k\varepsilon$, so the $e^{\varepsilon}-1$ form never wins, and you need the tanh form of the chapter. And when you know more than each release's ε, for example that the noise is Gaussian, the next two sections do much better.

B.3. Gaussian releases: k of them are one

B.3.1. The question

You add Gaussian noise of standard deviation σ to k answers, each with sensitivity Δ. What is the exact (ε, δ) guarantee of all k together? And how much noise must each answer get so that the whole set meets a total budget?

B.3.2. The answer

The k releases are exactly as private as **one** Gaussian release whose sensitivity is $\sqrt{k}\,\Delta$, with the same noise σ. In units of the noise, that single release has the shift

$$\mu_k = \frac{\sqrt{k}\,\Delta}{\sigma}. \tag{B.19}$$

So the smallest valid δ at a given ε is the exact Gaussian formula with μ_k in place of Δ/σ:

$$\delta(\varepsilon) = \Phi\Big(\frac{\mu_k}{2} - \frac{\varepsilon}{\mu_k}\Big) - e^{\varepsilon}\,\Phi\Big(-\frac{\mu_k}{2} - \frac{\varepsilon}{\mu_k}\Big). \tag{B.20}$$

Read backwards, this gives the noise for k releases at a total budget. If σ_1 is the noise that makes one release (ε, δ)-DP, then

$$\sigma_k = \sqrt{k}\,\sigma_1 \tag{B.21}$$

makes k releases together (ε, δ)-DP. The single-release formula is Equation 20.17 in Section 20.4, and Section A.7 derives it.

B.3.3. A worked example

You want 10 counts with sensitivity 1 to be $(1, 10^{-5})$-DP together. One count at $(1, 10^{-5})$ needs $\sigma_1 = 3.7306$, from the exact calibration. By Equation B.21 each of the 10 counts gets $\sigma_{10} = \sqrt{10} \times 3.7306 = 11.797$. Putting $\mu_{10} = \sqrt{10}/11.797$ back into Equation B.20 and solving for ε at $\delta = 10^{-5}$ gives 1.0000, as it should.

Compare this with basic composition. Splitting the budget evenly gives each count $(0.1, 10^{-6})$, and the exact calibration for that share needs $\sigma = 36.305$. That is 3.08 times more noise for the same total guarantee. With 100 counts the two answers are $\sigma_{100} = 37.306$ and 362.02, a factor of 9.70.

B.3.4. Why it works

The idea. The privacy loss of one Gaussian release is itself a normal random variable. Losses add, and a sum of independent normal variables is normal, with the means added and the variances added. The sum of k losses turns out to be exactly the loss of one release with $\sqrt{k}$ times the shift. Since the smallest δ depends only on the distribution of the loss, the two have the same δ at every ε.

1. **The loss of one release is normal.** Take one count whose true value is 0 on D and Δ on D', and write the output on D as $y = z$, where z is the noise. The same output y sits at distance $z - \Delta$ from the centre on D'. The normal density with standard deviation σ is proportional to $e^{-z^2/(2\sigma^2)}$, so the loss is a difference of two exponents:

$$L = \frac{(z-\Delta)^2 - z^2}{2\sigma^2} = \frac{\Delta^2 - 2\Delta z}{2\sigma^2}. \tag{B.22}$$

   This is a straight line in the noise z. Its mean is $\Delta^2/(2\sigma^2) = \mu^2/2$, because z has mean 0. Its variance is $(\Delta/\sigma^2)^2\sigma^2 = \mu^2$, because multiplying z by a constant multiplies the variance by its square. A straight-line function of a normal variable is normal, so on D

$$L \sim \mathcal{N}\Big(\frac{\mu^2}{2},\ \mu^2\Big), \qquad \mu = \frac{\Delta}{\sigma}. \tag{B.23}$$

2. **Add k independent losses.** With fresh noise for each release, the k losses are independent, and the total loss is their sum (Section B.1). Means add, and so do variances of independent terms. A sum of independent normal variables is normal (Section E.1 proves it). So the total loss is normal with mean $k\mu^2/2$ and variance $k\mu^2$.
3. **Recognize one release.** A single release with shift $\mu_k = \sqrt{k}\,\mu$ has, by step 1, a loss with mean $\mu_k^2/2 = k\mu^2/2$ and variance $\mu_k^2 = k\mu^2$. That is the same normal distribution as in step 2.
4. **The exact δ depends only on the loss.** By the definition of (ε, δ)-DP in the opening, the smallest δ at a given ε is the largest gap $\Pr_D[S] - e^\varepsilon \Pr_{D'}[S]$ over sets of outputs. The gap is largest when S holds exactly the outputs with $p > e^\varepsilon q$, so the smallest δ is $\sum_y (p - e^\varepsilon q)_+$, where $(x)_+ = \max(x, 0)$. Factor p out of each term, and note that $e^\varepsilon q/p = e^{\varepsilon - L}$. This gives

$$\delta(\varepsilon) = \sum_y p(y)\big(1 - e^{\varepsilon - L(y)}\big)_+ = \mathbb{E}_D\big[(1 - e^{\varepsilon - L})_+\big]. \tag{B.24}$$

   The right side is an average over the loss alone. So two mechanisms whose losses have the same distribution on D have the same $\delta(\varepsilon)$ for every ε. By steps 2 and 3, the k releases have the $\delta(\varepsilon)$ of one release at μ_k, which is Equation B.20. The other direction, with D and D' swapped, gives the same value, because the Gaussian pair is symmetric.

There is a second way to see the same result. Stack the k answers into one vector. In the worst case, changing one record moves every answer by Δ, so the vector moves by $(\Delta, \dots, \Delta)$, whose length is $\sqrt{k\Delta^2} = \sqrt{k}\,\Delta$. Gaussian noise with the same σ in every coordinate looks the same in every direction. So you can turn the axes until the shift points along the first one, and the other $k - 1$ coordinates then carry no evidence at all. What is left is one Gaussian release with shift $\sqrt{k}\,\Delta$.

Adaptive queries. Suppose each query is chosen after seeing the earlier answers, and each still has sensitivity Δ and noise σ. If every query moves by exactly Δ, step 1 gives the same

normal distribution for each loss whatever the history was. A term whose distribution is the same whatever happened before is independent of what happened before, so steps 2 to 4 hold unchanged. Queries that move by less than Δ can only help, but proving that for an adaptive sequence takes the composition theorem of Gaussian DP (Section 32.6, Section K.3), which this page does not repeat.

B.3.5. Checking it

To test this, the script simulates 400,000 runs of 16 counts with noise $\sigma = 4$. Each count has $\mu = 0.25$, so the 16 together should behave like one release with $\mu_{16} = 4 \times 0.25 = 1$. Its loss should then have mean $\frac{1}{2}$ and variance 1, and the simulated total loss has mean 0.4971 and variance 1.0001. Averaging $(1 - e^{1-L})_+$ over the simulated losses estimates $\delta(1)$ as 0.1264. The formula Equation B.20 with $\mu_{16} = 1$ gives 0.1269. Figure B.3 shows the simulated losses for 1, 4 and 16 counts against the normal curve of a single release.

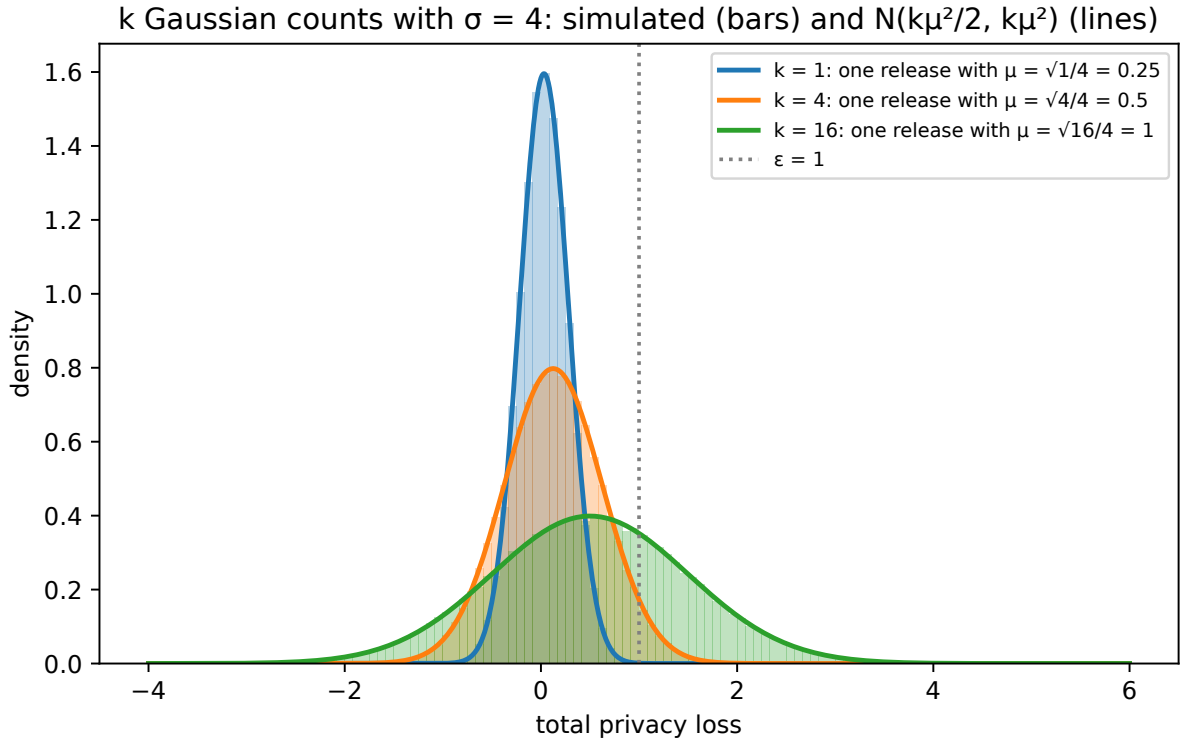

Figure B.3.: The total privacy loss of k Gaussian counts with noise $\sigma = 4$ and sensitivity 1, for $k = 1$, 4 and 16. Bars are simulated losses; lines are the normal distribution $\mathcal{N}(k\mu^2/2, k\mu^2)$ of one release with shift $\mu_k = \sqrt{k}/4$. The mean grows like k and the width like $\sqrt{k}$.

The result is exact, not a bound. Nothing was approximated in steps 1 to 4.

B.3.6. Recipe and pitfalls

To release k answers with Gaussian noise under a total budget (ε, δ), follow three steps.

1. Find σ_1, the exact noise for one release of sensitivity Δ at (ε, δ), by solving Equation 20.17 (Section A.7).
2. Multiply by the square root of the number of releases, $\sigma_k = \sqrt{k}\,\sigma_1$.
3. Add fresh noise $\mathcal{N}(0, \sigma_k^2)$ to each answer.

The other way round, given σ and k, put $\mu_k = \sqrt{k}\,\Delta/\sigma$ into Equation B.20 and solve for ε at your δ. When the releases have different sensitivities Δ_i or noise levels σ_i, the same steps give one release with $\mu^2 = \sum_i (\Delta_i/\sigma_i)^2$, because means and variances still add.

The sensitivity Δ must be the ℓ_2 sensitivity of each release under the neighbouring relation you claim. For example, a sum of values between $-C$ and C, for a clipping norm C, has sensitivity C under add/remove but $2C$ under replace-one. The result needs plain Gaussian noise. With subsampling, where each step uses only a random subset of the records, as in private stochastic gradient descent (SGD), the loss of a step is no longer normal, and Section C.5 shows what to do instead. Laplace releases do not combine into one Laplace release, so for them you need advanced composition or the accountants below.

B.4. Rényi DP: a summary of the loss that adds

B.4.1. The question

Many pipelines mix mechanisms, or use noise whose loss is not normal, so the exact shortcut of the previous section does not apply. You want a summary of each mechanism that you can add up across releases, and convert to (ε, δ) once at the end. What is that summary for the Gaussian mechanism, and why does it add?

B.4.2. The answer

Rényi differential privacy (RDP) summarizes the loss by averages of exponentials of it. A single number cannot capture both the typical and the rare large losses, so RDP keeps one such average for each **order** $\alpha > 1$, a dial that sets how much weight large losses get. For each order, the Rényi divergence between the two output distributions P (on D) and Q (on D') is

$$D_\alpha(P\|Q) = \frac{1}{\alpha - 1} \ln \int p(y)^\alpha q(y)^{1-\alpha}\, \mathrm{d}y. \tag{B.25}$$

The integral is the average, on D, of $e^{(\alpha-1)L}$, because $p^\alpha q^{1-\alpha} = p\,(p/q)^{\alpha-1}$. So it weighs outputs with a large loss heavily, more so for larger α.

A mechanism is $(\alpha, \varepsilon(\alpha))$-RDP when, for every neighbouring pair,

$$D_\alpha(P\|Q) \le \varepsilon(\alpha). \tag{B.26}$$

The function $\alpha \mapsto \varepsilon(\alpha)$ is its **RDP curve**. The Gaussian mechanism with sensitivity Δ and noise σ has a straight line for its curve,

$$\varepsilon(\alpha) = \frac{\alpha \Delta^2}{2\sigma^2}, \tag{B.27}$$

and RDP curves add under composition. So k Gaussian releases have the curve $k\alpha\Delta^2/(2\sigma^2)$. The chapter states these as Equation 29.7 and Equation 29.10.

B.4.3. A worked example

Take $\Delta = 1$, $\sigma = 1$ and $\alpha = 2$. The formula gives $D_2 = 2 \times 1/(2 \times 1) = 1$. Undoing the logarithm and the factor $1/(\alpha - 1)$ in the definition, the integral inside is $e^{(\alpha-1)D_\alpha} = e^{(2-1)\times 1} = e = 2.7183$. You can check this with the derivation below, which shows the integrand is a normal bump with exactly that area (Figure B.4). Two such releases have $D_2 = 1 + 1 = 2$.

B.4.4. Why it works

The Gaussian curve, by completing the square. Put p at centre 0 and q at centre Δ, both with standard deviation σ. Write $c = 1/(\sigma\sqrt{2\pi})$ for the constant in front of the normal density.

1. **Combine the exponents.** Since $\alpha + (1 - \alpha) = 1$, the constants combine to a single c, and

$$p^\alpha q^{1-\alpha} = c \, \exp\Big(- \frac{\alpha y^2 + (1-\alpha)(y-\Delta)^2}{2\sigma^2} \Big). \tag{B.28}$$

2. **Expand the numerator.** Multiply out $(y - \Delta)^2 = y^2 - 2y\Delta + \Delta^2$ and collect terms:

$$\alpha y^2 + (1-\alpha)(y-\Delta)^2 = y^2 - 2(1-\alpha)\Delta y + (1-\alpha)\Delta^2. \tag{B.29}$$

3. **Complete the square.** The first two terms are the start of $\big(y - (1-\alpha)\Delta\big)^2$, which also contains $(1-\alpha)^2\Delta^2$. Adding and subtracting that term gives

$$y^2 - 2(1-\alpha)\Delta y + (1-\alpha)\Delta^2 = \big(y - (1-\alpha)\Delta\big)^2 + (1-\alpha)\Delta^2(1 - (1-\alpha)). \tag{B.30}$$

   The last term simplifies to $(1-\alpha)\alpha\Delta^2 = -\alpha(\alpha-1)\Delta^2$.

4. **Integrate.** Putting this back into step 1, the exponent is $-\big(y - (1-\alpha)\Delta\big)^2/(2\sigma^2)$ plus the constant $+\alpha(\alpha-1)\Delta^2/(2\sigma^2)$, whose sign flips because of the minus in front of the fraction. So

$$\int p^\alpha q^{1-\alpha} \, \mathrm{d}y = e^{\alpha(\alpha-1)\Delta^2/(2\sigma^2)} \int c \, e^{-(y-(1-\alpha)\Delta)^2/(2\sigma^2)} \, \mathrm{d}y = e^{\alpha(\alpha-1)\Delta^2/(2\sigma^2)}. \tag{B.31}$$

   The integral that remains is a normal density centred at $(1-\alpha)\Delta$, so it equals 1.

5. **Take the logarithm and divide by** $\alpha - 1$**.** This gives $D_\alpha = \alpha\Delta^2/(2\sigma^2)$. The value grows with the shift, so the worst neighbouring pair is the one whose answers are Δ apart, which gives Equation B.27.

Why the curves add. For two independent releases the joint density is a product, $p(y_1, y_2) = p_1(y_1)p_2(y_2)$, and the same for q. A power of a product is the product of the powers, so the integrand splits into a factor for y_1 and a factor for y_2. The double integral of such a product is the product of the two single integrals:

$$\iint p_1^{\alpha} q_1^{1-\alpha}\, p_2^{\alpha} q_2^{1-\alpha}\, \mathrm{d}y_1\, \mathrm{d}y_2 = \int p_1^{\alpha} q_1^{1-\alpha}\, \mathrm{d}y_1 \cdot \int p_2^{\alpha} q_2^{1-\alpha}\, \mathrm{d}y_2. \tag{B.32}$$

Taking the logarithm turns this product into a sum, and dividing by $\alpha - 1$ gives D_{α} of the pair as the sum of the two divergences. When the second release is chosen from the first output, do the inner integral over y_2 first, with y_1 fixed. That inner integral is $e^{(\alpha-1)D_{\alpha}}$ for the mechanism chosen after y_1, so it is at most $e^{(\alpha-1)\varepsilon_2(\alpha)}$ whatever y_1 was. Replacing it by that bound leaves a constant times the first release's integral. So the curves still add, now as an upper bound (Section 29.5). Unlike the composition of (ε, δ) guarantees, nothing like δ is added at each step; the only slack comes in the one conversion at the end.

For k Gaussian releases the sum is $k\alpha\Delta^2/(2\sigma^2) = \alpha(\sqrt{k}\,\Delta)^2/(2\sigma^2)$, the curve of one release with $\sqrt{k}$ times the shift. That agrees with Section B.3. Other mechanisms have their own curves. The Laplace curve, for example, levels off at the pure ε of the mechanism (Equation 29.8).

Converting to (ε, δ). At the end you convert the summed curve once. For any order α, the mechanism is (ε, δ)-DP with

$$\varepsilon = \varepsilon(\alpha) + \frac{\ln(1/\delta)}{\alpha - 1}, \tag{B.33}$$

and you take the order that makes this smallest. The reason is the bad-event fact Equation B.7, with the tail $\Pr[L > \tau]$ bounded by Markov's inequality applied to $e^{(\alpha-1)L}$, whose average is what RDP controls. Section D.3 derives it. For example, take 1000 Gaussian steps with sensitivity 1 and noise $\sigma = 20$. Their summed curve is $1000\alpha/800 = 1.25\alpha$. At $\delta = 10^{-5}$ you minimize $1.25\alpha + 11.5129/(\alpha - 1)$ over the grid of orders that the accounting chapters use, which runs from 1.1 to 512. The best is $\varepsilon = 8.838$, at $\alpha = 4$. The exact answer from Section B.3 is 7.511, so the conversion costs 18%.

B.4.5. Checking it

A numerical integral of $p^{\alpha}q^{1-\alpha}$ on a fine grid, which uses no formula for the result, confirms the curve. It gives 1.0000 at $\alpha = 2$ and 5.0000 at $\alpha = 10$ with $\sigma = 1$, and 0.0625 at $\alpha = 2$ with $\sigma = 4$. These match $\alpha/(2\sigma^2)$ to every digit shown. Figure B.4 shows why step 4 works. The product $p^2 q^{-1}$ is a normal bump centred at $(1 - \alpha)\Delta = -1$, on the far side of p from q, and its area is e^1.

B.4.6. Recipe and pitfalls

To account with RDP, follow three steps.

1. Write down each release's RDP curve on a grid of orders, such as $\alpha\Delta^2/(2\sigma^2)$ for a Gaussian release.
2. Add the curves order by order.
3. Convert once, at the order that gives the smallest ε.

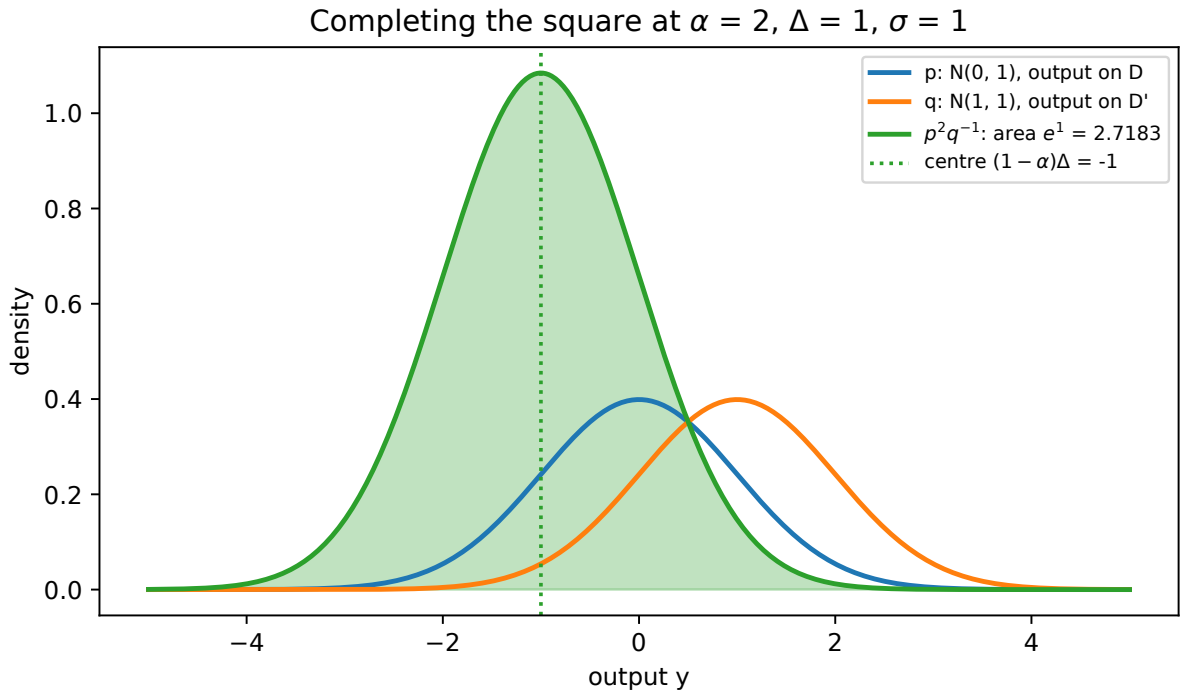

Figure B.4.: The two output densities of a Gaussian release with $\Delta = 1$ and $\sigma = 1$ (blue on D, orange on D'), and the integrand $p^\alpha q^{1-\alpha}$ for $\alpha = 2$ (green). Completing the square shows that the integrand is a normal bump centred at $(1-\alpha)\Delta = -1$, scaled up by $e^{\alpha(\alpha-1)\Delta^2/(2\sigma^2)} = e$, so its area is $e = 2.7183$ and $D_2 = 1$.

Do not convert each release to (ε, δ) first and then compose, because that throws away the curve and lands you back at basic or advanced composition. The grid of orders must reach small orders, because a steep summed curve makes large orders expensive, and the best order for many steps can be 2 or less. The converted ε overstates the exact one by an amount that shrinks slowly with k, from 57% at one step to 10% at 10,000 steps in the comparison below. When every release is a plain Gaussian, use the exact result of Section B.3 instead.

B.5. Comparing the four accountants

B.5.1. The question

You now have four ways to add up the cost of k releases: basic, advanced, RDP and exact. For the same mechanism, how different are their answers, and which should you use?

B.5.2. The answer

Fix one mechanism, a Gaussian release with sensitivity 1 and noise $\sigma = 20$, and a total $\delta = 10^{-5}$. Table B.3 gives the total ε of k releases under each accountant, from the script. Each accountant assumes something different. Two of them use the release's exact privacy curve, the smallest δ for each ε from Equation B.20 with $k = 1$.

- **Basic** gives each release the share δ/k, reads its ε_0 off the release's exact curve, and adds the k values of ε_0.
- **Advanced** spends a fraction κ of δ on the releases, $\kappa\delta/k$ each, and the rest on δ'. It reads ε_0 off the exact curve, applies Equation B.9, and keeps the best κ on a grid from $10^{-1/4}$ down to 10^{-10}.
- **RDP** adds the curves Equation B.27 and converts once.
- **Exact** is Equation B.20 with $\mu_k = \sqrt{k}/20$.

Table B.3.: Total ε at $\delta = 10^{-5}$ for k Gaussian releases with sensitivity 1 and noise $\sigma = 20$, under four accountants.

k	Basic	Advanced	RDP	Exact	RDP ÷ exact
1	0.160	0.864	0.251	0.160	1.57
10	1.892	3.502	0.771	0.561	1.37
100	21.510	16.462	2.524	1.993	1.27
1,000	238.578	105.863	8.838	7.511	1.18
10,000	2,601.968	938.234	36.513	33.104	1.10

B.5.3. A worked example

Take $k = 1000$, the size of a short training run. Basic composition gives each step $\delta = 10^{-8}$ and reports $\varepsilon = 238.578$. Advanced composition reports 105.863, or 68.008 with the chapter's sharper tanh form. RDP reports 8.838, and the exact answer is 7.511. So the two accountants that see

each release only as one $(\varepsilon_0, \delta_0)$ pair overstate ε by a factor of 9 to 32, while RDP overstates it by 18%.

B.5.4. Why it works

The order of the columns follows how much each accountant knows about a release. Basic and advanced composition know only one point $(\varepsilon_0, \delta_0)$ of each release's privacy curve. A Gaussian release has a whole curve of valid pairs, and collapsing it to one point throws away how the release behaves at every other point. Advanced composition still wins over basic for large k, because it uses the cancellation of Section B.2. RDP keeps a whole curve of exponential moments, which adds exactly, and loses only in the one conversion at the end. The exact accountant keeps the whole distribution of the loss, which for Gaussian noise is a normal distribution described by two numbers.

At $k = 1$ basic composition equals the exact answer, since there is nothing to add. Advanced composition is worst there, because its $\sqrt{2\ln(1/\delta')}$ factor is paid even for one release. As k grows, basic composition grows like k, advanced like $\sqrt{k}$ until its drift term takes over, and RDP and exact both like $\sqrt{k}$.

B.5.5. Checking it

Figure B.5 plots the four accountants for k from 1 to 10,000, on log axes, and their ratio to the exact answer. The basic line has slope 1, so it grows like k. The RDP and exact lines run parallel, with slope one half, so they grow like $\sqrt{k}$. RDP's excess shrinks from 1.57 times the exact value at one release to 1.10 times at 10,000, because the conversion's extra term $\ln(1/\delta)/(\alpha - 1)$ matters less as the curve grows. The exact line is the true value, so every other line lies above it. The script's value at $k = 1000$, 7.511, is also the one the RDP chapter quotes for this mechanism.

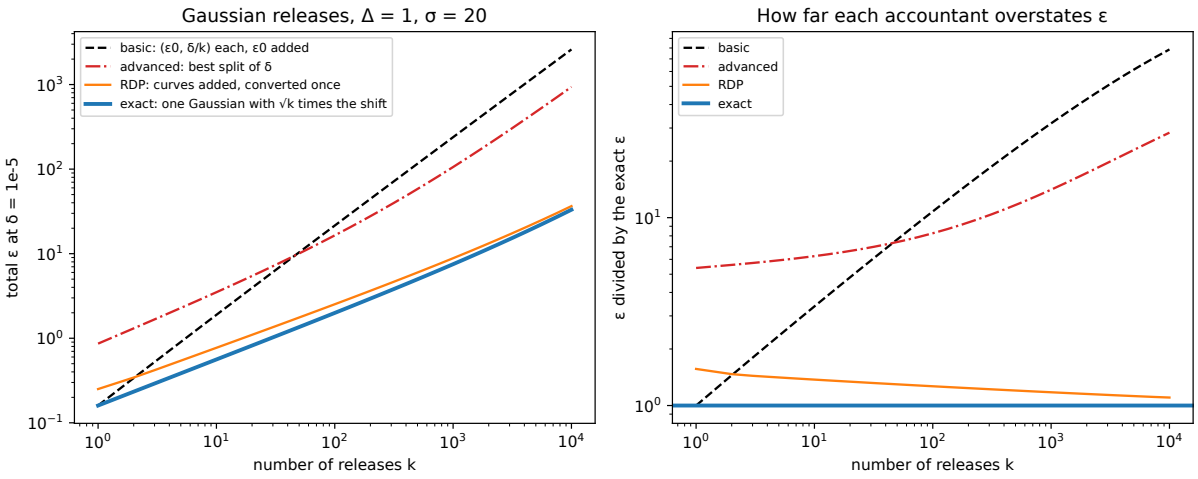

Figure B.5.: Left: the total ε at $\delta = 10^{-5}$ of k Gaussian releases with sensitivity 1 and noise $\sigma = 20$, on log axes, under basic composition (dashed), advanced composition with the best split of δ (dash-dot), RDP converted once (orange) and the exact answer (thick blue). Right: each accountant's ε divided by the exact one.

B.5.6. Recipe and pitfalls

Choose the accountant by what you know about each release.

1. **Every release is a plain Gaussian.** Use the exact result of Section B.3. It is a closed formula and the true answer.
2. **The releases mix mechanisms, or are subsampled, as in private training.** Use RDP, or a numerical accountant of the privacy loss distribution (PLD), which computes the exact answer to a chosen precision (Section 34.3). Section C.5 works through the subsampled case.
3. **You know only each release's $(\varepsilon_0, \delta_0)$.** Use optimal composition (Section 21.4), with advanced composition as a quick check by hand.
4. **Only a few releases, or pure DP with different budgets.** Basic composition is simple and close enough, and it is exact for the worst case of pure DP.

Report one accountant, chosen before you look at the results, and state which one it was and what δ it used. Every accountant needs the same neighbouring relation for every release, and none of them covers budgets chosen on the fly. For those cases, see Section 36.4.

B.6. Code

The script `code/appendix-derivations/apx_core_composition.py` computes every number on this page and draws its five figures. It simulates the 10-count Laplace dashboard and rebuilds the adaptive randomized-response table. It computes the advanced bound and checks it against the exact loss of composed randomized response, and simulates the random walk. For Gaussian releases it simulates the summed loss, checks Equation B.20 and the $\sqrt{k}$ noise recipe, and integrates the Rényi divergence numerically. Finally, it runs the four accountants on one mechanism. Run it with

```
uv run python code/appendix-derivations/apx_core_composition.py
```

Table B.4 collects the main numbers it prints.

Table B.4.: The main numbers printed by the appendix's script, with the default seed 0.

Check	Printed values
10 Laplace counts at $\varepsilon = 0.1$	largest loss 1.0000; reached in 0.000997 of runs (exact 0.000977); mean 0.0484
Two-output pair	$(1, 0.0476)$-DP, yet $\Pr[L > 1] = 0.50$
Mean loss of one step, $\varepsilon = 0.1$ and 1	bound 0.0105 and 1.7183; randomized response 0.0050 and 0.4621
Advanced, $k = 100$, $\varepsilon = 0.1$, $\delta' = 10^{-5}$	$4.7985 + 1.0517 = 5.8502$; tanh form 5.2981; optimal 4.3068; basic 10
Exact tail at 5.8502	$\Pr[L > \varepsilon'] = 1.022 \times 10^{-8}$; exact $\delta = 1.956 \times 10^{-9}$

Check	Printed values
16 Gaussian counts, $\sigma = 4$	loss mean 0.4971 (0.5), variance 1.0001 (1); $\delta(1)$ 0.1264 simulated, 0.1269 exact
Noise for $(1, 10^{-5})$ in total	$\sigma_1 = 3.7306$; $\sigma_{10} = 11.797$ against 36.305 by basic splitting
Rényi divergence, numerical against formula	1.0000, 5.0000, 0.0625
1000 Gaussian steps, $\sigma = 20$	RDP 8.838 at $\alpha = 4$; exact 7.511

Three things stand out. Basic composition is exact for the worst case of pure DP but very loose for the typical case. Advanced composition is valid with a large margin: in the worked example the true δ is smaller than the promised one by a factor of $10^{-5}/(1.956 \times 10^{-9}) = 5{,}112$. And for Gaussian noise the exact answer is as easy to compute as any bound, so there is no reason to use a bound.

C. Accounting for DP-SGD

This appendix follows one training run from the clipped gradient to its final guarantee of differential privacy (DP). The run is stochastic gradient descent (SGD) with per-example clipping and Gaussian noise, which is called DP-SGD. A training algorithm is **differentially private** when adding or removing one record changes the probability of any set of outcomes by at most a factor e^{ε}, plus a small slack δ. The **sensitivity** of a computation is the most that one record can move its result. The **Gaussian mechanism** adds normal noise to such a result, and its privacy depends only on the sensitivity divided by the noise's standard deviation. Appendix Section A.7 derives the Gaussian mechanism's exact guarantee, and Section B.4 derives the Rényi divergence, the tool that adds up the cost of many steps. This page uses both and restates each where it is needed.

The five sections answer the questions a practitioner asks, in the order a training run raises them. Clipping fixes the sensitivity, and the noise then turns each step into a Gaussian mechanism. Random batches make each step cheaper, and a curve built from the Rényi divergence measures that cheaper step exactly. Finally, an accountant adds the steps up and converts the total into one (ε, δ). Every number uses the book's running example, so you can check each one against the chapters. It trains on 10,000 records for 100 epochs. Each batch is drawn at random and holds 100 records on average, and the run and reports its guarantee at $\delta = 10^{-5}$. Table C.1 maps each section to the chapter sections that use its formula.

Table C.1.: The five derivations of this appendix and the chapter sections that use them.

Section	Formula it derives	Used in
Section C.1	the clipped sum has sensitivity C	Section 39.3, Section 39.7, Section 33.4
Section C.2	one step has ratio $1/\sigma$; T unsampled steps have $\sqrt{T}/\sigma$	Section 39.3, Section 39.5, Section 20.4
Section C.3	$\varepsilon' = \ln\left(1 + q(e^{\varepsilon} - 1)\right)$	Section 33.3
Section C.4	the binomial sum for the subsampled Gaussian's Rényi curve	Section 33.5, Section 33.6, Equation 39.1
Section C.5	$\varepsilon = \min_{\alpha} \left[T\varepsilon(\alpha) + \ln(1/\delta)/(\alpha - 1)\right]$	Section 33.7, Section 29.8, Section 37.3

The notation is that of the DP-SGD chapter, and each symbol is introduced where it first appears. Two datasets are **neighbours** when one of them is the other with one record added. Write D for a dataset and $D' = D \cup \{x\}$ for the same dataset with the record x added. This **add/remove**

relation is the one the book uses for DP-SGD. The reason is the way DP-SGD draws its batches, by an independent coin flip for each record, so that adding a record simply adds one more coin (Section 18.1, and Section C.3).

C.1. Clipping gives the sum a sensitivity

C.1.1. The question

The noise has to hide any one record's contribution, so you need a bound on how far one record can move the sum of gradients. But a gradient can have any length. A mislabelled record far from the decision boundary can have a gradient a thousand times longer than a typical one, and nothing about the model bounds it. How do you get a bound that holds for every model and every record?

C.1.2. The answer

Write g_i for the **per-example gradient** of record i, the gradient of that record's own loss at the current weights. You rescale each one so that its length is at most a number C that you choose, the **clipping norm**. Rescaling keeps the direction and caps the length:

$$\bar{g}_i = g_i \min\Big(1, \frac{C}{\|g_i\|}\Big), \qquad \bar{G}(D) = \sum_{i \in D} \bar{g}_i. \tag{C.1}$$

Here $\|g_i\|$ is the Euclidean length of the gradient and $\bar{G}(D)$ is the **clipped sum** over the records of a dataset D. Its ℓ_2 sensitivity is the largest length of $\bar{G}(D') - \bar{G}(D)$ over neighbouring datasets, and it is

$$\Delta_2 \bar{G} = C \quad \text{under add/remove}, \qquad \Delta_2 \bar{G} = 2C \quad \text{under replace-one}. \tag{C.2}$$

Under **replace-one**, the other common relation, neighbouring datasets have the same size and differ in the value of one record. The book uses the add/remove relation for DP-SGD, so the sensitivity is C.

C.1.3. A worked example

Take $C = 1$ and a dataset D of two records with two-dimensional gradients. The first is $(3, 4)$, of length 5, so clipping divides it by 5 and gives $(0.60, 0.80)$. The second is $(0.3, -0.4)$, of length 0.5, which is shorter than C and stays as it is. The clipped sum is $\bar{G}(D) = (0.90, 0.40)$.

Now add a third record x with gradient $(-2.4, 0.7)$, of length 2.5. Clipping divides it by 2.5 and gives $(-0.96, 0.28)$, so $\bar{G}(D') = (-0.06, 0.68)$. The sum moved by $(-0.96, 0.28)$, which is exactly the new record's clipped gradient. Its length is $\sqrt{0.96^2 + 0.28^2} = 1.00$, which is C.

Under the replace-one relation, change the first record's gradient from $(3, 4)$ to $(-3, -4)$ instead. Its clipped term goes from $(0.60, 0.80)$ to $(-0.60, -0.80)$, so the sum becomes $(-0.30, -1.20)$. It moved by $(-1.20, -1.60)$, of length 2.00, which is $2C$.

C.1.4. Why it works

1. **A clipped gradient has length at most C.** If $\|g_i\| \le C$, the factor $\min(1, C/\|g_i\|)$ is 1 and the gradient is unchanged. Otherwise the factor is $C/\|g_i\|$, and the length becomes $\|g_i\| \cdot C/\|g_i\| = C$. Either way $\|\bar{g}_i\| \le C$, and the direction is the same because the factor is positive.
2. **The other records' terms do not change.** Each record's gradient is computed from that record alone and from the current weights. The weights come from the earlier noisy steps, which are already released, so they are fixed when this step runs. Adding x therefore leaves every other term of the sum exactly as it was.
3. **Add/remove: the sum moves by one clipped gradient.** By step 2, $\bar{G}(D') - \bar{G}(D) = \bar{g}_x$, and by step 1 its length is at most C. That is the first half of Equation C.2.
4. **Replace-one: the sum moves by a difference of two.** If record x is replaced by x', the sum moves by $\bar{g}_{x'} - \bar{g}_x$. The triangle inequality says that the length of a difference is at most the sum of the lengths, so it is at most $C + C = 2C$. The worked example reaches $2C$, because two gradients that point in opposite directions give the largest difference.

Nothing in these steps used the loss, the architecture or the data. That is why clipping gives a sensitivity for every model.

C.1.5. Checking it

This appendix's script, described in the Code section at the end, draws 20,000 random datasets of five two-dimensional gradients, with lengths that are often far above C, and a random new record for each. The largest change of the clipped sum, in units of C, is 1.0000 when the record is added and 2.0000 when it replaces another. Both bounds are reached, so neither can be improved.

Figure C.1 shows the mechanism. On the left, each gradient outside the circle of radius C is pulled back onto it, along its own direction, and those inside are left alone. On the right, adding one record moves the clipped sum by that record's clipped gradient, so the new sum always lands inside a circle of radius C around the old one.

C.1.6. Recipe and pitfalls

Clip every per-example gradient to a norm C that is fixed before training, and the sum has sensitivity C under add/remove. The clipping norm is not a privacy parameter. The next section sets the noise to σC, a fixed multiple σ of the clipping norm. So a larger C means more noise in the same proportion, and the two changes cancel in ε (Section C.2). The clipping norm affects only accuracy, which Section 39.4 studies.

Step 2 is where implementations break the argument. Batch normalization makes each record's gradient depend on the other records in the batch, so one record can move every term of the sum. A clipping norm computed from the current batch, such as its median gradient length, has the same flaw in another place. The noise level then depends on the data, so it can itself reveal something about the records.

Two other cases double the sensitivity. Clipping the mean gradient of a group of records, a microbatch, has sensitivity $2C$. The group's clipped mean is a vector of length at most C both

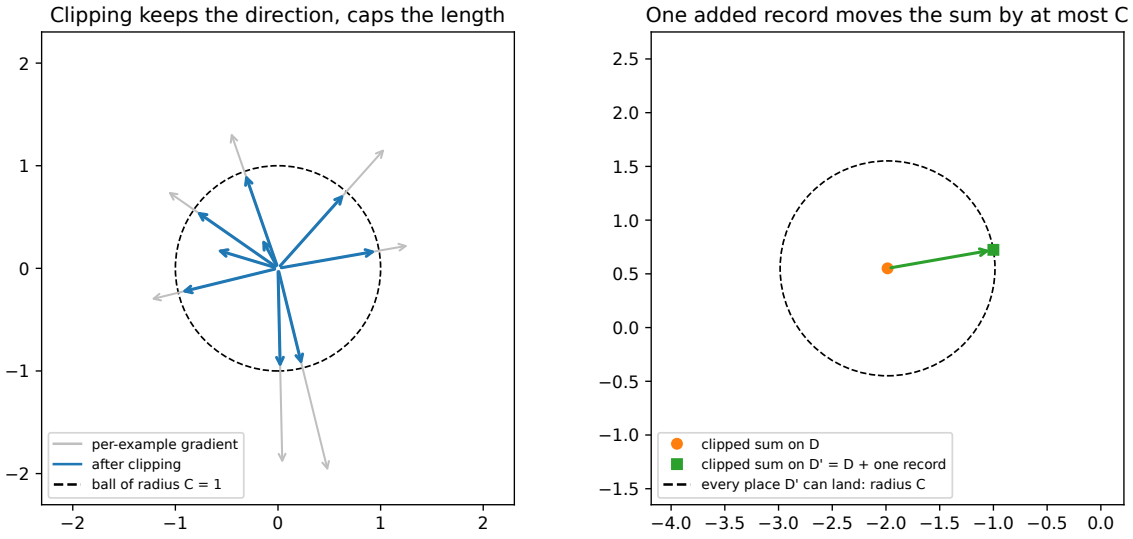

Figure C.1.: Left: nine random per-example gradients (grey) and the same gradients after clipping to norm $C = 1$ (blue), with the ball of radius C dashed. Right: the clipped sum on D and on D plus one record, with the circle of radius C around the first, inside which the second must land.

before and after one member is added, and the two vectors can point in opposite directions, as in the replace-one example above (Section 39.7). The replace-one relation also has sensitivity $2C$. In both cases the program that adds up the privacy cost, the **accountant**, must be told, because it assumes C (Section 33.4).

C.2. One noisy step is a Gaussian mechanism

C.2.1. The question

Each step releases the clipped sum plus noise. How much noise makes that one step private, and what do the rest of the update and the later steps cost?

C.2.2. The answer

DP-SGD adds normal noise to the clipped sum, independently in every coordinate. Its standard deviation is σC, where the number σ is the **noise multiplier**, the noise's standard deviation in units of the sensitivity. So step number t of training releases

$$G_t = \bar{G} + \xi_t, \qquad \xi_t \sim \mathcal{N}(0, \sigma^2 C^2 I). \tag{C.3}$$

Here I is the identity matrix, which says that the noise ξ_t has the same spread in every direction.

A Gaussian mechanism is described by one ratio, the sensitivity divided by the noise's standard deviation, which the book calls μ. For one step it is

$$\mu = \frac{\Delta_2 \bar{G}}{\sigma C} = \frac{C}{\sigma C} = \frac{1}{\sigma}. \tag{C.4}$$

A larger ratio means the two output distributions overlap less, so an observer can tell them apart more easily. The exact trade-off between ε and δ is the probability mass where the distribution with the record exceeds e^{ε} times the one without it. For the mechanism with ratio μ that mass gives the condition

$$\delta \geq \delta_{\mu}(\varepsilon) = \Phi\Big(\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big) - e^{\varepsilon}\,\Phi\Big(-\frac{\mu}{2} - \frac{\varepsilon}{\mu}\Big), \tag{C.5}$$

where $\Phi(z)$ is the probability that a standard normal variable is at most z (Section 20.4, and Section A.7 for a derivation from scratch). Without sampling, every record is used in every step. If the run has T steps, they act together like one Gaussian mechanism with ratio

$$\mu_T = \frac{\sqrt{T}}{\sigma}. \tag{C.6}$$

C.2.3. A worked example

Take $\sigma = 1$, so one step has $\mu = 1$. Solving Equation C.5 for $\delta = 10^{-5}$ gives $\varepsilon = 4.38$ for a single step, which is already a large privacy cost. The cost grows quickly with the number of steps if every record is used in each one. For example, 100 steps have $\mu_T = \sqrt{100} = 10$ and $\varepsilon = 91.82$, and the running example's 10,000 steps have $\mu_T = 100$ and $\varepsilon = 5425.51$. Nobody would report such a number, and the next two sections show how random batches bring it down to single digits.

The DP-SGD chapter has a full-batch row in Table 39.4, where every batch is the whole dataset, so its 100 epochs are 100 steps. For a target of $\varepsilon = 4$ that row uses $\sigma = 10.8$. So $\mu_T = \sqrt{100}/10.8 = 0.926$, and the script gives $\varepsilon = 4.005$, the target up to the rounding of σ.

C.2.4. Why it works

1. **Only the ratio matters.** Compare the noisy sum on D and on D'. The two are normal distributions with the same spread, centred s apart, where the shift s is the length of $\bar{G}(D') - \bar{G}(D)$. Rotate the space so that this shift lies along the first axis. The noise has the same spread in every direction, so rotating it leaves it unchanged. Every other coordinate then has the same noise on both datasets and tells an observer nothing. What is left is one coordinate, $\mathcal{N}(0, \sigma^2 C^2)$ against $\mathcal{N}(s, \sigma^2 C^2)$. Dividing the output by σC changes no probability of any event, so this is the pair $\mathcal{N}(0, 1)$ against $\mathcal{N}(s/(\sigma C), 1)$.
2. **The worst shift gives ratio $1/\sigma$.** By Section C.1 the shift is at most C, so the ratio is at most $C/(\sigma C) = 1/\sigma$. A smaller ratio is never less private, because the two distributions then overlap more. Notice that the clipping norm cancels, which is why it is not a privacy parameter.
3. **The rest of the update is free.** The learning rate, the division by the expected batch size B, momentum, Adam and the new weights are all computed from G_t and from earlier released values, without looking at the data again. Such a computation is called **post-processing**, and it cannot reveal more than its input. The reason is that an attacker who

sees G_t could run the same computation herself, so any event about the processed output is an event about G_t, and its probability obeys the same bound (Section 19.1).

4. **Unsampled steps add up like one Gaussian.** The **privacy loss** of an output y is the logarithm of how much more likely y is on D' than on D. For the pair $\mathcal{N}(\mu, 1)$ against $\mathcal{N}(0, 1)$, the loss is

$$\ln \frac{e^{-(y-\mu)^2/2}}{e^{-y^2/2}} = \mu y - \frac{\mu^2}{2}. \tag{C.7}$$

With $y \sim \mathcal{N}(\mu, 1)$, this is a normal variable with mean $\mu^2/2$ and variance μ^2. Each step draws fresh noise, independent of the earlier steps. So over T steps the joint likelihood ratio is the product of the steps' ratios, and the losses add. Each step's loss has this same distribution whatever happened before, so the sum is normal with mean $T\mu^2/2$ and variance $T\mu^2$. That is exactly the loss of one Gaussian mechanism with ratio $\sqrt{T}\mu = \sqrt{T}/\sigma$. Since δ for a given ε is computed from the distribution of the loss alone, the two have the same guarantee, and Section B.3 proves it in full.

C.2.5. Checking it

The full-batch check above recovers the chapter's $\varepsilon = 4$ to three digits. It also confirms step 4, because the chapter solved its row for 100 composed steps, while here the 100 steps are one Gaussian with $\mu_T = 10/\sigma$. The script solves Equation C.5 by bisection on ε, working with logarithms, because at $\mu_T = 100$ both terms underflow to zero in ordinary arithmetic. The value at 10,000 steps, 5425.51, agrees with the 5425.5 quoted in Amplification by subsampling.

C.2.6. Recipe and pitfalls

Set the noise to σC, and one step is a Gaussian mechanism with ratio $1/\sigma$, whatever C is. Keep everything after the noise a function of the noisy sum and of public numbers. Dividing by the number of records actually in the batch is the common mistake here, because that count depends on the data and changes when x is added. Divide by the expected batch size B instead, the sampling rate times the number of records, which is public. And never compose unsampled steps for a long run, because ε grows at least like $\mu_T^2/2 = T/(2\sigma^2)$, the average privacy loss, and reaches the thousands.

C.3. Random batches make each step cheaper

C.3.1. The question

DP-SGD does not use every record in every step. Each step draws a random batch, and with $q = 0.01$ your record is in it only one time in a hundred. How much cheaper is a step that probably did not see you?

C.3.2. The answer

Under **Poisson sampling**, each record enters the batch independently with probability q, the **sampling rate**, by its own coin flip. If a step is ε-DP when it runs on whatever batch it is given, then the step run on a Poisson sample is ε'-DP under add/remove, with

$$\varepsilon' = \ln\left(1 + q(e^{\varepsilon} - 1)\right). \tag{C.8}$$

This is **amplification by subsampling**. When ε is small, $e^{\varepsilon} - 1$ is close to ε, and the logarithm of a number close to 1 is close to that number minus 1. So for small ε

$$\varepsilon' \approx q\varepsilon, \tag{C.9}$$

and the step becomes about $1/q$ times cheaper. When the step also has a slack δ, the same argument shrinks that slack to $q\delta$ (Equation 33.5).

C.3.3. A worked example

Take $q = 0.01$ and a step with $\varepsilon = 1$. Then $e - 1 = 1.71828$, so $1 + q(e^{\varepsilon} - 1) = 1.017183$ and $\varepsilon' = \ln 1.017183 = 0.017037$. The step costs about 0.017 instead of 1, almost $q\varepsilon = 0.01$. Table C.2 shows how the saving shrinks for larger ε.

Table C.2.: Amplification by Poisson sampling at rate $q = 0.01$. For small ε the cost shrinks by about q; for large ε it only drops by about $\ln(1/q) = 4.6$.

Base ε	0.1	1	5	10
Sampled ε', $q = 0.01$	0.0011	0.0170	0.9059	5.3993
$q\varepsilon$	0.0010	0.0100	0.0500	0.1000

C.3.4. Why it works

The idea is that with probability $1 - q$ your record is not used, and then the output has exactly the distribution it would have without you. Only the remaining fraction q of the time can the output differ. So every likelihood ratio becomes a weighted average of 1, with weight $1 - q$, and the old ratio, with weight q.

A tiny case shows it. Suppose a step's output y is three times as likely when your record is used. Under sampling, y's probability with you in the dataset is $(1 - q) \cdot p + q \cdot 3p$, where p is its probability without you. With $q = 0.01$ that is $0.99p + 0.03p = 1.02p$, so the ratio has fallen from 3 to 1.02. Here are the steps in general.

1. **Fix everyone else's coin.** Let U be the set of other records that were drawn. Each record has its own coin, so given U, record x is drawn with probability q, independently of U.

2. **Write both outputs given U.** Let P_0 be the output distribution of the step run on U, and P_1 that of the step run on $U \cup \{x\}$. On D the output is drawn from P_0. On D' it is drawn from P_0 when the coin of x says no, and from P_1 when it says yes. So for every set of outputs S,
$$P_{D'}(S \mid U) = (1-q)P_0(S) + qP_1(S). \tag{C.10}$$
3. **Use the step's own guarantee.** The sets U and $U \cup \{x\}$ are neighbours, and the step is ε-DP, so $P_1(S) \le e^{\varepsilon} P_0(S)$ for every S.
4. **Put it into the mixture.** Replacing $P_1(S)$ by the larger $e^{\varepsilon}P_0(S)$ gives
$$P_{D'}(S \mid U) \le (1-q)P_0(S) + qe^{\varepsilon}P_0(S) = (1 + q(e^{\varepsilon}-1))P_0(S). \tag{C.11}$$
5. **Average over U.** Both datasets draw the other records' coins with the same probabilities. The bound of step 4 holds for every U with the same factor, so it holds for the averages over U too. This is Equation C.8 in the direction "D' against D".
6. **Check the other direction.** DP also needs $P_D(S) \le e^{\varepsilon'} P_{D'}(S)$. The step's guarantee holds with either dataset first, so it also gives $P_1(S) \ge e^{-\varepsilon}P_0(S)$, so the mixture is at least $(1 - q + qe^{-\varepsilon})P_0(S)$. Dividing, $P_0(S) \le P_{D'}(S)/(1 - q + qe^{-\varepsilon})$. To compare the two factors, write $a = e^{\varepsilon}$ and multiply out:
$$(1 - q + q/a)(1 + q(a-1)) = 1 + q(1-q)\frac{(a-1)^2}{a} \ge 1. \tag{C.12}$$
So $1/(1 - q + qe^{-\varepsilon}) \le 1 + q(e^{\varepsilon} - 1)$, and this direction is never the worse one.

C.3.5. Checking it

The script takes a count with Laplace noise, whose density falls like $e^{-\varepsilon|y-\text{count}|}$, with $\varepsilon = 1$. Adding the record moves the count by 1, so the noisy count's density ratio between "used" and "not used" ranges from e^{-1} to e. It computes the mixture's likelihood ratio on a grid of outputs. At $q = 0.01$ the largest log ratio, with the record against without it, is 0.017037, equal to Equation C.8, so the bound is reached and cannot be improved. The other direction's largest log ratio is 0.006341, smaller, as step 6 says. Figure C.2 shows the same at $q = 0.1$, where the effect is easier to see. The ratio without sampling climbs to e, while the mixture's ratio stays below $1 + 0.1(e - 1) = 1.172$.

C.3.6. Recipe and pitfalls

For a step that is ε-DP on its batch, Poisson sampling at rate q makes it $\ln(1 + q(e^{\varepsilon} - 1))$-DP. For small ε this is about $q\varepsilon$. For large ε it is about $\varepsilon - \ln(1/q)$, because when the record is drawn, which happens with probability q, it is fully exposed.

The proof needs Poisson sampling, because step 1 needs an independent coin for your record. A batch of exactly B records drawn at random has no such coin. When your record enters such a batch it pushes another one out, which is a replacement, so the analysis needs the replace-one relation and twice the sensitivity. Shuffling the data and cutting it into batches is worse, because then your record is in exactly one batch per epoch and is never "not used" (Section 33.4).

Finally, do not add up these per-step numbers over a long run. The slacks add up too, so with 10,000 steps each step may only have a tiny share of δ. A Gaussian step with a tiny δ needs a

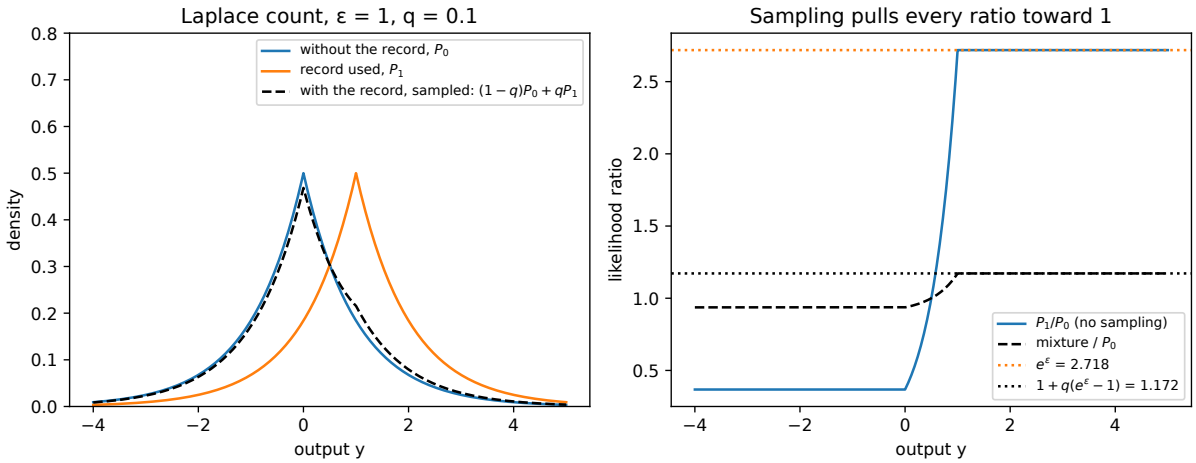

Figure C.2.: Left: a Laplace count with $\varepsilon = 1$ without the record (P_0), with the record used (P_1), and the Poisson-sampled output with the record, the mixture $0.9P_0 + 0.1P_1$ (dashed). Right: the likelihood ratios P_1/P_0 and mixture/P_0 against the output, with the bounds e^ε and $1 + q(e^\varepsilon - 1)$ dotted.

large ε, and there amplification only subtracts $\ln(1/q)$. Section 33.7 shows that the total runs into the thousands, and the next section gives the quantity that composes well.

C.4. The Rényi curve of a sampled Gaussian step

C.4.1. The question

A single (ε, δ) pair says how often the privacy loss is large, but not how large it gets when it is, so pairs add up badly over 10,000 steps. A curve that summarizes the whole distribution of the loss composes by simple addition. What is that curve for one sampled Gaussian step?

C.4.2. The answer

The **Rényi divergence** of order $\alpha > 1$ between two distributions P and Q is a log-average of a power of their likelihood ratio,

$$D_\alpha(P\|Q) = \frac{1}{\alpha - 1} \ln \mathbb{E}_{y\sim Q}\left[\left(\frac{P(y)}{Q(y)}\right)^\alpha\right]. \tag{C.13}$$

A mechanism has **Rényi differential privacy (RDP)** curve $\varepsilon(\alpha)$ when this divergence between its outputs on any two neighbouring datasets is at most $\varepsilon(\alpha)$, for every order α. A larger order weights large ratios more heavily. For the plain Gaussian mechanism with noise multiplier σ the curve is the straight line $\alpha/(2\sigma^2)$ (Section B.4).

For one DP-SGD step, divide the noisy sum by C. Then the output without the record is $P_0 = \mathcal{N}(0, \sigma^2)$, and with the record it is the mixture $P_q = (1-q)P_0 + qP_1$ with $P_1 = \mathcal{N}(1, \sigma^2)$.

This one-dimensional pair is the worst case, as the derivation below explains. Its RDP curve is $\varepsilon_{q,\sigma}(\alpha) = D_\alpha(P_q \| P_0)$, and for integer α it is a finite sum,

$$\varepsilon_{q,\sigma}(\alpha) = \frac{1}{\alpha - 1} \ln A_\alpha, \qquad A_\alpha = \sum_{j=0}^{\alpha} \binom{\alpha}{j} (1-q)^{\alpha-j} q^j e^{(j^2-j)/(2\sigma^2)}. \tag{C.14}$$

Here $\binom{\alpha}{j}$ is the binomial coefficient, the number of ways to choose j of α factors. For small q the curve is close to its leading term,

$$\varepsilon_{q,\sigma}(\alpha) \approx \frac{\alpha q^2 (e^{1/\sigma^2} - 1)}{2} \approx \frac{\alpha q^2}{2\sigma^2} \quad \text{for large } \sigma. \tag{C.15}$$

C.4.3. A worked example

Take the running example, $q = 0.01$ and $\sigma = 1$, at order $\alpha = 2$. The sum has three terms, one for each j (Table C.3).

Table C.3.: The three terms of A_2 for $q = 0.01$ and $\sigma = 1$.

j	$\binom{2}{j}(1-q)^{2-j} q^j$	$e^{(j^2-j)/2}$	Term
0	$0.99^2 = 0.9801$	1	0.980100
1	$2 \times 0.99 \times 0.01 = 0.0198$	1	0.019800
2	$0.01^2 = 0.0001$	$e = 2.718$	0.000272

They add up to $A_2 = 1.00017183$, so $\varepsilon_{q,\sigma}(2) = \ln A_2/(2-1) = 1.7181 \times 10^{-4}$. Without sampling the curve at $\alpha = 2$ is $2/(2\sigma^2) = 1$, so sampling made this order almost six thousand times cheaper.

C.4.4. Why it works

First, why one dimension and one shift of exactly 1 is enough. Given which other records were drawn, the step's output with the record is a mixture of "not drawn" and "drawn", as in Section C.3. As in Section C.2, rotating the space leaves one coordinate in which the two components differ, by at most C, and a smaller shift is never worse. Averaging over the other records' coins cannot increase the divergence. The reason is that the average of $(P/Q)^\alpha$ weighted by Q is a convex function of the pair (P, Q), so a mixture of pairs is never further apart than the worst pair in it. Section 33.5 gives these reduction steps in full, so what remains is the pair P_q and P_0. The derivation then takes five steps.

1. **Write the mixture's ratio.** Dividing the mixture by P_0 gives $P_q/P_0 = (1-q) + q\,r$, where $r = P_1/P_0$ is the Gaussian likelihood ratio. The normalizing constants cancel, and

$$r(y) = \frac{e^{-(y-1)^2/(2\sigma^2)}}{e^{-y^2/(2\sigma^2)}} = e^{(2y-1)/(2\sigma^2)}. \tag{C.16}$$

   So by the definition, $A_\alpha = \mathbb{E}_{y \sim P_0}\big[(1 - q + q\,r(y))^\alpha\big]$.

2. **Expand the power.** For a whole number α, the binomial theorem expands the power of a sum of two numbers into $\alpha + 1$ terms. At $\alpha = 2$ it is the familiar $(a + b)^2 = a^2 + 2ab + b^2$. Here the two numbers are $1 - q$ and qr, so

$$(1 - q + qr)^\alpha = \sum_{j=0}^{\alpha} \binom{\alpha}{j} (1 - q)^{\alpha - j} q^j r^j. \tag{C.17}$$

3. **Average term by term.** The average of a sum is the sum of the averages, and $(1-q)^{\alpha-j}q^j$ is a constant. So A_α is the same sum with each r^j replaced by its average $\mathbb{E}[r^j]$ under P_0.
4. **Each average is a Gaussian moment generating function (MGF).** The MGF of a random variable y is the average of $e^{\lambda y}$, as a function of a number λ. For $y \sim \mathcal{N}(0, \sigma^2)$ it is

$$\mathbb{E}[e^{\lambda y}] = e^{\lambda^2 \sigma^2 / 2}. \tag{C.18}$$

   To see why, complete the square in the exponent of the integrand, $\lambda y - y^2/(2\sigma^2) = -(y - \lambda\sigma^2)^2/(2\sigma^2) + \lambda^2\sigma^2/2$. After you take out the constant $e^{\lambda^2\sigma^2/2}$, what is left is a normal density centred at $\lambda\sigma^2$, and it integrates to 1. Now $r^j = e^{-j/(2\sigma^2)} e^{(j/\sigma^2)y}$, so taking $\lambda = j/\sigma^2$ gives

$$\mathbb{E}[r^j] = e^{-j/(2\sigma^2)}\, e^{j^2/(2\sigma^2)} = e^{(j^2 - j)/(2\sigma^2)}. \tag{C.19}$$

   For example, at $j = 2$ and $\sigma = 1$ this is $e^{-1} \cdot e^2 = e$, the factor in the last row of Table C.3.
5. **Assemble.** Putting each average back into the sum gives A_α of Equation C.14, and dividing its logarithm by $\alpha - 1$ gives the curve.

The small-q form comes from looking at which terms matter. Without the exponential factors, the terms add up to $(1 - q + q)^\alpha = 1$. The factors for $j = 0$ and $j = 1$ are $e^0 = 1$, so those two terms cost nothing, and

$$A_\alpha = 1 + \sum_{j=2}^{\alpha} \binom{\alpha}{j} (1 - q)^{\alpha - j} q^j \big(e^{(j^2 - j)/(2\sigma^2)} - 1\big). \tag{C.20}$$

For small q the $j = 2$ term dominates, because every later term carries q^3 or a higher power. That term is about $\frac{\alpha(\alpha-1)}{2} q^2 (e^{1/\sigma^2} - 1)$, so A_α is 1 plus a small number. The logarithm of 1 plus a small number is close to that small number, so dividing by $\alpha - 1$ gives Equation C.15. Its second form follows because $e^{1/\sigma^2} - 1$ is close to $1/\sigma^2$ when σ is large. Both forms are approximations, not bounds. You will also see the curve quoted as $q^2\alpha/\sigma^2$, which is the leading term of the upper bound Abadi et al. (2016) proved for small q, and about twice Equation C.15 for large σ (Section 33.6).

Last, the direction. The guarantee must hold with either dataset first, so the curve is the larger of $D_\alpha(P_q \| P_0)$ and $D_\alpha(P_0 \| P_q)$. The first one puts the dataset with the record first, and it is called the **remove** direction. It is always the larger for the subsampled Gaussian, which is why accountants compute only it. Appendix Section L.1 derives this step by step, and the script checks it below.

C.4.5. Checking it

The curve can be computed in two independent ways, and the script does both: by the binomial sum, and by averaging $(1 - q + qr)^\alpha$ numerically on a fine grid of outputs. At $\alpha = 2$, 8 and 32 the two agree to all seven printed digits: 1.718134×10^{-4}, 8.936439×10^{-4} and 11.24628. A Monte

Carlo average of r^2 over two million normal draws gives 2.7084, against the exact $e = 2.7183$. The other direction is smaller at each of the three orders: 1.6022×10^{-4}, 5.7239×10^{-4} and 1.6923×10^{-3}.

Table C.4 compares the exact curve with its small-q form at the running example's q and σ.

Table C.4.: The RDP curve of one DP-SGD step with $q = 0.01$, $\sigma = 1$, against its small-q form and against no sampling.

α	2	4	8	16	32
Exact Equation C.14	1.7181×10^{-4}	3.6315×10^{-4}	8.9364×10^{-4}	3.0879	11.246
Small-q form Equation C.15	1.7183×10^{-4}	3.4366×10^{-4}	6.8731×10^{-4}	1.3746×10^{-3}	2.7493×10^{-3}
Exact / small-q	1.00	1.06	1.30	2246.32	4090.67
No sampling, $\alpha/(2\sigma^2)$	1	2	4	8	16

Up to $\alpha = 8$ the approximation is within 30%, but then it fails abruptly, and at $\alpha = 16$ it is 2246 times too small. Figure C.3 shows why. The terms with large j grow like $q^j e^{j^2/(2\sigma^2)}$, and the last one overtakes the $j = 2$ term near $\alpha = 2\sigma^2 \ln(1/q)$ (Section 33.6). So the exact curve follows the small-q line, then climbs steeply near $\alpha = 2\sigma^2 \ln(1/q) = 9.2$ and runs toward the unsampled line. At high orders the divergence looks at the rare outputs where the record was clearly used, and there sampling saves only about $\ln(1/q)$. With more noise the approximation holds further: at $\alpha = 8$ the exact curve is 1.019 times the small-q form for $\sigma = 2$ and 1.004 times for $\sigma = 4$.

C.4.6. Recipe and pitfalls

For integer orders, compute Equation C.14 with logarithms, since the terms span many orders of magnitude. For orders between the integers, average $(1 - q + qr)^\alpha$ numerically, as the chapters' accountants do. Use Equation C.15 only for estimates at orders below $2\sigma^2 \ln(1/q)$, never as the curve itself.

The curve assumes Poisson sampling and the add/remove relation, like Section C.3. It also assumes the sensitivity is exactly the clipping norm. If something in your code makes the sensitivity $2C$, such as microbatches or the replace-one relation, give the accountant the noise multiplier $\sigma/2$ instead of σ, because the ratio is then $2C/(\sigma C) = 1/(\sigma/2)$.

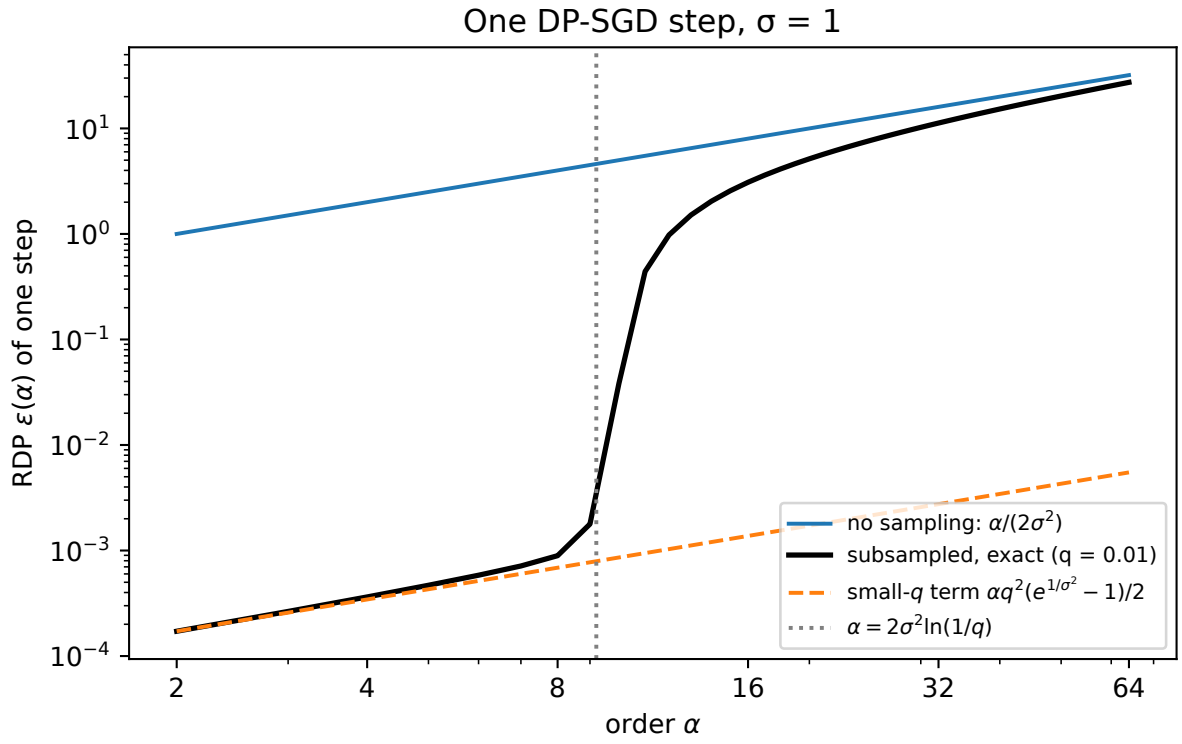

Figure C.3.: The RDP curve of one DP-SGD step against the order α, on log scales, for $q = 0.01$ and $\sigma = 1$: exact (black), the small-q term $\alpha q^2(e^{1/\sigma^2} - 1)/2$ (dashed) and no sampling, $\alpha/(2\sigma^2)$. The dotted line marks $\alpha = 2\sigma^2 \ln(1/q)$, where the small-$q$ form breaks.

C.5. From batch, noise and epochs to the final ε

C.5.1. The question

You train with n records, an expected batch of B, noise multiplier σ and a number of epochs E. What (ε, δ) do you report? And the reverse question, which a practitioner asks more often: for a target ε, how much noise do you need?

C.5.2. The answer

The sampling rate is $q = B/n$, and one epoch is $n/B = 1/q$ steps, so there are $T = E\,n/B$ steps in all. The RDP accountant multiplies the per-step curve by T and converts it to (ε, δ) at the best order, using Mironov's conversion:

$$\varepsilon = \min_{\alpha} \Big[T\,\varepsilon_{q,\sigma}(\alpha) + \frac{\ln(1/\delta)}{\alpha - 1} \Big]. \tag{C.21}$$

The second term is the price of converting, which this page calls the conversion **toll**. The minimum runs over a grid of orders. The book's grid has the orders from 1.1 to 10.9 in steps of 0.1, followed by whole orders up to 512. It takes $\varepsilon_{q,\sigma}(\alpha)$ from Equation C.14 at whole orders and from the numerical average between them.

C.5.3. A worked example

The running example has $n = 10{,}000$ records and $B = 100$, so the sampling rate is $q = 0.01$. Each of its 100 epochs has 100 steps, so $T = 10{,}000$. The script finds that the best order is $\alpha = 4.3$, where one step costs $\varepsilon_{q,\sigma}(4.3) = 3.9400 \times 10^{-4}$. Multiplying by the 10,000 steps gives a composed curve of 3.9400 at that order. The conversion then adds $\ln(10^5)/(4.3 - 1) = 11.5129/3.3 = 3.4888$. So $\varepsilon = 3.9400 + 3.4888 = 7.4287$, which you would report as $(7.43, 10^{-5})$. Table C.5 gives ε after each number of epochs.

Table C.5.: The ε at $\delta = 10^{-5}$ of the running example ($q = 0.01$, $\sigma = 1$) after each number of epochs. "Every record in every step" composes unsampled Gaussian steps exactly (Section C.2); the RDP columns use Mironov's conversion, Equation C.21, and the improved conversion of Balle et al. (2020).

Epochs	Steps T	Every record in every step	RDP, Mironov	Best order for Mironov	RDP, improved
1	100	91.8	1.61	8.9	1.21
5	500	344.5	2.07	8.3	1.65
10	1,000	633.9	2.54	7.9	2.10
20	2,000	1189.8	3.34	7.2	2.87
50	5,000	2800.6	5.18	5.5	4.59
100	10,000	5425.5	7.43	4.3	6.71

Sampling turns thousands into single digits. The **improved conversion** of From Rényi DP to (ε, δ) subtracts two small corrections from the conversion term $\ln(1/\delta)/(\alpha - 1)$ and gives 6.71 at 100

epochs, the number the chapters report. A **privacy loss distribution (PLD)** accountant tracks the whole distribution of the loss instead of one curve, and Section 34.8 reports 6.2377 for the same run as its upper bound.

C.5.4. Why it works

1. **The curves add.** By the definition, the Rényi divergence of the whole run is set by the average of the α-th power of its likelihood ratio, and step 2 below writes that as the average of $e^{(\alpha-1)L}$ for the privacy loss L. The run's likelihood ratio is the product of the steps' ratios, so $e^{(\alpha-1)L}$ is a product of per-step factors. Average this product one step at a time, starting from the last. With everything before it held fixed, the last step is a subsampled Gaussian step, so its factor averages to at most $e^{(\alpha-1)\varepsilon_{q,\sigma}(\alpha)}$, whatever the earlier steps did. That number is a constant, so it comes out of the average, and the next step is treated the same way. After T steps the average is at most $e^{(\alpha-1)T\varepsilon_{q,\sigma}(\alpha)}$, so the composed curve is $T\varepsilon_{q,\sigma}(\alpha)$, even though each step depends on the earlier ones (Section B.4).
2. **The average of a power is the Rényi divergence.** Let L be the privacy loss, $\ln(P(y)/Q(y))$ with y drawn from P, where P is the output distribution on the dataset with the record. Then
$$\mathbb{E}_{y\sim P}\big[e^{(\alpha-1)L}\big] = \int P\Big(\frac{P}{Q}\Big)^{\alpha-1}\mathrm{d}y = \int Q\Big(\frac{P}{Q}\Big)^{\alpha}\mathrm{d}y = e^{(\alpha-1)D_\alpha(P\|Q)}. \tag{C.22}$$
3. **Markov's inequality bounds the chance of a large loss.** For a variable that cannot be negative, the chance that it is at least a is at most its average divided by a. Apply it to $e^{(\alpha-1)L}$ at the level $a = e^{(\alpha-1)\varepsilon}$. With step 2 and the composed curve of step 1, this gives
$$\Pr[L > \varepsilon] \le e^{(\alpha-1)(T\varepsilon_{q,\sigma}(\alpha)-\varepsilon)}. \tag{C.23}$$
4. **A rare large loss is all that δ has to cover.** Split any set of outputs S into the outputs where the loss is at most ε and those where it is larger. On the first part, P is at most e^{ε} times Q, by the definition of L. The second part has probability at most the chance of a loss above ε. Adding the two parts,
$$P(S) \le e^{\varepsilon}Q(S) + \Pr[L > \varepsilon], \tag{C.24}$$
so the run is (ε,δ)-DP as soon as the chance of a loss above ε is at most δ.
5. **Solve for ε.** Set the bound of step 3 equal to δ, take logarithms and divide by $\alpha-1$. This gives
$$\varepsilon = T\varepsilon_{q,\sigma}(\alpha) + \frac{\ln(1/\delta)}{\alpha-1}. \tag{C.25}$$
It holds at every order, so the smallest value over the orders also holds, which is Equation C.21. Appendix Section D.3 derives the conversion, and its improved form, in more detail.

The minimum sits between the extremes because the two terms pull in opposite directions. Figure C.4 shows them for the running example. The composed curve $T\varepsilon_{q,\sigma}(\alpha)$ rises with the order, slowly at first and then steeply past $\alpha \approx 8$, where the curve leaves its small-q form. The conversion toll $\ln(1/\delta)/(\alpha-1)$ falls. Their sum is smallest at $\alpha = 4.3$, where it is 7.43. A longer run makes the first term larger and pushes the best order down, from 8.9 after one epoch to 4.3 after 100.

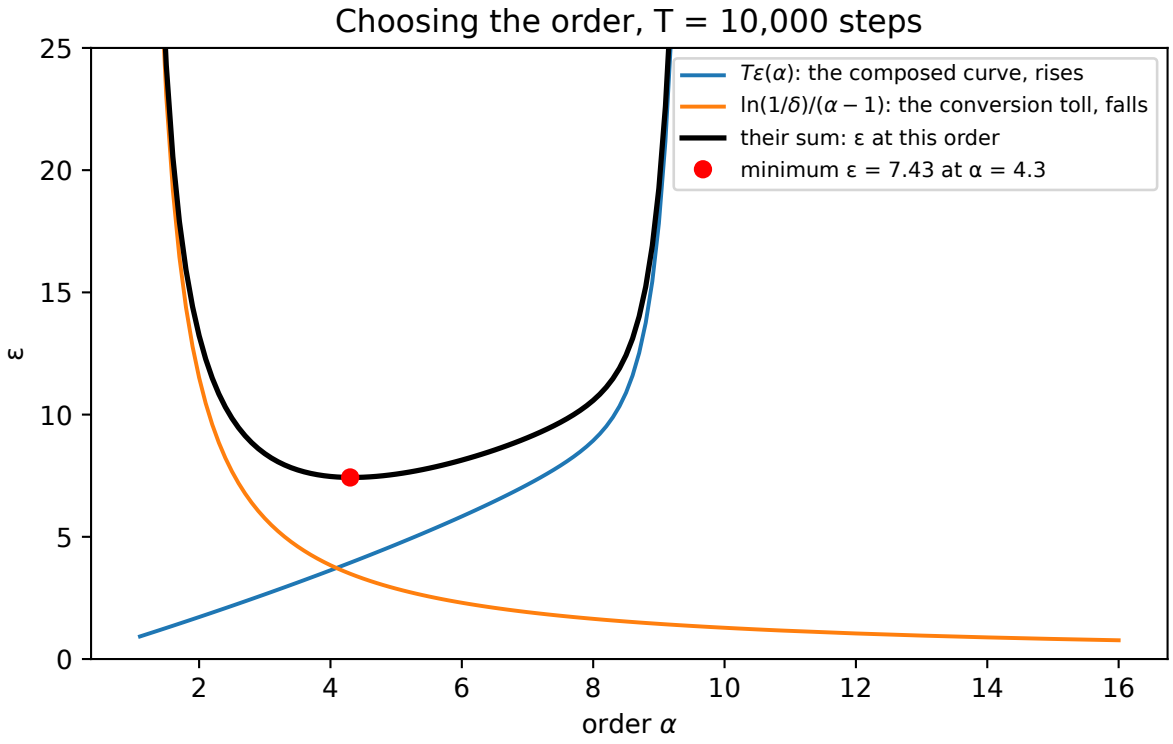

Figure C.4.: The two terms of Equation C.21 for the running example after $T = 10{,}000$ steps, against the order α: the composed curve $T\varepsilon(\alpha)$, the conversion toll $\ln(1/\delta)/(\alpha - 1)$, and their sum, with its minimum, $\varepsilon = 7.43$ at $\alpha = 4.3$, marked.

C.5.5. Checking it

The script's accountant reproduces the chapters' numbers to every printed digit: 7.4287 with Mironov's conversion and 6.71 with the improved one, as in Section 33.7. Restricting the grid to whole orders, where Equation C.14 is exact, costs little, giving 7.4692 at $\alpha = 4$. Figure C.5 plots ε against the number of epochs. Without sampling it grows nearly in proportion to the number of steps, while the RDP accountant grows slowly. The PLD upper bounds from Section 34.8, marked as crosses, sit below the RDP curves. A PLD bound is proved for every pair of neighbouring datasets, like the RDP bound, and it is the tightest such number for this run. Both are therefore valid guarantees, and with the improved conversion RDP overstates ε by about 8% at 100 epochs, since $6.71/6.24 = 1.08$.

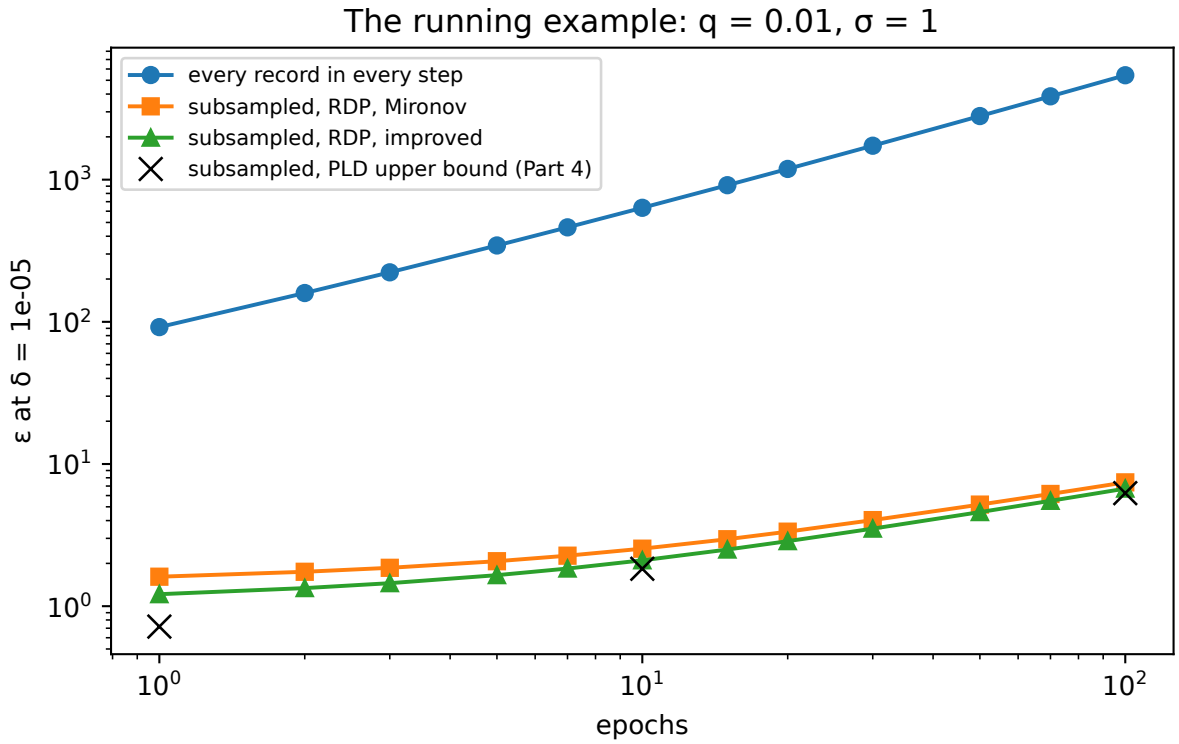

Figure C.5.: The ε at $\delta = 10^{-5}$ of the running example against the number of epochs, on log scales: every record in every step (exact Gaussian composition), the subsampled run with the RDP accountant under Mironov's and the improved conversion, and the PLD upper bound that Part 4's numerical accountant reports (crosses).

C.5.6. Recipe and pitfalls

To get ε from a training configuration, follow these steps.

1. Compute the sampling rate q, which is B/n, and the number of steps $T = E\,n/B$.
2. Compute the per-step curve $\varepsilon_{q,\sigma}(\alpha)$ on a grid of orders, with Equation C.14 at whole orders.
3. Multiply the curve by T.

4. At each order add the toll $\ln(1/\delta)/(\alpha - 1)$, or use the improved conversion, and report the smallest value with its δ.

To go the other way, from a target ε to a noise multiplier, search over σ. More noise never makes a step less private, so ε falls as σ grows, and bisection finds the smallest σ that meets the target. Table C.6 shows the result for the running example's q and T. The improved column matches Table 39.2 of the DP-SGD chapter.

Table C.6.: The noise multiplier needed for each target ε with $q = 0.01$ and $T = 10{,}000$ steps, found by bisection on σ.

Target ε at $\delta = 10^{-5}$	1	2	4	8
σ, Mironov's conversion	4.974	2.617	1.484	0.962
σ, improved conversion	4.126	2.278	1.358	0.917

Most mistakes in reported numbers come from a mismatch between the accountant and the code, not from the accountant itself. Five are common.

- **Sampling must be Poisson, or the analysis must match the sampler.** The whole saving rests on the independent coin of Section C.3. If the code draws batches of exactly B records, a new record pushes another one out, so the sum has sensitivity $2C$ and the accountant needs $\sigma/2$. For the running example that gives $\varepsilon = 47.42$ instead of 6.71, with the improved conversion. Shuffling and cutting into batches has no simple amplification at all (Section 33.4).
- **State the neighbouring relation.** The numbers here are for adding or removing one record. A replace-one guarantee is a different statement and needs twice the sensitivity.
- **The clipping norm is not a privacy parameter.** Changing C changes accuracy, not ε, because the noise scales with it. A paper that reports C in place of σ, q and T has not said how private the model is.
- **Report ε with δ.** The same run is $(5.89, 10^{-3})$, $(7.43, 10^{-5})$ and $(8.71, 10^{-7})$ under Mironov's conversion. An ε without its δ means nothing, and δ should be well below $1/n = 10^{-4}$. A mechanism that published one random record in full would satisfy $\delta = 1/n$, so a larger δ allows a real leak.
- **Count every run, including tuning.** Each training run that looks at the private data spends budget, including the runs you discard. Choosing the best of several runs by a score computed on private data leaks more than one run does (Section 40.3, and Section M.3 for the derivation).

C.6. Code

The script `apx_core_dp_sgd.py` computes every number on this page and draws its figures. It rewrites the accountant in a few dozen lines rather than importing the chapters' code, so it is an independent check. It clips random gradients to test the sensitivity, solves the exact Gaussian curve with logarithms, checks amplification on a Laplace count, computes the subsampled Gaussian's curve by the binomial sum and by numerical averaging, and converts it to ε and back to σ. From the repository root, run:

```
uv run python code/appendix-derivations/apx_core_dp_sgd.py
```

The script is code/appendix-derivations/apx_core_dp_sgd.py, and tests/test_appendix_core_dp_sgd.py checks that its output still matches this page. Table C.7 summarizes the output with the default seed.

Table C.7.: The script's output with the default seed.

Check	Result
Clipped sum, 20,000 random datasets	Largest change: $1.0000\,C$ (add/remove), $2.0000\,C$ (replace-one)
Unsampled Gaussian steps, $\sigma = 1$	$\varepsilon = 4.38$, 91.82 and 5425.51 after 1, 100 and 10,000 steps
Full batch, $\sigma = 10.8$, 100 steps	$\varepsilon = 4.005$, the chapter's target of 4
Amplification, Laplace count, $\varepsilon = 1$, $q = 0.01$	Largest log ratio 0.017037, equal to the formula; other direction 0.006341
Subsampled Gaussian, $q = 0.01$, $\sigma = 1$	Binomial sum and numerical average agree to seven digits; remove direction larger
Small-q form	Within 30% up to $\alpha = 8$; 2246 times too small at $\alpha = 16$
Running example, 100 epochs	$\varepsilon = 7.43$ (Mironov, $\alpha = 4.3$), 6.71 (improved)
Noise for $\varepsilon = 1$	$\sigma = 4.974$ (Mironov), 4.126 (improved)
Fixed-size batches	$\varepsilon = 47.42$ against 6.71 for Poisson

The main thing to take from it is how much each idea is worth on the running example. Clipping and the noise make one step cost $\varepsilon = 4.38$, so 10,000 steps without sampling cost 5425.51. Sampling, measured by the Rényi curve and converted once, brings the same run down to 7.43, and the improved conversion to 6.71. Two independent ways of computing the curve agree to seven digits, so the remaining gap to the PLD accountant comes from the conversion and from keeping only a curve, not from numerical error.

D. What ε means, and converting between definitions

A **mechanism** M is a randomized algorithm: it takes a dataset and returns a random output. Two datasets D and D' are **neighbours**, written $D \sim D'$, when one is the other with one person's record added or removed. The definition of privacy has two parameters, a multiplicative limit ε and a small additive slack δ. The mechanism is (ε, δ)**-differentially private** when, for every pair of neighbours and every set S of outputs,

$$\Pr[M(D) \in S] \leq e^{\varepsilon} \Pr[M(D') \in S] + \delta. \tag{D.1}$$

The **privacy loss** of an output y is the log of how much more likely y is when the data are D than when they are D'. Write $p(y)$ and $q(y)$ for the probability (or density) of y under $M(D)$ and $M(D')$. Then the privacy loss L is

$$L(y) = \ln \frac{p(y)}{q(y)}. \tag{D.2}$$

Pure differential privacy (DP), the case $\delta = 0$, is written ε-DP. It is the same as asking that $|L(y)| \leq \varepsilon$ for every output. One direction holds because a single output is itself a set of outputs, and the other because a set's probability is the sum over its outputs. The absolute value appears because neighbours come in both orders, so the definition also holds with D and D' swapped. Section A.1 builds these definitions slowly, with examples.

This appendix answers two practical questions. The first is what a number like $\varepsilon = 1$ promises. The first two sections read the definition as a limit on any test an attacker can run, and as a limit on how far an attacker's belief can move. The second question is how to report (ε, δ) when your accountant tracks something else. An **accountant** is the code that adds up the privacy cost of many releases from the same data, which is called composition. Accountants track Rényi differential privacy (RDP), zero-concentrated differential privacy (zCDP) or Gaussian differential privacy (GDP), because those compose more simply, and the last three sections convert each of them to (ε, δ). Table D.1 lists the five results and the chapter sections that state or use them.

Table D.1.: The results of this appendix and the chapter sections that state or use them.

Section	What it derives	Stated or used in
Section D.1	Every test has $\text{FPR} + e^{\varepsilon}\,\text{FNR} \geq 1 - \delta$	Section 18.5, Section 18.6, Section 32.3
Section D.2	Posterior odds are at most e^{ε} times the prior odds	Section 18.7
Section D.3	RDP gives $\varepsilon = \varepsilon(\alpha) + \ln(1/\delta)/(\alpha - 1)$	Section 29.8, Section 30.3, Section 30.4

Section	What it derives	Stated or used in
Section D.4	ρ-zCDP gives $\varepsilon = \rho + 2\sqrt{\rho \ln(1/\delta)}$	Section 31.3, Section 31.5
Section D.5	μ-GDP: the curve G_μ and its exact (ε, δ)	Section 32.4, Section 32.5, Section 32.6, Section 20.4

A running example. Most sections below use one mechanism, the Gaussian mechanism. It adds normal noise to a query, and the noise has standard deviation σ. Here the query's **sensitivity** Δ is the most its value can move between neighbours, measured as a Euclidean distance when the query returns a vector.

Dividing the output by σ, and then subtracting the query's value on D, changes nothing about privacy, because you can undo both steps. After them, the output on D is a unit normal centred at 0, and the output on D' is a unit normal centred a distance $\mu = \Delta/\sigma$ away, for the neighbours whose query values are the full sensitivity apart. A smaller shift is harder to detect, so this pair is the worst one (Section D.5 shows why). So the two output distributions are

$$P = \mathcal{N}(0, 1) \text{ on } D, \qquad Q = \mathcal{N}(\mu, 1) \text{ on } D'. \tag{D.3}$$

Taking the log of the ratio of the two normal densities, the y^2 terms cancel and the privacy loss is a straight line in the output,

$$L(y) = -\frac{y^2}{2} + \frac{(y-\mu)^2}{2} = \frac{\mu^2}{2} - \mu y. \tag{D.4}$$

When y is drawn from the distribution P, so that y is standard normal, the loss is a shifted and scaled normal variable, which is again normal. It is therefore normal with mean $\mu^2/2$ and variance μ^2. Throughout, the standard normal distribution function Φ gives the probability that a standard normal variable Z is at most x,

$$\Phi(x) = \Pr[Z \le x], \tag{D.5}$$

and Φ^{-1} is its inverse. Unless a section says otherwise, the numbers use $\delta = 10^{-5}$, and logarithms are natural.

D.1. What ε means for any test

D.1.1. The question

An attacker sees the output and must guess whether the data were D or D', for example whether your record was used. It may know everything else and compute anything. What does $\varepsilon = 1$ stop it from doing?

D.1.2. The answer

Any guessing rule can be written as a set S of outputs: the attacker says "D'" when the output lands in S, and "D" otherwise. It can be wrong in two ways. Its **false positive rate (FPR)** is how often it says "D'" when the data were D, so $\text{FPR} = \Pr[M(D) \in S]$. Its **false negative rate (FNR)** is how often it says "D" when the data were D', so $\text{FNR} = \Pr[M(D') \notin S]$. If M is (ε, δ)-DP, then every test, against every pair of neighbours, satisfies both

$$\text{FPR} + e^{\varepsilon}\,\text{FNR} \geq 1 - \delta \qquad \text{and} \qquad e^{\varepsilon}\,\text{FPR} + \text{FNR} \geq 1 - \delta. \tag{D.6}$$

The chapter on the definition (Section 18.5) writes α and β for the two error rates. This page needs α for a Rényi order, so it writes them FPR and FNR. There are two inequalities because the definition holds in both orders of the pair.

D.1.3. A worked example

Take $\varepsilon = 1$ and $\delta = 0$, and an attacker who accepts 5% false positives. The first inequality says $0.05 + e\,\text{FNR} \geq 1$, so $\text{FNR} \geq 0.95/e = 0.3495$. The second says $e \times 0.05 + \text{FNR} \geq 1$, so $\text{FNR} \geq 1 - 0.1359 = 0.8641$. Both must hold, so the attacker misses at least **86.4%** of the time, and it catches D' at most 13.6% of the time.

Notice which inequality did the work. The first one alone would allow a miss rate as low as 35%. At a low FPR the second one is much stronger. Low FPR is exactly where attackers want to operate, because an attack that rarely raises a false alarm is one whose accusations can be trusted. For comparison, a coin that says "D'" 5% of the time, ignoring the output, catches D' 5% of the time. So $\varepsilon = 1$ lets the best attacker catch D' at most $0.136/0.05 = e \approx 2.7$ times as often as that coin.

Other false positive rates give other limits. At $\text{FPR} = 0.01$ the attacker misses at least 0.9728 of the time, and at $\text{FPR} = 0.25$ at least 0.3204. With $\delta = 10^{-5}$ the limit at $\text{FPR} = 0.05$ drops only to 0.864076, because δ lowers each of the two bounds by exactly δ.

D.1.4. Why it works

Each inequality is the definition applied to one set. The proof also uses one rule twice: the probability that the output is outside S is one minus the probability that it is inside, so $\Pr[M(D) \notin S] = 1 - \text{FPR}$ and $\Pr[M(D') \in S] = 1 - \text{FNR}$.

1. **The first inequality.** Apply the definition to the set of outputs where the test says "D", the complement of S. It gives $\Pr[M(D) \notin S] \leq e^{\varepsilon}\Pr[M(D') \notin S] + \delta$. The left side is $1 - \text{FPR}$ and the probability on the right is FNR. So $1 - \text{FPR} \leq e^{\varepsilon}\,\text{FNR} + \delta$, which rearranges to the first inequality.
2. **The second inequality.** If D and D' are neighbours, so are D' and D, so the definition also holds with the two datasets swapped. Apply it in that order to S itself: $\Pr[M(D') \in S] \leq e^{\varepsilon}\Pr[M(D) \in S] + \delta$. The left side is $1 - \text{FNR}$ and the probability on the right is FPR, which gives the second inequality.

3. **Tests that flip a coin.** An attacker may also randomize, saying "D'" with some probability that depends on the output. In that case, think of its coin U as part of the output. Releasing $(M(D), U)$, with U independent of the data, is still (ε, δ)-DP, because for each value of U the inequality holds for the matching slice of the set, and averaging both sides over U keeps it. So steps 1 and 2 apply to randomized tests too.

A tiny case shows that the bound is reached. In randomized response, one person reports a bit: the true bit with probability $e^{\varepsilon}/(1+e^{\varepsilon})$, the flipped bit otherwise. Each report is exactly e^{ε} times as likely under one value of the bit as under the other, so the mechanism is ε-DP. Let the bit be 1 under D and 0 under D', and let the test say "D'" when the report is 0. It errs when the report is flipped, in either world, so $\mathrm{FPR} = \mathrm{FNR} = 1/(1+e^{\varepsilon})$, which is 0.2689 at $\varepsilon = 1$. Then

$$\mathrm{FPR} + e^{\varepsilon}\,\mathrm{FNR} = \frac{1+e^{\varepsilon}}{1+e^{\varepsilon}} = 1, \tag{D.7}$$

so the first inequality holds with equality, and by symmetry so does the second. So randomized response meets both bounds at once, and neither inequality can be strengthened if it is to hold for every ε-DP mechanism.

D.1.5. Checking it

The script for this page (see Section D.7) lists every possible test against three people who each run randomized response with $\varepsilon = \ln 3$, for neighbours that differ in the first person's bit. There are 8 report vectors, and a test is any subset of them, so there are $2^8 = 256$ tests. The smallest slack, the amount by which a test clears the tighter of the two inequalities, is exactly 0: no test breaks the bound, and several tests meet it.

Figure D.1 draws the forbidden region, with the FPR across and the FNR up. Each pair of lines is the lower edge of where a test can be, and a smaller ε pushes that edge up towards the diagonal $\mathrm{FPR} + \mathrm{FNR} = 1$, which is what a test that ignores the output achieves. The dots are randomized response, which sits on the corner of each region.

D.1.6. Recipe and pitfalls

To turn a guarantee into an attack limit, pick the false positive rate you care about. The attacker's true positive rate (TPR) is the fraction of the time it correctly says "D'", so $\mathrm{TPR} = 1 - \mathrm{FNR}$. The second inequality caps it at

$$\mathrm{TPR} \le e^{\varepsilon}\,\mathrm{FPR} + \delta. \tag{D.8}$$

Auditing, which tests a privacy claim by attacking the system, runs this in reverse. If an attack measures a TPR and an FPR against a trained model, the mechanism's ε must be at least $\ln\left((\mathrm{TPR} - \delta)/\mathrm{FPR}\right)$.

Three things go wrong in practice. The bound is for the worst mechanism with this ε, and most mechanisms sit strictly inside it, so a weak attack says little about how private the mechanism really is. At very small FPR the δ term dominates, since at $\mathrm{FPR} = 0$ the bound still allows a TPR of δ, so δ must be tiny. And the guarantee covers only the mechanism's own kind of neighbours. A guarantee for neighbours that add or remove one record says less about neighbours that replace one record with another. Section 18.5 proves the converse, that the two inequalities for all tests are the same as (ε, δ)-DP, and Section 18.6 turns them into a bound on membership advantage.

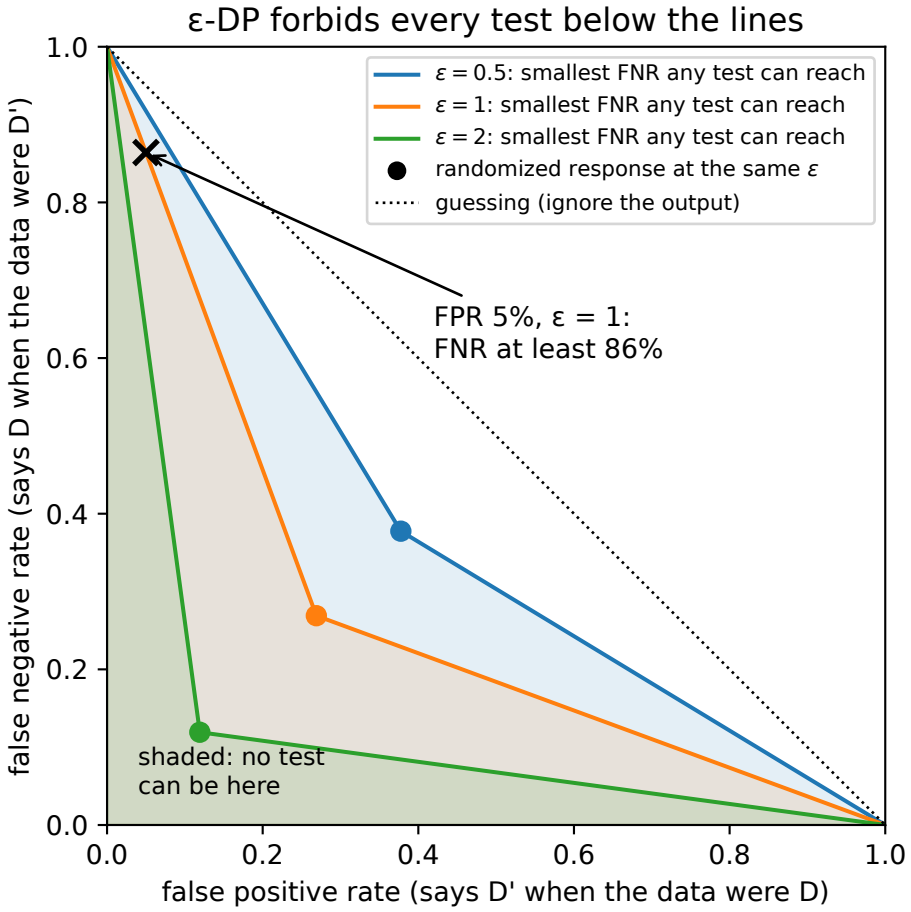

Figure D.1.: The false positive and false negative rates that tests can reach under ε-DP with $\delta = 0$, for $\varepsilon = 0.5$, 1 and 2. The shaded area below each pair of lines is forbidden for every test. The dots mark randomized response at the same ε, the cross marks the worked example at 5% false positives, and the dotted diagonal is guessing without looking at the output.

D.2. What ε means for an attacker's belief

D.2.1. The question

People often ask a different question: "after the release, how sure can someone be about my record?" Take the strongest attacker. It knows every record except yours, so it knows the data are one of two neighbours, D or D', which differ only in your record. Before the release it believes D with some prior probability π. How large can its belief be afterwards?

D.2.2. The answer

The **odds** of D are its probability divided by the probability of D', so the prior odds are $\pi/(1-\pi)$. If M is ε-DP, then after any output y the posterior odds are within a factor e^{ε} of the prior odds, and the posterior probability is capped:

$$\frac{\Pr[D \mid y]}{\Pr[D' \mid y]} \le e^{\varepsilon}\,\frac{\pi}{1-\pi}, \qquad \Pr[D \mid y] \le \frac{e^{\varepsilon}\pi}{e^{\varepsilon}\pi + 1 - \pi}. \tag{D.9}$$

The same argument with $e^{-\varepsilon}$ gives the matching lower limits.

D.2.3. A worked example

Take $\varepsilon = 1$ and a prior of 1%, so the prior odds are $0.01/0.99 = 0.010101$. The output can multiply them by at most e, which brings them to 0.027457. Any odds o turn back into a probability as $o/(1+o)$, so the posterior is at most $0.027457/1.027457 = 0.0267$. In words, a suspicion of 1% can rise to at most **2.7%**. With a prior of 50% the prior odds are 1, so the posterior odds are at most e and the posterior is at most $e/(1+e) = 0.7311$, or **73%**.

Table D.2 gives the cap for other values. Small priors stay small unless ε is large: at $\varepsilon = 4$ a prior of 1% can rise to 36%.

Table D.2.: The largest posterior probability of D after one output of an ε-DP mechanism, from Equation D.9.

ε	Prior 0.01	Prior 0.5
0.5	0.0164	0.6225
1	0.0267	0.7311
2	0.0695	0.8808
4	0.3555	0.9820

D.2.4. Why it works

The argument is Bayes' rule written in odds. A table with the two hypotheses as rows shows it (Table D.3). Each row multiplies the prior by the chance of seeing y under that hypothesis, and the posterior divides each product by their sum c.

Table D.3.: Bayes' rule for two hypotheses, where $c = \pi\, p(y) + (1-\pi)\, q(y)$ is the total chance of seeing y.

Hypothesis	Prior	Chance of y	Prior × chance	Posterior
D	π	$p(y)$	$\pi\, p(y)$	$\pi\, p(y)/c$
D'	$1-\pi$	$q(y)$	$(1-\pi)\, q(y)$	$(1-\pi)\, q(y)/c$

1. **Divide the two posteriors.** The sum c is the same in both rows, so it cancels in the ratio. What is left is the prior odds times the ratio of the chances, which is $e^{L(y)}$:

$$\frac{\Pr[D \mid y]}{\Pr[D' \mid y]} = \frac{\pi}{1-\pi} \cdot \frac{p(y)}{q(y)} = \frac{\pi}{1-\pi}\, e^{L(y)}. \tag{D.10}$$

2. **Use pure DP.** Under ε-DP, $L(y) \le \varepsilon$ for every output, so $e^{L(y)} \le e^{\varepsilon}$. This gives the odds bound of Equation D.9.
3. **Turn odds into a probability.** The map $o \mapsto o/(1+o)$ grows with o, so the largest odds give the largest probability. Put in $o = e^{\varepsilon}\pi/(1-\pi)$ and multiply top and bottom by $1-\pi$ to get the probability bound.

With numbers, take randomized response at $\varepsilon = 1$, your bit 1 under D, and a report of 1. Then $p(y) = e/(1+e) = 0.7311$ and $q(y) = 0.2689$. With a prior of 1%, the products are $0.01 \times 0.7311 = 0.007311$ and $0.99 \times 0.2689 = 0.266252$. Their sum is $c = 0.273563$, so the posterior is $0.007311/0.273563 = 0.0267$, exactly the cap.

With δ. Under (ε, δ)-DP the privacy loss is not bounded everywhere, so the bound cannot hold for every output. It is tempting to say that it holds except on outputs of total probability δ, but that is false in general. For example, Section D.5 shows that the Gaussian running example with $\mu = 1$ is $(4.3772, 10^{-5})$-DP. Yet, when the data are D, its privacy loss exceeds 4.3772 with probability 5.284×10^{-5}, more than five times δ.

What does hold is the same bound at a larger level $\varepsilon' > \varepsilon$, except on a set of outputs whose probability is a small multiple of δ. To prove it, let B be the set of outputs whose loss exceeds ε', and write $\Pr_P[B]$ and $\Pr_Q[B]$ for its probability under D and D'.

1. The definition, applied to B, says $\Pr_P[B] - e^{\varepsilon} \Pr_Q[B] \le \delta$.
2. On B each output has $q(y) < e^{-\varepsilon'} p(y)$, because its loss exceeds ε'. Adding over B gives $\Pr_Q[B] < e^{-\varepsilon'} \Pr_P[B]$.
3. Put step 2 into step 1. Since $\Pr_Q[B]$ is less than $e^{-\varepsilon'} \Pr_P[B]$, replacing it by $e^{-\varepsilon'} \Pr_P[B]$ makes the left side smaller, and the left side was already at most δ. So $\Pr_P[B]\,(1 - e^{\varepsilon - \varepsilon'}) < \delta$, and therefore

$$\Pr_P[B] < \frac{\delta}{1 - e^{\varepsilon - \varepsilon'}}. \tag{D.11}$$

Outside B the loss is at most ε', so steps 1 to 3 of the pure case go through with ε' in place of ε. So the posterior bound holds at level ε', except on outputs whose probability under D is at most $\delta/(1 - e^{\varepsilon - \varepsilon'})$. With $\varepsilon' = \varepsilon + 1$ that exception is $\delta/(1 - e^{-1}) = 1.582 \times 10^{-5}$. For the Gaussian example the true probability of a loss above $4.3772 + 1$ is 5.381×10^{-7}, well inside the bound.

D.2.5. Checking it

The script draws 2,000,000 people whose bit is 1 with probability 1% and runs randomized response at $\varepsilon = 1$. Among the reports of 1, the fraction that came from a true 1 is 0.0267, the cap of Equation D.9. Randomized response reaches the cap, so the cap cannot be lowered.

Figure D.2 shows the mechanism of the proof. In log odds, the output adds $L(y)$ to the prior's log odds, so ε-DP keeps the posterior inside a band of half-width ε around the diagonal. In probabilities the same band bends. The reason is that turning log odds back into a probability squeezes large log odds towards 1 and very negative ones towards 0, while leaving the middle stretched.

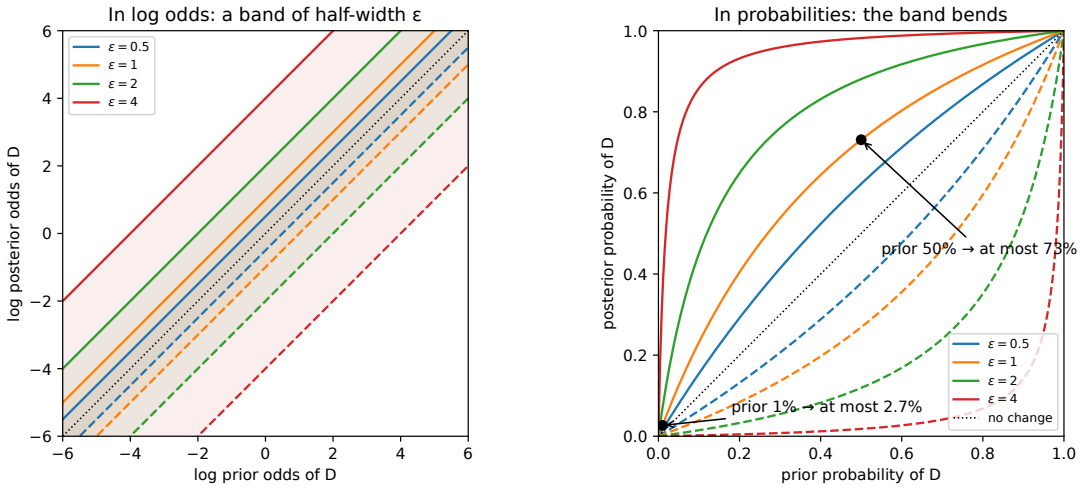

Figure D.2.: The largest (solid) and smallest (dashed) posterior of D after one output of an ε-DP mechanism, for $\varepsilon = 0.5$, 1, 2 and 4. Left: on the scale of log odds the posterior stays within a band of half-width ε around the prior (dotted diagonal). Right: the same band on the scale of probabilities, with the two worked examples at $\varepsilon = 1$ marked.

D.2.6. Recipe and pitfalls

To explain ε to someone who thinks in probabilities, ask for their prior π and give them the cap $e^{\varepsilon}\pi/(e^{\varepsilon}\pi + 1 - \pi)$. The guarantee limits the *change* in belief, not the belief itself. An attacker who is already 99% sure stays about that sure, and DP promises only that the output does not make it much surer. The bound is per person and per release. For correlated records, such as a household, first work out the guarantee for the whole group, and for repeated releases first add up their privacy cost. With $\delta > 0$, quote the bound at a larger level ε' together with the exception of Equation D.11. Section 18.7 states the result and discusses weaker attackers.

D.3. From Rényi DP to (ε, δ)

D.3.1. The question

Your accountant tracks RDP because RDP composes by adding. At the end it hands you a curve, one number for each order α (defined next), and you must report (ε, δ). How do you turn the curve into ε?

The **Rényi divergence** of order $\alpha > 1$ is a log average of a power of the likelihood ratio p/q. Written with the privacy loss, with y drawn from $P = M(D)$, it is

$$D_\alpha(P\|Q) = \frac{1}{\alpha - 1} \ln \mathbb{E}_P\big[e^{(\alpha-1)L}\big]. \tag{D.12}$$

The expectation is the average of $(p/q)^{\alpha-1}$ weighted by p, which is the integral of $p^\alpha q^{1-\alpha}$, the form in which it is often defined. A mechanism has **RDP curve** $\varepsilon(\alpha)$ when $D_\alpha(M(D)\|M(D')) \le \varepsilon(\alpha)$ for every pair of neighbours. Multiplying by $\alpha - 1$ and exponentiating, this says that

$$\mathbb{E}_P\big[e^{(\alpha-1)L}\big] \le e^{(\alpha-1)\varepsilon(\alpha)}. \tag{D.13}$$

In words, the curve bounds the moment generating function (MGF) of the privacy loss, the average of $e^{\lambda L}$, at the point $\lambda = \alpha - 1$.

D.3.2. The answer

For every order $\alpha > 1$, a mechanism with RDP curve $\varepsilon(\alpha)$ is (ε, δ)-DP with

$$\varepsilon = \varepsilon(\alpha) + \frac{\ln(1/\delta)}{\alpha - 1}. \tag{D.14}$$

Every order gives a valid guarantee, so you report the smallest ε over the orders you have computed, usually a fixed grid. This is Mironov's conversion.

D.3.3. A worked example

For the Gaussian running example with $\mu = \Delta/\sigma = 1$, the curve is $\varepsilon(\alpha) = \alpha/2$ (step 4 below derives it). With $\delta = 10^{-5}$, the second term's numerator is $\ln(1/\delta) = 11.5129$. So at order 2 the conversion gives $1 + 11.5129 = 12.5129$, and at order 32 it gives $16 + 11.5129/31 = 16.3714$. Between the two, at order 5.8, it gives $2.9 + 11.5129/4.8 = 5.2985$, which is the best possible (step 5). Yet the exact ε of this mechanism at $\delta = 10^{-5}$ is 4.3772 (Section D.5), so the conversion overstates it by 0.9213.

D.3.4. Why it works

The proof has two moves. Markov's inequality turns the MGF bound into a bound on the chance that the loss is large. Then a small loss everywhere except on a rare set gives (ε, δ)-DP.

1. **Markov's inequality on the loss.** Fix a target level ε. Markov's inequality says that a quantity X that is never negative exceeds a level t with probability at most $\mathbb{E}[X]/t$. The reason is that those outcomes alone already contribute at least t times their probability to the average. The quantity $e^{(\alpha-1)L}$ is never negative, and it exceeds $e^{(\alpha-1)\varepsilon}$ exactly when $L > \varepsilon$, since $\alpha - 1 > 0$. So, using Equation D.13 in the last step,

$$\Pr_P[L > \varepsilon] \le \frac{\mathbb{E}_P\left[e^{(\alpha-1)L}\right]}{e^{(\alpha-1)\varepsilon}} \le e^{(\alpha-1)(\varepsilon(\alpha)-\varepsilon)}. \tag{D.15}$$

2. **Solve for ε.** Set the right side equal to δ and take logs: $(\alpha-1)(\varepsilon(\alpha)-\varepsilon) = -\ln(1/\delta)$. Solving for ε gives Equation D.14. So at that ε, the loss exceeds ε with probability at most δ.
3. **A rare large loss gives (ε, δ)-DP.** Take any set S of outputs and split it in two. On the part where $L \le \varepsilon$, each output has $p(y) \le e^{\varepsilon} q(y)$, so that part has P-probability at most e^{ε} times its Q-probability, which is at most $e^{\varepsilon} \Pr_Q[S]$. The other part lies inside the set where $L > \varepsilon$, which has P-probability at most δ by step 2. Adding the two parts gives $\Pr_P[S] \le e^{\varepsilon} \Pr_Q[S] + \delta$. RDP also bounds the divergence with the two datasets swapped, because swapped neighbours are still neighbours, so the same argument gives the other direction. Section A.6 uses the same split to calibrate the Gaussian mechanism. Note the direction: a rare large loss is enough for (ε, δ)-DP, but Section D.2 showed that (ε, δ)-DP does not force the large loss to be that rare.

A tiny case shows step 3 at work, before the Gaussian. Take three outputs with probabilities $p = (0.6, 0.39, 0.01)$ under D and $q = (0.6, 0.3999, 0.0001)$ under D', and $\varepsilon = 0.1$. Only the third output has a loss above 0.1, namely $\ln 100 = 4.605$, and its probability under D is 0.01. Step 3 then promises $(0.1, 0.01)$-DP. Checking all 8 sets directly, the largest value of $\Pr_P[S] - e^{0.1} \Pr_Q[S]$ is 0.00989, just below the promised 0.01.

4. **The Gaussian's curve.** Under P the loss is normal with mean $\mu^2/2$ and variance μ^2, so its MGF is that of a normal variable. For a normal variable X with mean m and variance v, that MGF is

$$\mathbb{E}[e^{\lambda X}] = e^{\lambda m + \lambda^2 v/2}. \tag{D.16}$$

   So with $\lambda = \alpha - 1$, $m = \mu^2/2$ and $v = \mu^2$, the exponent is $(\alpha-1)\mu^2/2 + (\alpha-1)^2\mu^2/2$, which factors as $(\alpha-1)\,\alpha\mu^2/2$. Dividing by $\alpha - 1$ then gives $\varepsilon(\alpha) = \alpha\mu^2/2$, a straight line through the origin. Section B.4 derives it in more detail and shows why curves add under composition.
5. **The best order.** The conversion is $g(\alpha) = \alpha\mu^2/2 + \ell/(\alpha-1)$, where $\ell = \ln(1/\delta)$. The first term grows with the order and the second shrinks, so the best order is in between. The slope is $g'(\alpha) = \mu^2/2 - \ell/(\alpha-1)^2$, which is zero when $(\alpha-1)^2 = 2\ell/\mu^2$. The first term is a straight line and the second curves upward, so their sum curves upward and this point is its minimum:

$$\alpha^* = 1 + \frac{\sqrt{2\ell}}{\mu}, \qquad \varepsilon = \frac{\mu^2}{2} + \mu\sqrt{2\ell}. \tag{D.17}$$

For the second formula, the first term at α^* is $\mu^2/2 + \mu\sqrt{2\ell}/2$, and the second is $\ell\mu/\sqrt{2\ell} = \mu\sqrt{2\ell}/2$. At $\mu = 1$, $\sqrt{2 \times 11.5129} = 4.7985$, so $\alpha^* = 5.7985$ and $\varepsilon = 0.5 + 4.7985 = 5.2985$.

The improved conversion. Step 3 is wasteful. The smallest valid δ is the largest value of $\Pr_P[S] - e^{\varepsilon} \Pr_Q[S]$ over sets S. That largest value comes from the set of outputs with $L > \varepsilon$, and each such output adds $p - e^{\varepsilon} q = p\,(1 - e^{\varepsilon - L})$. So the exact δ counts an output with $L > \varepsilon$ only in proportion $1 - e^{\varepsilon - L}$, which is small when L is just above ε, while step 3 charges it in full. The improved conversion (Balle et al. 2020; Canonne, Kamath & Steinke 2020) bounds that proportion by the smallest multiple of $e^{(\alpha-1)L}$ that lies above it, whose average Equation D.13 controls. It gives

$$\varepsilon = \varepsilon(\alpha) + \ln \frac{\alpha - 1}{\alpha} - \frac{\ln \delta + \ln \alpha}{\alpha - 1}. \tag{D.18}$$

Section 30.4 derives it. For the Gaussian with $\mu = 1$ its best order is 5.43, where it gives 4.7284. It saves 0.5701 of the 0.9213 by which Mironov's conversion overstates the exact 4.3772.

D.3.5. Checking it

The script averages e^{2L} over 2,000,000 Gaussian outputs; the log of that average, divided by 2, estimates the Rényi divergence of order 3 as 1.4965, against $\alpha\mu^2/2 = 1.5$ from step 4. At Mironov's $\varepsilon = 5.2985$ the chance that the loss exceeds ε is 7.992×10^{-7}, below the 10^{-5} that step 1 guarantees. The exact δ at that ε is smaller still, 1.300×10^{-7}. So the true δ is 76.9 times smaller than the 10^{-5} you report. At the improved conversion's 4.7284 the exact δ is 2.098×10^{-6}, so it too holds with room to spare.

Figure D.3 draws the conversion as a function of the order. The dashed line and the dashed hyperbola are its two terms, and their sum has a single minimum at $\alpha^* = 5.80$. The improved conversion lies below at every order, and neither reaches the exact value. The reason is that the RDP curve keeps only the MGF values of the privacy loss, so a conversion from it must allow for every loss distribution with those values.

D.3.6. Recipe and pitfalls

Compose in RDP, by adding the curves at each order of a fixed grid, such as the 154 orders from 1.1 to 512 that Part 4 uses. Then convert once, at the end, taking the smallest ε over the grid. Use the improved formula, because it is never worse and needs one more line of code. It can return a negative number when $\varepsilon(\alpha)$ is tiny, and then you report 0.

Three things go wrong. Converting each step to (ε, δ) and then adding the steps' ε's (basic composition) wastes most of the advantage of RDP. A grid can miss the best order. The conversion is flat near its minimum, so a grid point close to the best order loses little, but a grid with no point near it can lose a lot. And the curve must hold for every pair of neighbours under the relation you claim. Section 30.3 measures where each step of the proof loses, and Section 30.6 explains how to choose the grid.

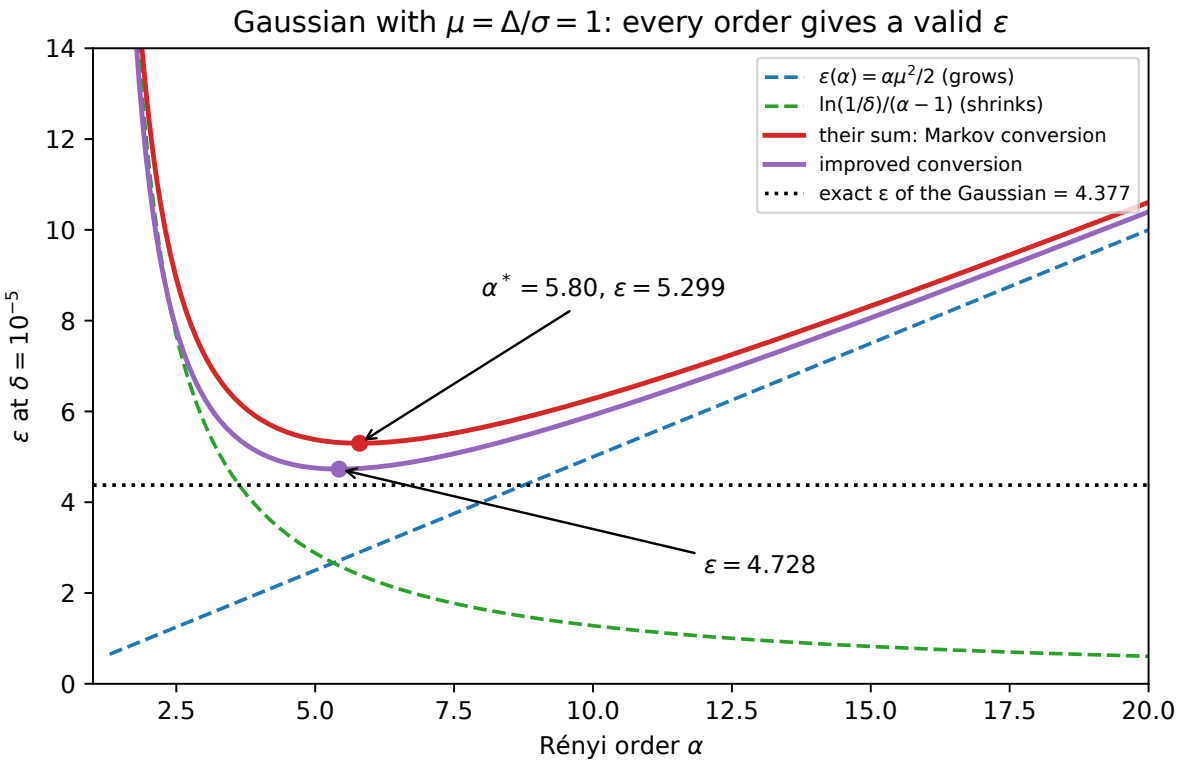

Figure D.3.: The two terms of Mironov's conversion for the Gaussian mechanism with $\mu = 1$ at $\delta = 10^{-5}$: the Rényi curve $\alpha/2$, which grows, and $\ln(1/\delta)/(\alpha - 1)$, which shrinks. Their sum (red) is smallest at $\alpha^* = 5.80$. The improved conversion (purple) and the exact ε of the Gaussian (dotted) are shown for comparison.

D.4. From zero-concentrated DP to (ε, δ)

D.4.1. The question

When every step adds Gaussian noise, the RDP curve is a straight line through the origin. A line is fixed by its slope, so you could keep one number instead of a curve. What is that number, and what (ε, δ) does it give?

D.4.2. The answer

A mechanism is **ρ-zCDP** when its RDP curve lies under the line of slope ρ through the origin: $\varepsilon(\alpha) \le \rho\alpha$ for every order $\alpha > 1$. The word "concentrated" in the name says that the privacy loss then has tails no heavier than a normal variable's. Such a mechanism is (ε, δ)-DP with

$$\varepsilon = \rho + 2\sqrt{\rho \ln(1/\delta)}. \tag{D.19}$$

Three facts make ρ easy to track. First, the Gaussian mechanism with sensitivity Δ and noise σ is ρ-zCDP with $\rho = \Delta^2/(2\sigma^2)$. Second, running several mechanisms adds their ρ's. Third, an ε-DP mechanism, such as a Laplace count, is $(\varepsilon^2/2)$-zCDP (Bun & Steinke 2016, Proposition 1.4). For calibration, though, you need the reverse. Solving Equation D.19 for ρ, a target (ε, δ) is met by any

$$\rho \le \left(\sqrt{\varepsilon + \ln(1/\delta)} - \sqrt{\ln(1/\delta)}\right)^2. \tag{D.20}$$

D.4.3. A worked example

You answer ten count queries, each with $\Delta = 1$ and Gaussian noise of $\sigma = 5$. Each costs $\rho = 1/(2 \times 25) = 0.02$, so the ten cost 0.2. You also release one Laplace count at $\varepsilon = 0.5$, which costs $0.5^2/2 = 0.125$. So the total is $\rho = 0.325$, and the whole release is $(\varepsilon, 10^{-5})$-DP with

$$\varepsilon = 0.325 + 2\sqrt{0.325 \times 11.5129} = 4.1937. \tag{D.21}$$

Going the other way, a single Gaussian query that must be $(1, 10^{-5})$-DP can have ρ up to $(\sqrt{12.5129} - \sqrt{11.5129})^2 = 0.02082$. That means $\sigma = 1/\sqrt{2\rho} = 4.901$ for a sensitivity of 1.

D.4.4. Why it works

1. **Plug the line into the RDP conversion.** By Equation D.14 with $\varepsilon(\alpha) = \rho\alpha$, every order gives a valid ε, namely $g(\alpha) = \rho\alpha + \ell/(\alpha - 1)$, with $\ell = \ln(1/\delta)$.
2. **Find where the slope is zero.** The slope is $g'(\alpha) = \rho - \ell/(\alpha - 1)^2$. It is zero when $(\alpha - 1)^2 = \ell/\rho$, that is, at $\alpha^* = 1 + \sqrt{\ell/\rho}$.
3. **Check that it is a minimum.** The term $\rho\alpha$ is a straight line, and $\ell/(\alpha - 1)$ curves upward for $\alpha > 1$. Their sum curves upward, so its only flat point is its lowest point.
4. **Evaluate.** At α^* the first term is $\rho + \rho\sqrt{\ell/\rho} = \rho + \sqrt{\rho\ell}$. The second is $\ell/\sqrt{\ell/\rho} = \sqrt{\rho\ell}$. Their sum is $\rho + 2\sqrt{\rho\ell}$, which is Equation D.19.
5. **The Gaussian's ρ.** Step 4 of Section D.3 showed that the Gaussian's curve is exactly the line $\alpha\mu^2/2$ with $\mu = \Delta/\sigma$. So $\rho = \mu^2/2 = \Delta^2/(2\sigma^2)$.

6. **Composition.** RDP curves add at each order when mechanisms run one after another (Section B.4). Lines through the origin add to a line whose slope is the sum of the slopes, so the ρ's add.
7. **Pure DP.** An ε-DP mechanism has a privacy loss between $-\varepsilon$ and ε. A variable confined to an interval has light tails, and Hoeffding's lemma, which bounds the MGF of such a variable by a normal one's, turns that into the line $\alpha\varepsilon^2/2$. Section 31.4 proves it, along with the sharper slope $\varepsilon\tanh(\varepsilon/2)$.
8. **The inverse.** Write $x = \sqrt{\rho}$, so that Equation D.19 reads $x^2 + 2x\sqrt{\ell} = \varepsilon$. Adding ℓ to both sides then completes the square, $(x + \sqrt{\ell})^2 = \varepsilon + \ell$, and taking the positive root and squaring it gives Equation D.20.

The one-step Gaussian with $\Delta = 1$ and $\sigma = 1$ is 0.5-zCDP, and it shows that this section and the last agree. Step 2 gives $\alpha^* = 1 + \sqrt{11.5129/0.5} = 5.7985$, and Equation D.19 gives $0.5 + 2\sqrt{0.5 \times 11.5129} = 5.2985$, the same as the minimum found for the curve $\alpha/2$ in Section D.3.

D.4.5. Checking it

For a Gaussian mechanism the zCDP line is exact, so the only slack is in the conversion. Table D.4 compares Equation D.19 with the improved RDP conversion on the same line, minimized over 20,001 orders, and with the exact ε of the Gaussian with $\mu = \sqrt{2\rho}$. The simple formula is 13% to 27% above the exact value, more so at small ρ. The improved conversion removes between 49% and 68% of that gap.

Table D.4.: The ε at $\delta = 10^{-5}$ of a ρ-zCDP mechanism, from the simple formula and the improved conversion, against the exact ε of the Gaussian mechanism with the same ρ.

ρ	$\mu = \sqrt{2\rho}$	Simple, Equation D.19	Improved conversion	Exact Gaussian
0.125	0.5000	2.5243	2.1657	1.9931
0.2	0.6325	3.2349	2.8136	2.5944
0.5	1.0000	5.2985	4.7284	4.3772
5	3.1623	20.1743	19.0473	17.8566

D.4.6. Recipe and pitfalls

Keep the budget in ρ, add it up, and convert once at the end. Do not add up the ε's of the parts instead. Because ε grows like the square root of ρ, the ε's of two halves add to more than the ε of the whole. Pure-DP steps enter at $\varepsilon^2/2$, which is close to the best possible slope for small ε and wasteful for large ones.

The big pitfall is subsampling. Differentially private stochastic gradient descent (SGD), DP-SGD for short, runs each step on a random sample of the data, which makes each step much more private at small orders. But the sampled step's RDP curve bends sharply upward at large orders. Any line that stays above the whole curve is then as steep as the line without sampling, so zCDP loses the whole gain. Accountants for DP-SGD therefore use RDP curves or numerical methods (Section 31.8). Section 31.5 states the conversion with its improved version.

D.5. Gaussian DP and its exact (ε, δ) curve

D.5.1. The question

For the Gaussian mechanism, both conversions above leave slack. Is there one number that describes its privacy exactly, and turns into the exact (ε, δ)?

D.5.2. The answer

A mechanism is **μ-GDP** when no pair of neighbours is easier to tell apart than $\mathcal{N}(0,1)$ from $\mathcal{N}(\mu,1)$. In terms of errors, every test with false positive rate FPR has a false negative rate of at least

$$G_\mu(\mathrm{FPR}) = \Phi(\Phi^{-1}(1-\mathrm{FPR}) - \mu). \tag{D.22}$$

The Gaussian mechanism is μ-GDP with $\mu = \Delta/\sigma$, with no slack. It is (ε, δ)-DP exactly when δ is at least

$$\delta(\varepsilon) = \Phi\Big(-\frac{\varepsilon}{\mu} + \frac{\mu}{2}\Big) - e^{\varepsilon}\,\Phi\Big(-\frac{\varepsilon}{\mu} - \frac{\mu}{2}\Big). \tag{D.23}$$

When several GDP mechanisms run one after another, their μ's add like the sides of a right-angled triangle, $\mu = \sqrt{\mu_1^2 + \cdots + \mu_k^2}$.

D.5.3. A worked example

Take $\mu = 1$, the Gaussian mechanism with $\sigma = \Delta$. The best test says "D'" when the output is above a threshold (step 1 below). An attacker who accepts 5% false positives uses the threshold $\Phi^{-1}(0.95) = 1.6449$, and misses with probability at least $G_1(0.05) = \Phi(1.6449 - 1) = 0.7405$. At $\varepsilon = 1$, Equation D.23 gives $\delta(1) = \Phi(-0.5) - e\,\Phi(-1.5) = 0.308538 - e \times 0.066807 = 0.126937$. To report ε at $\delta = 10^{-5}$, solve Equation D.23 for ε by bisection, which repeatedly halves an interval that contains the answer. This works because $\delta(\varepsilon)$ falls as ε grows: a larger ε asks less of every test. Table D.5 gives the result for three values of μ.

Table D.5.: The exact δ at $\varepsilon = 1$ and the exact ε at $\delta = 10^{-5}$ of μ-GDP, from Equation D.23.

μ	0.5	1	2
$\delta(1)$	0.0068	0.1269	0.5099
ε at $\delta = 10^{-5}$	1.9931	4.3772	9.9973

Composition is just as quick. Four releases with $\sigma = 2\Delta$ each have $\mu_i = 0.5$, so together they have $\mu = \sqrt{4 \times 0.25} = 1$. They are 1-GDP, and so $(4.3772, 10^{-5})$-DP.

D.5.4. Why it works

The first three steps find the best test, which gives the curve G_μ. The next three find the (ε, δ) guarantee that the curve implies, and the last one handles composition.

1. **The best test thresholds the output.** The Neyman–Pearson lemma says that, among tests with the same false positive rate, the one with the fewest misses says "D'" on the outputs where $q(y)/p(y)$ is largest. The reason is that each output in the region costs $p(y)$ in false positives and buys $q(y)$ in detections, so the best buys go first. For the pair $\mathcal{N}(0,1)$ and $\mathcal{N}(\mu,1)$, the ratio is $q(y)/p(y) = e^{-L(y)} = e^{\mu y - \mu^2/2}$, which grows with y. So the best test says "D'" when y is above a threshold τ.
2. **Its two errors.** Under D, y is standard normal, so $\text{FPR} = \Pr[Z > \tau] = 1 - \Phi(\tau)$, and the threshold for a given FPR is $\tau = \Phi^{-1}(1 - \text{FPR})$. Under D', $y = \mu + Z$, so the test misses when $\mu + Z \le \tau$, which has probability $\Phi(\tau - \mu)$.
3. **Substitute.** Putting $\tau = \Phi^{-1}(1 - \text{FPR})$ into $\Phi(\tau - \mu)$ gives Equation D.22. For the Gaussian mechanism, a pair of neighbours whose query values differ by $s \le \Delta$ gives the pair $\mathcal{N}(0,1)$ and $\mathcal{N}(s/\sigma, 1)$, with shift $s/\sigma \le \Delta/\sigma$. A larger shift is easier to detect, because G_μ falls as μ grows, so the worst pair has $\mu = \Delta/\sigma$.
4. **One (ε, δ) guarantee is one line.** By Section D.1, (ε, δ)-DP asks every test to have $\text{FNR} \ge 1 - \delta - e^\varepsilon \text{FPR}$. The best tests have $\text{FNR} = G_\mu(\text{FPR})$, so the condition is $\delta \ge 1 - G_\mu(\text{FPR}) - e^\varepsilon \text{FPR}$ for every FPR, and the smallest valid δ is the largest value of the right side. The other inequality of Equation D.6 gives the same number. Reflecting the output, $y \mapsto \mu - y$, swaps the two normals, so it turns each test into one with the two error rates swapped, and the two inequalities into each other.
5. **Find the touching point.** Lowering the threshold by a small step h adds the outputs just below τ to the region. That raises FPR by about $p(\tau)h$ and lowers the miss rate by about $q(\tau)h$, so the curve's slope at that point is $-q(\tau)/p(\tau) = -e^{\mu\tau - \mu^2/2}$. As FPR grows the threshold drops, so this slope gets flatter. The quantity $1 - G_\mu(\text{FPR}) - e^\varepsilon \text{FPR}$ therefore rises while the miss rate falls faster than e^ε per unit of FPR, and falls afterwards. So it is largest where the slope equals $-e^\varepsilon$. Setting $\mu\tau - \mu^2/2 = \varepsilon$ gives $\tau = \varepsilon/\mu + \mu/2$.
6. **Read off δ.** At that threshold, $\text{FPR} = 1 - \Phi(\tau) = \Phi(-\tau)$ and the detection rate is $1 - \Phi(\tau - \mu) = \Phi(\mu - \tau)$. So $\delta(\varepsilon) = \Phi(\mu - \tau) - e^\varepsilon \Phi(-\tau)$, which is Equation D.23.
7. **Composition.** Each release adds independent noise, so k releases give a vector of k outputs, $\mathcal{N}(0, I)$ under D and $\mathcal{N}(\mu, I)$ under D' with $\mu = (\mu_1, \dots, \mu_k)$. Only the direction of μ carries evidence, and along it the shift is the length of μ, $\sqrt{\mu_1^2 + \cdots + \mu_k^2}$. Section B.3 proves this rotation step.

At $\mu = 1$ and $\varepsilon = 1$, step 5 gives $\tau = 1 + 0.5 = 1.5$. Step 6 then gives $\text{FPR} = \Phi(-1.5) = 0.066807$ and a detection rate of $\Phi(-0.5) = 0.308538$, which are the numbers of the worked example. Section A.7 reaches the same formula by a different route. There, $\Phi(-0.5)$ is the chance that the privacy loss exceeds ε, and $e\,\Phi(-1.5)$ is the correction subtracted from it. With $\mu = \Delta/\sigma$ the two derivations give the same curve.

D.5.5. Checking it

Searching over 20,001 thresholds for the largest $1 - G_1(\text{FPR}) - e\,\text{FPR}$ gives 0.126937, the value of Equation D.23. A simulation of the threshold test at $\text{FPR} = 0.05$ with 1,000,000 draws per world

gives a false positive rate of 0.0497 and a false negative rate of 0.7413, against the exact 0.7405.

Figure D.4 shows both halves of the derivation. On the left, each curve G_μ has a dashed line of slope $-e$ that just touches it. The line starts at $1-\delta(1)$ on the vertical axis, so the gap below 1 is the exact δ at $\varepsilon = 1$. On the right, the whole curve $\delta(\varepsilon)$ falls steeply, and the dots mark where it crosses 10^{-5}.

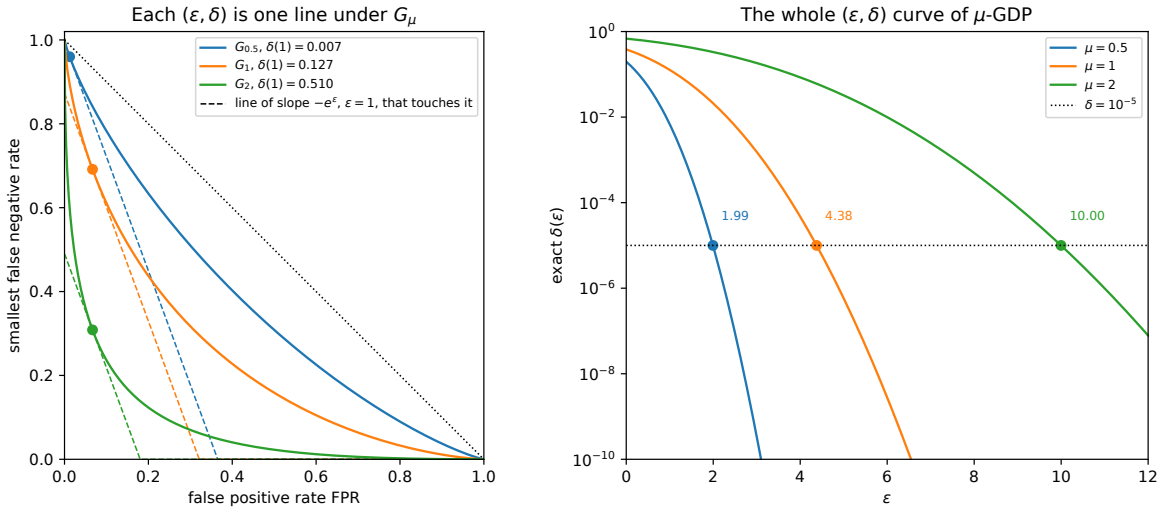

Figure D.4.: Left: the trade-off curves G_μ for $\mu = 0.5$, 1 and 2, the smallest false negative rate of any test at each false positive rate. Each dashed line has slope $-e$ and touches its curve at the dot; it meets the vertical axis at $1-\delta(1)$. Right: the exact $\delta(\varepsilon)$ of μ-GDP on a log scale, with the ε at $\delta = 10^{-5}$ marked.

D.5.6. Recipe and pitfalls

For a pipeline of Gaussian releases, compute $\mu_i = \Delta_i/\sigma_i$ for each, combine them as $\mu = \sqrt{\sum \mu_i^2}$, and solve Equation D.23 for ε at your δ. Nothing is lost along the way, so this ε is exact.

The formula is exact only for Gaussian noise with the ℓ_2 sensitivity Δ, the largest Euclidean distance between the query's values on neighbours. For subsampled DP-SGD, GDP comes from a central limit theorem and is only an approximation (Section 32.8). And one reported (ε, δ) pair keeps one touching line and forgets the rest of the curve. Section 32.5 shows that the whole family of lines rebuilds G_μ.

D.6. Summary

Table D.6 puts the four definitions side by side. Each one tracks a different summary of the privacy loss, and each converts to (ε, δ) at the end.

Table D.6.: The four ways to track privacy, how each composes and how each converts to (ε, δ).

Definition	What you track	How it composes	How to get (ε, δ)
(ε, δ)-DP	Two numbers	Add the ε's and the δ's (basic composition)	Nothing to do
RDP	A curve $\varepsilon(\alpha)$ over orders	Add the curves at each order	Smallest $\varepsilon(\alpha) + \ln(1/\delta)/(\alpha - 1)$ over orders, or the improved formula
ρ-zCDP	One number ρ	Add the ρ's	$\rho + 2\sqrt{\rho \ln(1/\delta)}$
μ-GDP	One number μ	Add the μ^2's	Solve Equation D.23 for ε

For the Gaussian mechanism with $\mu = 1$ at $\delta = 10^{-5}$, the three conversions give 5.2985 (Mironov's, which equals the zCDP formula here), 4.7284 (the improved conversion) and 4.3772 (GDP, exact).

D.7. Code

The script `code/appendix-derivations/apx_core_conversions.py` checks every number on this page. It enumerates every test against three people's randomized response, simulates the posterior and the threshold test, and checks the Gaussian's Rényi divergence by Monte Carlo. It also minimizes both RDP conversions over orders, inverts the exact Gaussian $\delta(\varepsilon)$ by bisection, and computes Φ^{-1} by bisection on Φ, which it evaluates with the standard library's complementary error function. Run it with

```
uv run python code/appendix-derivations/apx_core_conversions.py
```

Table D.7.: The checks the script prints, with seed 0.

Check	Printed	Expected
Least slack over all 256 tests, $\varepsilon = \ln 3$	0.000000	at least 0
Posterior from 2,000,000 randomized-response draws, prior 1%, $\varepsilon = 1$	0.0267	0.0267
Rényi divergence of order 3 by Monte Carlo, $\mu = 1$	1.4965	1.5

Check	Printed	Expected
Three outputs: largest $\Pr_P[S] - e^{0.1}\Pr_Q[S]$	0.00989	at most 0.01
$\Pr[L > 5.2985]$ for the Gaussian, $\mu = 1$	7.992×10^{-7}	at most 10^{-5}
$\delta(1)$ for $\mu = 1$ by search over thresholds	0.126937	0.126937
Threshold test at FPR $= 0.05$, $\mu = 1$, simulated miss rate	0.7413	0.7405

Every bound holds, and the ones that should be tight are tight. Randomized response reaches both the testing bound and the posterior cap. The Gaussian's privacy loss is normal, which is why its RDP curve, its zCDP parameter and its GDP curve are all exact descriptions. So for the RDP curve and the zCDP parameter, all the slack comes from the final conversion to (ε, δ).

E. Sums, limits and counting

This appendix proves five facts about sums of random variables and about counting that the chapters use without a full proof. The first finds the distribution of a sum of two independent variables by adding up the ways the sum can arise. That replaces a theorem the book takes as given, namely that the moment generating function of a distribution pins it down. The second counts: it finds the most likely value of a binomial count, how tall that peak is, and how large $n!$ is. The third proves the central limit theorem (CLT) by swapping one term at a time for a normal one. The fourth shows that the length of a normal vector in d dimensions rarely exceeds $\sqrt{d}$ by much. The fifth finds the tail of the difference of two Laplace variables. They sit together because each is a statement about a sum or a count. They also share their tools. The proofs add up the ways a sum can happen, compare neighbouring terms through their ratio, and apply Markov's inequality to an exponential.

Table E.1 lists where each result is stated or used.

Table E.1.: The derivations of this appendix and the chapter sections that state or use them.

Derivation	Where the chapters state or use it
Section E.1: sums by convolution, rotation invariance of the normal	Section 1.2.2 and the sections on the Poisson, Laplace and normal in Probability distributions; Section 3.5; Section 20.4; Section 27.1
Section E.2: Stirling's formula, the binomial mode and its height	Section 9.4; Section 9.6; Section 12.4; Section 13.5
Section E.3: the central limit theorem	The normal section of Probability distributions; Section 32.7 and every normal approximation in the book
Section E.4: the length of a normal vector	Section 28.4
Section E.5: the difference of two Laplace variables	Section 42.8; Section 27.1

E.1. A sum's distribution, found by convolution

E.1.1. What the chapter uses

Probability distributions identifies the distribution of a sum in four places. The sum of two independent Poisson counts is Poisson, and the difference of two independent exponential variables

is Laplace. Any weighted sum of independent normal variables is normal, and the sum of n independent Exp(1) variables has the Gamma$(n, 1)$ density. Each time the chapter multiplies moment generating functions (MGFs), recognizes the product, and then relies on a theorem stated in Section 1.2.2: two distributions with the same MGF near 0 are the same. The chapter says that the proof of that theorem "needs more analysis than this book uses, so take it as given".

The same chapter states two facts about a normal vector $X \sim \mathcal{N}(0, \sigma^2 I_d)$, whose d coordinates are independent $\mathcal{N}(0, \sigma^2)$ variables. Its projection onto any unit vector is $\mathcal{N}(0, \sigma^2)$. And the projections onto two perpendicular unit vectors are independent, because "for jointly normal variables zero covariance means independence", which the chapter does not prove. Section 3.5 and Section 20.4 use a stronger form: rotating the space does not change the distribution of X. They use it to compare the noise X with a shifted copy $X + v$: a rotation turns the shift v to point along the first axis, which reduces the comparison to one dimension. Finally, Section 27.1 states that the difference of two independent Lap$(1/\varepsilon)$ variables has density $\frac{\varepsilon}{4}(1 + \varepsilon|z|)e^{-\varepsilon|z|}$.

This section proves all of these without the uniqueness theorem. The tool is the **convolution**, which adds up the ways a sum can arise. Take independent variables X and Y, and write f and g for their densities. The density of the sum $X + Y$ at a point s is then

$$f_{X+Y}(s) = \int f(x)\, g(s - x)\, dx, \tag{E.1}$$

and for counts the integral becomes a sum over x. In every line below the variables are independent. In the last one, each X_i is normal with mean μ_i and variance σ_i^2, and the weights a_i are constants. As in the chapter, Exp(b) and Lap(b) have scale b, and an equals sign between distributions means that the left side has the distribution on the right.

$$\begin{aligned} &\text{Poisson}(\mu_1) + \text{Poisson}(\mu_2) = \text{Poisson}(\mu_1 + \mu_2), \qquad && \text{Exp}(b) - \text{Exp}(b) = \text{Lap}(b), \\ &\text{Exp}(1) + \cdots + \text{Exp}(1)\ (n \text{ terms}) = \text{Gamma}(n, 1), && \textstyle\sum_i a_i X_i \sim \mathcal{N}(\sum_i a_i \mu_i, \sum_i a_i^2 \sigma_i^2). \end{aligned} \tag{E.2}$$

For the normal vector, the claim is that rotating X leaves its distribution unchanged, so the coordinates of X along any two perpendicular unit vectors are independent $\mathcal{N}(0, \sigma^2)$ variables.

E.1.2. The idea

To find the chance that a sum takes a value, list every way it can take that value and add up their chances. Roll two fair dice and ask for a total of 4. The first die shows 1, 2 or 3, and the second must then show 3, 2 or 1. Each pair has chance $\frac{1}{6} \cdot \frac{1}{6}$, because the dice are independent, so the total is 3/36. Table E.2 writes this out.

Table E.2.: The ways two dice can total 4. Adding the last row gives Pr[total = 4] = 3/36.

First die x	1	2	3	4, 5, 6
Second die must show $4 - x$	3	2	1	impossible
Chance of this way	1/36	1/36	1/36	0

For a density the list of ways becomes an integral. The first variable takes a value x, the second must make up the rest, $s - x$, and independence multiplies the two densities. That is Equation E.1. Each identification in the chapter is one such integral, and each is short.

Rotation invariance has a different reason. The joint density of X depends on the point x only through its distance from the origin, so in two dimensions its contours are circles, and in d dimensions they are spheres. A rotation moves every point along its sphere and keeps every volume, so it leaves the density where it was. So a rotation that carries two perpendicular directions onto the first two coordinate axes does not change the distribution. Along the axes the coordinates are independent by definition, so they are independent along the two directions too.

E.1.3. Derivation

1. **Why Equation E.1 holds.** Fix a small width $\kappa > 0$ and the interval of that width around s. The sum lands in it when X is near some value x and Y lands within κ of $s-x$. Given $X = x$, that has chance about $g(s-x)\kappa$, because Y is independent of X and so its density does not change. Averaging over x with the density f gives $\kappa \int f(x)g(s-x)\,dx$, and dividing by κ gives the density. For counts the same step reads $\Pr[X+Y=k] = \sum_j \Pr[X=j]\Pr[Y=k-j]$, as in the dice.

2. **Poisson.** Take independent $N_1 \sim \text{Poisson}(\mu_1)$ and $N_2 \sim \text{Poisson}(\mu_2)$. The sum of step 1, with $\Pr[N=j] = e^{-\mu}\mu^j/j!$, is

$$\Pr[N_1+N_2=k] = \sum_{j=0}^{k} e^{-\mu_1}\frac{\mu_1^j}{j!}\,e^{-\mu_2}\frac{\mu_2^{k-j}}{(k-j)!} = \frac{e^{-(\mu_1+\mu_2)}}{k!}\sum_{j=0}^{k}\binom{k}{j}\mu_1^j\mu_2^{k-j}. \tag{E.3}$$

   The second form multiplies and divides by $k!$, and $\binom{k}{j} = k!/(j!(k-j)!)$. The binomial theorem says that the last sum is $(\mu_1+\mu_2)^k$. So $\Pr[N_1+N_2=k] = e^{-(\mu_1+\mu_2)}(\mu_1+\mu_2)^k/k!$, which is the Poisson$(\mu_1+\mu_2)$ probability.

3. **Exponential minus exponential.** Let $Y_1, Y_2 \sim \text{Exp}(b)$ be independent, each with density $f(y) = \frac{1}{b}e^{-y/b}$ for $y \geq 0$ and 0 for $y < 0$. The difference $Y_1 - Y_2$ equals x when $Y_1 = y$ and $Y_2 = y - x$, so the density of the difference at x is $\int f(y)f(y-x)\,dy$. Here y is the integration variable and x is the value of the difference. This is Equation E.1 for the sum $Y_1 + (-Y_2)$, whose second term has density $f(-z)$, so the copy of f appears shifted but not flipped. The integrand is non-zero only where both $y \geq 0$ and $y - x \geq 0$, that is for $y \geq \max(0, x)$, and on that range

$$f(y)f(y-x) = \frac{1}{b^2}e^{-y/b}e^{-(y-x)/b} = \frac{1}{b^2}e^{x/b}e^{-2y/b}. \tag{E.4}$$

   Integrating $e^{-2y/b}$ from a point c to infinity gives $\frac{b}{2}e^{-2c/b}$, so with $c = \max(0,x)$ the density of the difference is $\frac{1}{2b}e^{x/b}e^{-2\max(0,x)/b}$. When $x \geq 0$ this is $\frac{1}{2b}e^{-x/b}$, and when $x < 0$ it is $\frac{1}{2b}e^{x/b}$. Together they make $\frac{1}{2b}e^{-|x|/b}$, which is the Lap(b) density.

4. **Sums of exponentials.** Write $f_n(x) = x^{n-1}e^{-x}/(n-1)!$ for $x \geq 0$, the Gamma$(n,1)$ density. For $n = 1$ it is e^{-x}, the Exp(1) density. Suppose the sum of n independent Exp(1) variables has density f_n, and add one more. Use Equation E.1 with the sum at x and the integration variable y for the first term. Both terms are non-negative, so y can only lie between 0 and x:

$$\int_0^x \frac{y^{n-1}e^{-y}}{(n-1)!}\,e^{-(x-y)}\,dy = \frac{e^{-x}}{(n-1)!}\int_0^x y^{n-1}\,dy = \frac{e^{-x}}{(n-1)!}\cdot\frac{x^n}{n} = \frac{x^n e^{-x}}{n!}. \tag{E.5}$$

The exponentials combine to e^{-x}, which does not depend on y, so it leaves the integral. The result is f_{n+1}. By induction, the claim holds for every n.

5. **Sums of normals.** Start with two independent normals with mean 0, $X_1 \sim \mathcal{N}(0, \sigma_1^2)$ and $X_2 \sim \mathcal{N}(0, \sigma_2^2)$, and write $v = \sigma_1^2 + \sigma_2^2$. In Equation E.1 the two exponents add to $-\frac{y^2}{2\sigma_1^2} - \frac{(s-y)^2}{2\sigma_2^2}$. Completing the square in y rewrites this sum as

$$-\frac{v}{2\sigma_1^2\sigma_2^2}\Big(y - \frac{\sigma_1^2}{v}s\Big)^2 - \frac{s^2}{2v}, \tag{E.6}$$

which you can check by expanding both forms. The first term is the exponent of a normal density in y with variance $\sigma_1^2\sigma_2^2/v$, and integrating it over y gives $\sqrt{2\pi\sigma_1^2\sigma_2^2/v}$. The two normalizing factors $1/(\sigma_1\sqrt{2\pi})$ and $1/(\sigma_2\sqrt{2\pi})$ remain. Multiplying the three numbers leaves $1/\sqrt{2\pi v}$, so the sum has density $e^{-s^2/(2v)}/\sqrt{2\pi v}$, the $\mathcal{N}(0, v)$ density. Two simpler facts extend this to weighted sums with any means. First, multiplying $X \sim \mathcal{N}(\mu, \sigma^2)$ by a constant $a > 0$ gives $\mathcal{N}(a\mu, a^2\sigma^2)$. The reason is that $aX \le t$ is the event $X \le t/a$. Differentiating its probability in t gives the density of X at t/a times $1/a$, and that is the $\mathcal{N}(a\mu, a^2\sigma^2)$ density. A negative a also flips the sign, which the symmetry of the normal about its mean absorbs. Second, adding a constant only moves the mean. With these two facts, applying the two-term rule one term at a time gives the rule for $\sum_i a_i X_i$.

6. **Rotation invariance.** The coordinates of $X \sim \mathcal{N}(0, \sigma^2 I_d)$ are independent, so its joint density is the product of d normal densities. The exponents add up to the squared length $\|x\|^2 = x_1^2 + \cdots + x_d^2$:

$$p(x) = \prod_{i=1}^{d} \frac{e^{-x_i^2/(2\sigma^2)}}{\sigma\sqrt{2\pi}} = (2\pi\sigma^2)^{-d/2} e^{-\|x\|^2/(2\sigma^2)}. \tag{E.7}$$

In this appendix a **rotation** means any square matrix O whose rows are perpendicular unit vectors, which is also called an orthogonal matrix (it includes reflections). It keeps every length, $\|Ox\| = \|x\|$, because the coordinates of Ox are the components of x along the rows of O. It also keeps every volume, because the factor by which a matrix scales volumes is $|\det O|$, and $\det O = \pm 1$ since $O^\top O = I$. In two dimensions, for example, O turns the plane by an angle ϕ, and $\cos^2\phi + \sin^2\phi = 1$ is the reason lengths are kept. Now let $Y = OX$. For any region A, Y lands in A exactly when X lands in the region $O^{-1}A$ that O maps onto A. Substituting $x = O^{-1}y$, which keeps volume, gives $\Pr[Y \in A] = \int_A p(O^{-1}y)\,dy$. By Equation E.7, $p(O^{-1}y)$ depends only on $\|O^{-1}y\| = \|y\|$, so it equals $p(y)$. So Y has the same density as X.

7. **Perpendicular projections are independent.** Let u and v be perpendicular unit vectors. Choose a rotation O whose first row is u and whose second row is v; the other rows are any unit vectors that complete a perpendicular set. The first two coordinates of $Y = OX$ are then $\langle u, X\rangle$ and $\langle v, X\rangle$. By step 6, $Y \sim \mathcal{N}(0, \sigma^2 I_d)$, so these two coordinates are independent $\mathcal{N}(0, \sigma^2)$ variables. This also proves the chapter's general remark, if "jointly normal" means "linear functions of one vector of independent standard normals". Two such variables $A = \langle a, G\rangle$ and $B = \langle b, G\rangle$, with $G \sim \mathcal{N}(0, I_d)$, have covariance $\mathbb{E}[AB] = \sum_{i,j} a_i b_j \mathbb{E}[G_i G_j] = \sum_i a_i b_i = \langle a, b\rangle$, because $\mathbb{E}[G_i G_j]$ is 1 when $i = j$ and 0 otherwise. When that is 0, $a/\|a\|$ and $b/\|b\|$ are perpendicular unit vectors, so A and B are multiples of two independent normals, and adding constant means keeps them independent.

8. **Two Laplace variables with the same scale.** The density $\frac{\varepsilon}{4}(1+\varepsilon|z|)e^{-\varepsilon|z|}$ is the equal-scale case of the convolution in Section E.5 (step 5 there).

One more claim of the chapter needs no new proof. It says that the sum of two independent Lap(b) variables is not Laplace, because its MGF $1/(1-b^2\lambda^2)^2$ is not a Laplace MGF. That argument needs only the easy direction, which is that two variables with the same distribution have the same MGF. So it does not depend on the uniqueness theorem.

E.1.4. Checking it

The script of this appendix (see the Code section at the end) evaluates each convolution numerically and compares it with the closed form. For the sum of two Poisson counts with means 2 and 3, the largest gap to Poisson(5) is 3.3×10^{-16}, which is rounding error. The difference of two exponential densities, integrated on a grid, is within 7.2×10^{-5} of the Laplace density. Similarly, five exponential densities convolved on a grid are within 1.1×10^{-3} of the Gamma density. Both of these gaps are the error of the grid, so they shrink as the grid gets finer. Finally, the sum of normals with variances 1 and 4 matches the normal density with variance 5 to 1.2×10^{-12}.

Figure E.1 draws the integral of step 3. In each of the first three panels, the blue curve is $f(y)$ and the orange curve is its copy shifted by x. The green area under their product is the density of the difference at x. At $x = 0$ the two curves coincide and the overlap is largest, 0.5. Moving the copy either way shrinks the overlap at the same exponential rate, which is why the result is the two-sided Laplace shape in the last panel.

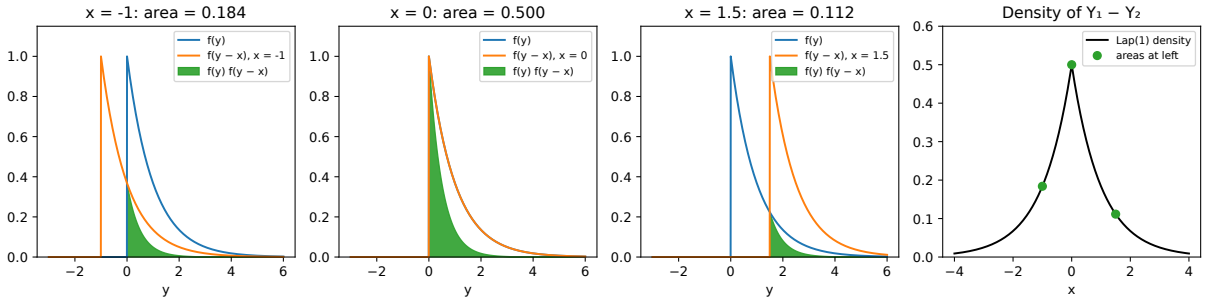

Figure E.1.: The density of $Y_1 - Y_2$ for independent Exp(1) variables at $x = -1$, 0 and 1.5, as the area under $f(y)f(y-x)$ (green), next to the Lap(1) density with those three areas marked.

For rotation invariance, the script draws a million points from $\mathcal{N}(0, I_2)$ and projects them onto $u = (\cos\phi, \sin\phi)$ and the perpendicular v, with $\phi = \pi/6$. The two projections have variances 0.9983 and 1.0010 and correlation -0.0005. Independence is a stronger claim than zero correlation, so the script also checks a joint probability. The chance that both projections exceed 1 is 0.0251, and the product of the two separate chances is $(1 - \Phi(1))^2 = 0.0252$, where Φ is the standard normal cumulative distribution function (CDF). Figure E.2 shows the circular contours and the two matching histograms.

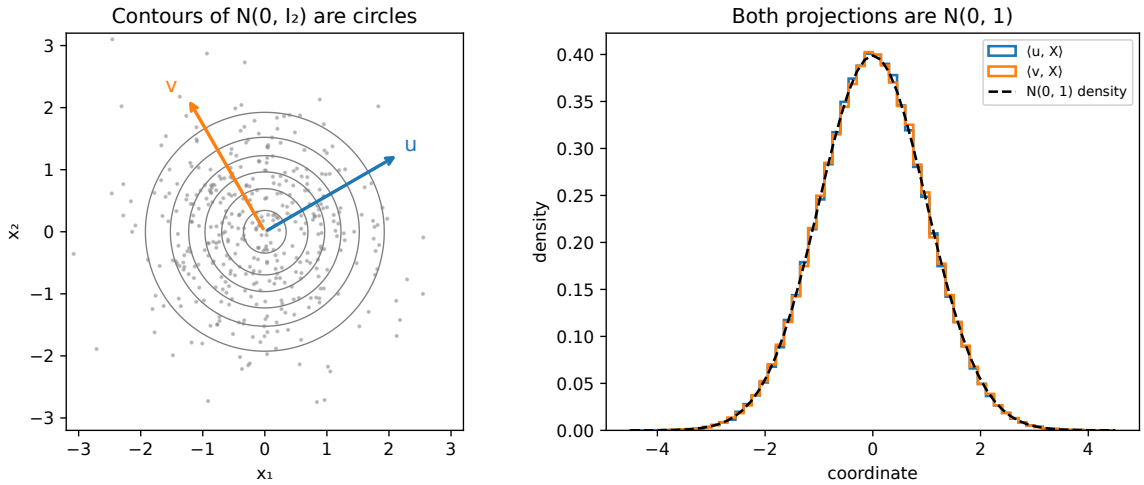

Figure E.2.: Left: contours of the $\mathcal{N}(0, I_2)$ density, which are circles, with 400 sample points and two perpendicular unit vectors u and v. Right: histograms of the projections $\langle u, X\rangle$ and $\langle v, X\rangle$ over 200,000 draws, against the $\mathcal{N}(0, 1)$ density.

E.1.5. What it does not cover

The derivations identify each sum that the book needs, one at a time. They do not prove the general theorem that an MGF finite near 0 determines the distribution. That theorem needs a way to recover a distribution from its transform, through complex numbers or a limit argument, and it stays cited to Blitzstein & Hwang (2019) and Billingsley (1995). Nothing in the book depends on it beyond the cases proved here.

E.2. Stirling's formula and the peak of a binomial

E.2.1. What the chapter uses

Four sections in the attacks part count with binomial probabilities. Write $X \sim \mathrm{Bin}(n, p)$ for the number of successes in n independent trials with success probability p. Write $\bar{p} = 1 - p$ and $p_k = \Pr[X = k] = \binom{n}{k} p^k \bar{p}^{n-k}$.

- Section 9.6 (Equation 9.14) says that the binomial weights "rise up to the middle value and fall after it". From that it shows that shifting $\mathrm{Bin}(m, \frac{1}{2})$ by one has total variation (TV) distance equal to the largest weight, $\binom{m}{\lfloor m/2 \rfloor} 2^{-m}$. It then says that this is about $\sqrt{2/(\pi m)}$ and leaves the proof to an exercise that takes Stirling's formula as given.
- Section 9.4 releases the exact sum K of m fair secret bits. Given K, the best guess sets every bit to the majority value, which gets $\max(K, m - K)$ bits right, so the expected fraction recovered is $\frac{1}{2} + \mathbb{E}|K - \frac{m}{2}|/m$. It approximates the fraction by $\frac{1}{2} + 1/\sqrt{2\pi m}$ through the central limit theorem and the mean absolute value $\sigma\sqrt{2/\pi}$ of a normal variable. That step assumes that the average distance $\mathbb{E}|K - \frac{m}{2}|$ follows the normal one, which the CLT alone does not give, because the CLT is a statement about probabilities, not averages.

- Section 12.4 (Equation 12.9) states that a binomial is unimodal. It then argues that the probability of the most likely count is close to the height $1/\sqrt{2\pi npq}$ of the normal curve, because "the density is nearly flat over a unit interval at the top".
- Section 13.5 (Equation 13.11) uses $\ln N! = N\ln N - N + O(\ln N)$, "Stirling's approximation of the factorial", without proof.

This section proves all of these. First, the binomial probabilities rise and then fall, with the most likely count at $\lfloor (n+1)p \rfloor$. Second, Stirling's formula holds with an explicit error r_n:

$$n! = \sqrt{2\pi n}\left(\frac{n}{e}\right)^n e^{r_n}, \qquad 0 < r_n \le \frac{1}{12n}. \tag{E.8}$$

Third, the fraction of bits recovered from the sum of m fair bits is exactly

$$\frac{1}{2} + \frac{1}{2}\binom{2j}{j}4^{-j}, \qquad j = \lfloor m/2 \rfloor, \tag{E.9}$$

and $\binom{2j}{j}4^{-j}\sqrt{\pi j} \to 1$, so the fraction is $\frac{1}{2} + 1/\sqrt{2\pi m}$ up to a relative error that vanishes.

Fourth, the height of the mode is close to the peak $1/\sqrt{2\pi npq}$ of the normal curve with the same mean and variance. The proof needs the count to have some spread, so it assumes $npq \ge 4$, and then

$$\left| \ln\left(\max_k p_k \cdot \sqrt{2\pi npq} \right) \right| \le \frac{3.5}{npq}. \tag{E.10}$$

E.2.2. The idea

The shape of the binomial comes from comparing each probability with the next one. Going from k to $k+1$ successes multiplies the probability by a ratio that gets smaller as k grows. While the ratio is above 1 the probabilities climb, and once it drops below 1 they fall, so there is one peak. With $n = 4$ and $p = \frac{1}{2}$ the ratios are $4, \frac{3}{2}, \frac{2}{3}, \frac{1}{4}$, and the probabilities $\frac{1}{16}, \frac{4}{16}, \frac{6}{16}, \frac{4}{16}, \frac{1}{16}$ climb twice and fall twice.

For the factorial, compare a sum with an integral. The logarithm $\ln n! = \ln 1 + \ln 2 + \cdots + \ln n$ is a sum of values of the slowly growing function $\ln x$, so it is close to $\int \ln x\, dx = x\ln x - x$. That gives $n\ln n - n$ with an error of order $\ln n$. Part of the error is exactly $\frac{1}{2}\ln n$, which becomes the $\sqrt{n}$ in Stirling's formula. What remains changes from n to $n+1$ by an amount that is always positive and adds up to a finite total, so it settles to a constant. A classical integral of $\sin^n$, due to Wallis, then shows that the constant is $\ln\sqrt{2\pi}$.

E.2.3. Derivation

1. **The ratio of neighbours.** Dividing the binomial formula at $k+1$ by the one at k, most factors cancel:

   $$\frac{p_{k+1}}{p_k} = \frac{n-k}{k+1}\cdot\frac{p}{\bar{p}}. \tag{E.11}$$

   As k grows the numerator $n-k$ falls and the denominator $k+1$ rises, so the ratio decreases. It is above 1 exactly when $(n-k)p > (k+1)\bar{p}$, which rearranges to $k < (n+1)p - 1$. So the probabilities rise while $k+1 < (n+1)p$ and do not rise after. The last count reached

by a rise is the largest whole number not above $(n+1)p$, so the largest probability is at $k^* = \lfloor (n+1)p \rfloor$. When $(n+1)p$ is a whole number the ratio there is exactly 1, and $k^* - 1$ ties with k^*.

2. **Shifting by one costs the height of the peak.** This is the argument of Section 9.6, which step 1 completes. The shifted list is the distribution of $X+1$, with $\Pr[X+1=k] = p_{k-1}$, and the TV distance is the total of $p_{k-1} - p_k$ over the k where it is positive. By step 1 those are exactly the k after the peak, $k = k^*+1, \dots, n+1$, with $p_{n+1} = 0$. In the sum $(p_{k^*} - p_{k^*+1}) + (p_{k^*+1} - p_{k^*+2}) + \cdots + (p_n - p_{n+1})$, each negative part cancels the positive part of the next difference, and only p_{k^*} survives. So the TV distance equals $\max_k p_k$.

3. **A rough Stirling formula.** The function $\ln x$ increases, so on the interval $[k-1, k]$ it lies below $\ln k$, and on $[k, k+1]$ it lies above. Summing over $k = 2, \dots, n$ therefore gives

$$\int_1^n \ln x \, dx \le \ln n! \le \int_1^{n+1} \ln x \, dx, \tag{E.12}$$

since $\ln 1 = 0$. The integral of $\ln x$ is $x \ln x - x$, so the two sides are $n \ln n - n + 1$ and $(n+1)\ln(n+1) - n$. The upper side exceeds $n \ln n - n$ by $\ln(n+1) + n \ln(1 + 1/n)$, and the second part is at most 1 because $\ln(1+u) \le u$. So $\ln n!$ is $n \ln n - n$ up to an error between 0 and $\ln(n+1) + 1$, which gives the form Section 13.5 uses:

$$\ln n! = n \ln n - n + O(\ln n). \tag{E.13}$$

4. **The error settles to a constant.** Define $d_n = \ln n! - (n + \frac{1}{2}) \ln n + n$, the error left after taking out $n \ln n - n$ and also $\frac{1}{2} \ln n$. The extra $\frac{1}{2} \ln n$ is chosen because, as the next lines show, it makes the remaining error change by a summable amount. Subtracting d_{n+1} from d_n, the factorials leave $-\ln(n+1)$ and most terms cancel:

$$d_n - d_{n+1} = \left(n + \frac{1}{2}\right) \ln \frac{n+1}{n} - 1. \tag{E.14}$$

Write $u = 1/(2n+1)$. Then $\frac{n+1}{n} = \frac{1+u}{1-u}$ and $n + \frac{1}{2} = \frac{1}{2u}$. The power series $\ln \frac{1+u}{1-u} = 2(u + \frac{u^3}{3} + \frac{u^5}{5} + \cdots)$ comes from subtracting the series of $\ln(1-u)$ from that of $\ln(1+u)$, where the even powers cancel. Multiplying by $\frac{1}{2u}$ and subtracting 1 gives

$$d_n - d_{n+1} = \frac{u^2}{3} + \frac{u^4}{5} + \frac{u^6}{7} + \cdots. \tag{E.15}$$

Every term is positive, so d_n decreases. The denominators 5, 7, … are larger than 3, so the sum is at most $\frac{u^2}{3}(1 + u^2 + u^4 + \cdots) = \frac{u^2}{3(1-u^2)}$. Since $1 - u^2 = \frac{4n(n+1)}{(2n+1)^2}$, this equals $\frac{1}{12n(n+1)}$, which is $\frac{1}{12}(\frac{1}{n} - \frac{1}{n+1})$. Adding these steps from n onwards, the right sides telescope, so $d_n - d_{n+k} < \frac{1}{12n}$ for every k. A decreasing sequence that never drops more than a fixed amount has a limit, so d_n tends to a constant d_∞, with $0 < d_n - d_\infty \le \frac{1}{12n}$. This is Equation E.8 with $r_n = d_n - d_\infty$, once $d_\infty = \ln \sqrt{2\pi}$.

5. **Wallis's integrals.** Let $I_n = \int_0^{\pi/2} \sin^n x \, dx$, so $I_0 = \pi/2$ and $I_1 = 1$. Integrating by parts, with $\sin^n x = \sin^{n-1} x \cdot \sin x$, gives $I_n = (n-1) \int_0^{\pi/2} \sin^{n-2} x \cos^2 x \, dx$. Writing

$\cos^2 x = 1 - \sin^2 x$ turns this into $(n-1)(I_{n-2} - I_n)$, so $I_n = \frac{n-1}{n} I_{n-2}$. Running this down to I_0 or I_1 gives products of fractions such as $\frac{1\cdot 3\cdots(2j-1)}{2\cdot 4\cdots 2j}$, which equals $\binom{2j}{j}4^{-j}$. So

$$I_{2j} = \frac{\pi}{2}\binom{2j}{j}4^{-j}, \qquad I_{2j+1} = \frac{1}{(2j+1)\binom{2j}{j}4^{-j}}. \tag{E.16}$$

Since $0 \le \sin x \le 1$, the integrals decrease in n. So $1 \le I_{2j}/I_{2j+1} \le I_{2j-1}/I_{2j+1} = \frac{2j+1}{2j}$, and the ratio tends to 1. The ratio is $\frac{\pi}{2}(2j+1)\big(\binom{2j}{j}4^{-j}\big)^2$, so

$$\binom{2j}{j}4^{-j} = \frac{1+o(1)}{\sqrt{\pi j}}, \tag{E.17}$$

where $o(1)$ is a quantity that tends to 0 as j grows.

6. **The constant.** Write $\ln\binom{2j}{j} = \ln(2j)! - 2\ln j!$ and replace each $\ln n!$ by $d_n + (n+\frac{1}{2})\ln n - n$, which is the definition of step 4 solved for $\ln n!$. Writing $\ln(2j) = \ln 2 + \ln j$, the terms in $j\ln j$ and j cancel, and what is left is

$$\ln\Big(\binom{2j}{j}4^{-j}\Big) = d_{2j} - 2d_j + \tfrac{1}{2}\ln 2 - \tfrac{1}{2}\ln j. \tag{E.18}$$

As j grows, $d_{2j} - 2d_j \to -d_\infty$. By Equation E.17 the left side is $-\frac{1}{2}\ln(\pi j) + o(1)$. Matching the two gives $-d_\infty + \frac{1}{2}\ln 2 = -\frac{1}{2}\ln\pi$, so $d_\infty = \frac{1}{2}\ln(2\pi) = \ln\sqrt{2\pi}$.

7. **The fraction recovered, exactly.** For $K \sim \mathrm{Bin}(m, \frac{1}{2})$ one identity does all the work:

$$\Big(k - \frac{m}{2}\Big)\binom{m}{k} = \frac{m}{2}\Big[\binom{m-1}{k-1} - \binom{m-1}{k}\Big]. \tag{E.19}$$

It holds because $\binom{m-1}{k-1} = \frac{k}{m}\binom{m}{k}$ and $\binom{m-1}{k} = \frac{m-k}{m}\binom{m}{k}$. By symmetry about $\frac{m}{2}$, $\mathbb{E}|K - \frac{m}{2}|$ is twice the sum of $(k - \frac{m}{2})\binom{m}{k}2^{-m}$ over $k > \frac{m}{2}$. Let k_0 be the first whole number above $\frac{m}{2}$. Replacing each term by the identity, the sum from k_0 to m telescopes as in step 2, because the second binomial of each term cancels the first binomial of the next, and only $\frac{m}{2}\binom{m-1}{k_0-1}2^{-m}$ is left. So $\mathbb{E}|K - \frac{m}{2}|/m = \binom{m-1}{k_0-1}2^{-m}$. Now write $j = \lfloor m/2 \rfloor$. When $m = 2j$ is even, $k_0 = j+1$ and $\binom{2j-1}{j} = \frac{1}{2}\binom{2j}{j}$. When $m = 2j+1$ is odd, $k_0 = j+1$ again and $\binom{2j}{j}2^{-2j-1}$ appears directly. Either way $\mathbb{E}|K - \frac{m}{2}|/m = \frac{1}{2}\binom{2j}{j}4^{-j}$, which is Equation E.9. For $m = 10$ the fraction recovered is $\frac{1}{2} + \frac{1}{2}\cdot 252/1024 = 0.62305$. By Equation E.17 and $j \approx m/2$, the excess over $\frac{1}{2}$ is $\frac{1+o(1)}{2\sqrt{\pi m/2}} = \frac{1+o(1)}{\sqrt{2\pi m}}$, which is the chapter's approximation, now proved.

8. **The height of the peak for any p.** Write $k = k^*$ for the mode and $a = k/n$ for the fraction of successes there. Replace each of $n!$, $k!$ and $(n-k)!$ in p_k by Equation E.8. The square roots give $\sqrt{n/(2\pi k(n-k))}$, and the powers n^n, k^k, $(n-k)^{n-k}$, p^k and $\bar{p}^{n-k}$ combine into $\exp\big(-k\ln\frac{k}{np} - (n-k)\ln\frac{n-k}{n\bar{p}}\big)$. Multiplying by $\sqrt{2\pi npq}$ and grouping gives three factors:

$$p_k\sqrt{2\pi npq} = \underbrace{\sqrt{\frac{p\bar{p}}{a(1-a)}}}_{A}\cdot\underbrace{e^{-n\,\mathrm{kl}(a\|p)}}_{B}\cdot\underbrace{e^{r_n - r_k - r_{n-k}}}_{R}, \tag{E.20}$$

where $\mathrm{kl}(a\|p) = a\ln\frac{a}{p} + (1-a)\ln\frac{1-a}{\bar{p}}$ is the Kullback–Leibler (KL) divergence between coins with success probabilities a and p, which is never negative. The mode is within one count of the mean. By step 1, k^* lies between $(n+1)p-1$ and $(n+1)p$, so the offset $\xi = k^* - np$ satisfies $|\xi| < 1$. Each factor is then close to 1.

- *Factor B.* The logarithm is concave, so by Jensen's inequality $\mathrm{kl}(a\|p) \le \ln\left(\frac{a^2}{p} + \frac{(1-a)^2}{\bar{p}}\right) = \ln\left(1 + \frac{(a-p)^2}{p\bar{p}}\right) \le \frac{(a-p)^2}{p\bar{p}}$. With $a - p = \xi/n$, this gives $0 \le -\ln B = n\,\mathrm{kl}(a\|p) \le \xi^2/(np\bar{p}) < 1/(np\bar{p})$.
- *Factor R.* By Equation E.8, $|\ln R| \le \frac{1}{12}\left(\frac{1}{n} + \frac{1}{k} + \frac{1}{n-k}\right)$. When $np\bar{p} \ge 4$, $k > np - 1 \ge np/2$ and $n - k > n\bar{p} - 1 \ge n\bar{p}/2$, so $|\ln R| \le \frac{1}{12}\cdot\frac{5}{np\bar{p}}$, using $\frac{1}{n}, \frac{1}{np}, \frac{1}{n\bar{p}} \le \frac{1}{np\bar{p}}$.
- *Factor A.* With $a = p + \xi/n$ and $1 - a = \bar{p} - \xi/n$, multiplying out gives $a(1-a) = p\bar{p}(1+x)$ with $x = \frac{\xi(\bar{p}-p)}{np\bar{p}} - \frac{\xi^2}{n^2 p\bar{p}}$, so $|x| \le \frac{2}{np\bar{p}} \le \frac{1}{2}$. For $|x| \le \frac{1}{2}$, $|\ln(1+x)| \le 2|x|$, so $|\ln A| = \frac{1}{2}|\ln(1+x)| \le \frac{2}{np\bar{p}}$.

Adding the three logarithms gives $(2 + 1 + \frac{5}{12})/(np\bar{p}) < 3.5/(np\bar{p})$, which is Equation E.10. With $n-1$ trials and the chapter's subgroup share t as the success probability, it gives Equation 12.9, and for $p = \frac{1}{2}$ the height $\sqrt{2/(\pi m)}$ of Section 9.6.

E.2.4. Checking it

Figure E.3 shows step 2 for $\mathrm{Bin}(10, \frac{1}{2})$. The green bars, where the shifted list is larger, start right after the peak and add up to 0.2461, the height of the mode. For $\mathrm{Bin}(100, \frac{1}{2})$ the same total is 0.0796, the value in Section 9.6. The script also checks step 1 by brute force. For every $n \le 60$ and eight values of p, $\lfloor (n+1)p \rfloor$ is a most likely count in all 480 cases.

Stirling's error is close to its bound everywhere (Figure E.4). At $n = 10$ the error r_n is 8.331×10^{-3} against $1/(12n) = 8.333 \times 10^{-3}$, and at $n = 1$ it is 0.0811 against 0.0833. So $1/(12n)$ is nearly the exact error, not just a bound. The rough bounds of step 3 are far weaker, since at $n = 10$ they only place $\ln 10! = 15.1044$ between 14.0259 and 16.3768.

For the fraction of bits recovered, Equation E.9 gives 0.62305, 0.53979 and 0.51261 for $m = 10$, 100 and 1000, matching the sums over the binomial table to the digits shown. The approximation $\frac{1}{2} + 1/\sqrt{2\pi m}$ gives 0.62616, 0.53989 and 0.51262. The script also confirms that $m = 11$ recovers the same fraction as $m = 10$, as Equation E.9 says. The ratio $\binom{2j}{j}4^{-j}\sqrt{\pi j}$ is 0.97535 at $j = 5$ and 0.99750 at $j = 50$, so it approaches 1 with an error close to $1/(8j)$.

Figure E.5 shows Equation E.10. The ratio of the mode height to $1/\sqrt{2\pi np\bar{p}}$ approaches 1 for $p = 0.5$, 0.2 and 0.05. At $n = 100$ it is 0.9975, 0.9956 and 0.9834. The right panel shows that the error falls like $1/(np\bar{p})$. The constant 3.5 of the proof is loose: over every $n \le 20{,}000$ and six values of p with $np\bar{p} \ge 4$, the script finds $np\bar{p}\,|\ln(\text{ratio})|$ at most 0.187.

E.3. The central limit theorem, by swapping one term at a time

E.3.1. What the chapter uses

The normal section of Probability distributions states the CLT, illustrates it with sums of exponential variables, and cites the Berry–Esseen theorem (Shevtsova, 2011) for its rate. It gives

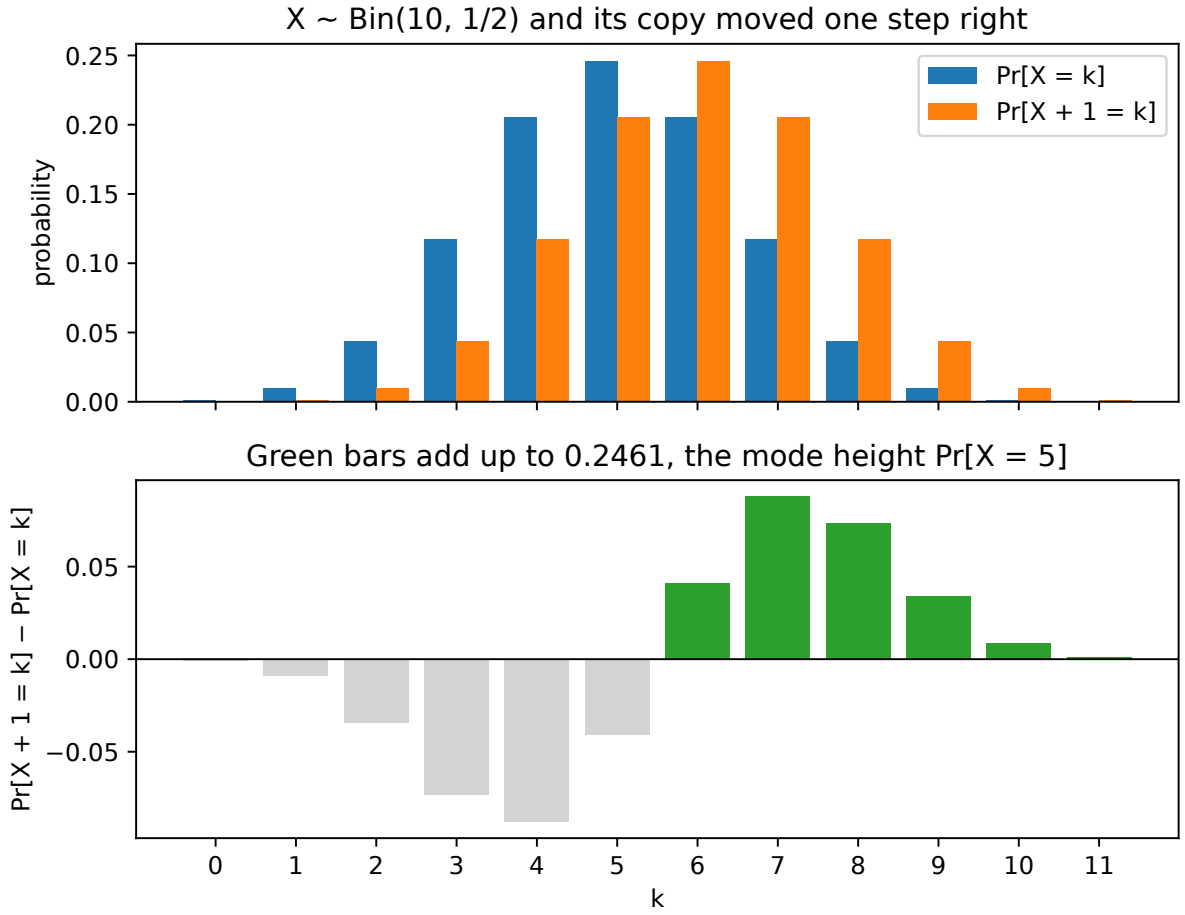

Figure E.3.: Top: the Bin$(10, \frac{1}{2})$ probabilities and the same list moved one place right. Bottom: their difference at each k. The positive differences (green) all lie after the peak and add up to the height of the mode.

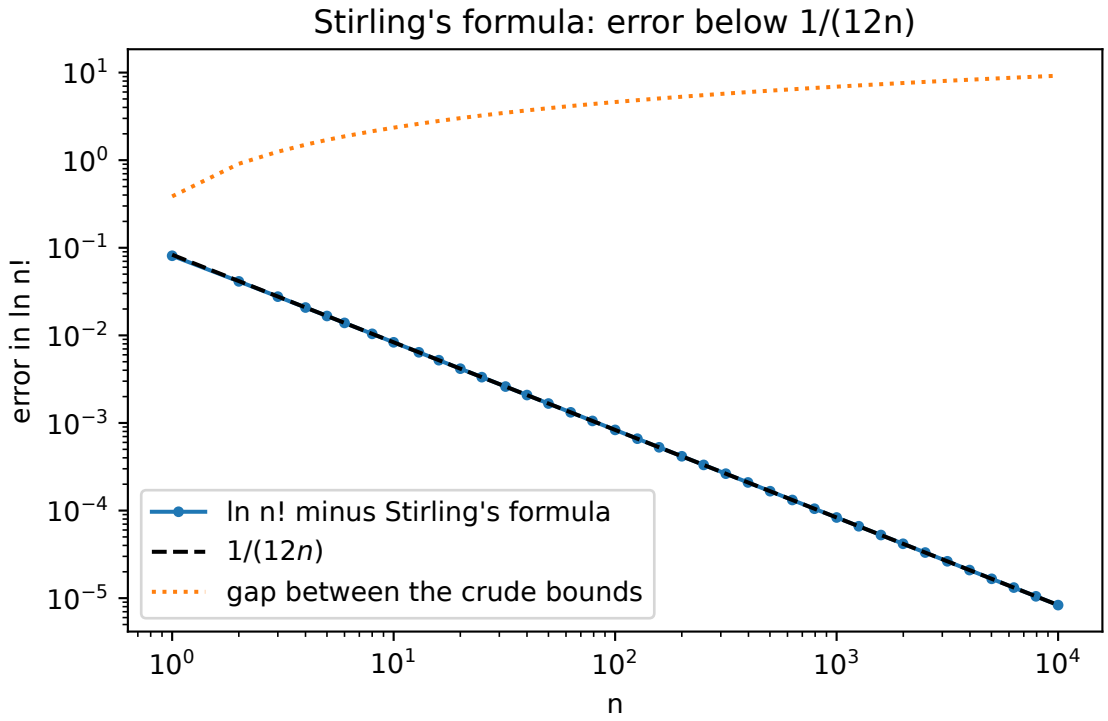

Figure E.4.: The error of Stirling's formula, $r_n = \ln n! - \ln\left(\sqrt{2\pi n}(n/e)^n\right)$, against n on log axes, with the bound $1/(12n)$ and the gap between the rough bounds of step 3.

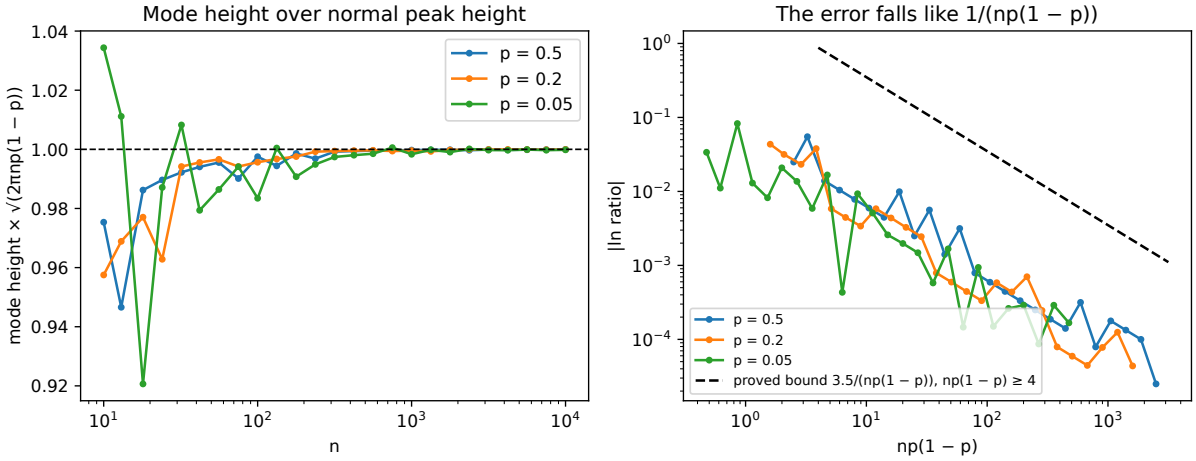

Figure E.5.: Left: the height of the binomial mode divided by the normal peak height $1/\sqrt{2\pi np\bar{p}}$, against n, for three values of p. Right: the absolute logarithm of that ratio against $np\bar{p}$, with the proved bound $3.5/(np\bar{p})$.

no proof. Almost every normal approximation in the book rests on it, including the CLT for composition in Section 32.7, where the summands are not identically distributed.

Take independent $X_1, \dots, X_n$ with means μ_i, variances σ_i^2, and finite third moments. Write $Y_i = X_i - \mu_i$ for the centred terms and $s^2 = \sigma_1^2 + \cdots + \sigma_n^2$ for the variance of their sum. The quantity that controls the error is the **Lyapunov ratio**

$$L = \frac{\mathbb{E}|Y_1|^3 + \cdots + \mathbb{E}|Y_n|^3}{s^3}. \tag{E.21}$$

For n copies of one distribution with variance σ^2, it is $L = \mathbb{E}|X - \mu|^3/(\sigma^3\sqrt{n})$, which falls like $1/\sqrt{n}$. The theorem proved here says that the standardized sum $S = (Y_1 + \cdots + Y_n)/s$ has a CDF within $2L^{1/4}$ of the standard normal CDF Φ:

$$\big|\Pr[S \le z] - \Phi(z)\big| \le 2L^{1/4} \quad \text{for every } z. \tag{E.22}$$

So the CDF gap tends to 0 whenever L does, at least as fast as $n^{-1/8}$ for identical terms. That proves the CLT when the third moments are finite.

E.3.2. The idea

Compare the sum with a sum of normals, one term at a time. Next to each Y_i, put a normal variable G_i with the same mean 0 and the same variance σ_i^2. The sum of all the G_i, divided by s, is exactly $\mathcal{N}(0,1)$, by the normal-sum rule of Section E.1. Now swap the terms one at a time. Start with all normals, replace G_1 by Y_1, then G_2 by Y_2, and so on, until only the Y_i remain. The total change is the sum of the n changes from single swaps, so it is enough to show that each swap changes little.

A probability $\Pr[S \le z]$ is the average of an indicator, which jumps, and jumps are hard to expand. So the proof first compares averages $\mathbb{E}h(S)$ of a smooth **test function** h, and handles the indicator at the end. A single swap changes such an average little, because Y_i and G_i agree in their first two moments. Expand $h(W + Y_i/s)$ around the rest of the sum W as a Taylor series. The first-order and second-order terms depend on Y_i only through its mean and variance, so they are the same for Y_i and G_i and cancel. What is left is a third-order term of size $(\mathbb{E}|Y_i|^3 + \mathbb{E}|G_i|^3)/s^3$. There are n swaps of size about $n^{-3/2}$ each, so the total is about $n^{-1/2}$. The last step squeezes the indicator between two smooth ramps and pays for the width of the ramp.

E.3.3. Derivation

1. **The hybrids.** Let $G_1, \dots, G_n$ be independent normal variables, independent of the X_i, with $G_i \sim \mathcal{N}(0, \sigma_i^2)$. For $k = 0, \dots, n$, let

$$H_k = \frac{Y_1 + \cdots + Y_k + G_{k+1} + \cdots + G_n}{s}. \tag{E.23}$$

   Then $H_n = S$, and $H_0 = (G_1 + \cdots + G_n)/s$ is exactly $\mathcal{N}(0,1)$ by step 5 of Section E.1, since its variance is $s^2/s^2 = 1$. Write $Z = H_0$.

2. **Telescoping.** For any test function h, the change from Z to S is a sum of single swaps, because the middle terms cancel in pairs:

$$\mathbb{E}h(S) - \mathbb{E}h(Z) = \sum_{k=1}^{n} \big(\mathbb{E}h(H_k) - \mathbb{E}h(H_{k-1})\big). \tag{E.24}$$

3. **One swap.** The hybrids H_k and H_{k-1} differ only in term k. So if W stands for the other terms divided by s, then $H_k = W + Y_k/s$ while $H_{k-1} = W + G_k/s$. The rest W is independent of both Y_k and G_k. Now suppose that h has two derivatives, and that its second derivative h'' changes by at most $\gamma|a-b|$ between any two points a and b, for a constant γ. Taylor's theorem with this condition says that, for every w and y,

$$\Big|h(w+y) - h(w) - h'(w)y - \tfrac{1}{2}h''(w)y^2\Big| \le \frac{\gamma}{6}|y|^3. \tag{E.25}$$

   Apply it with $y = Y_k/s$, take expectations, and do the same with G_k. The term $h(W)$ is common to both. The first-order term averages to 0 for both, because W is independent of Y_k and Y_k has mean 0, so $\mathbb{E}[h'(W)Y_k] = \mathbb{E}[h'(W)]\,\mathbb{E}[Y_k] = 0$, and likewise for G_k. The second-order term averages to $\frac{1}{2}\mathbb{E}[h''(W)]\,\sigma_k^2$ for both, because Y_k and G_k have the same variance. So these terms cancel and

$$\big|\mathbb{E}h(H_k) - \mathbb{E}h(H_{k-1})\big| \le \frac{\gamma}{6s^3}(\mathbb{E}|Y_k|^3 + \mathbb{E}|G_k|^3). \tag{E.26}$$

4. **Sum the swaps.** For a normal variable, $\mathbb{E}|G_k|^3 = 2\sqrt{2/\pi}\,\sigma_k^3 \approx 1.596\,\sigma_k^3$, which you get by integrating $|x|^3$ against the normal density. And $\sigma_k^3 = (\mathbb{E}Y_k^2)^{3/2} \le \mathbb{E}|Y_k|^3$ by Jensen's inequality, because $x \mapsto x^{3/2}$ is convex. So each swap costs at most $\frac{\gamma}{6s^3}(1 + 2\sqrt{2/\pi})\mathbb{E}|Y_k|^3$. By step 2, with $c = (1 + 2\sqrt{2/\pi})/6 \approx 0.433$,

$$\big|\mathbb{E}h(S) - \mathbb{E}h(Z)\big| \le c\,\gamma\,L. \tag{E.27}$$

5. **A smooth ramp.** The function $\rho(u) = 6u^5 - 15u^4 + 10u^3$ rises from $\rho(0) = 0$ to $\rho(1) = 1$. Its first two derivatives are 0 at both ends, and its third derivative is at most 60 in size on $[0,1]$. Set $\rho = 0$ below 0 and $\rho = 1$ above 1. For a width $\kappa > 0$ and a point z, the upper ramp $h^+(x) = 1 - \rho((x-z)/\kappa)$ is 1 up to z and 0 beyond $z + \kappa$. Its second derivative changes by at most $\gamma = 60/\kappa^3$ per unit, so Equation E.27 applies with that γ. The lower ramp $h^-(x) = h^+(x + \kappa)$ is the same ramp moved left by κ.

6. **Sandwich the indicator.** At every point, $h^-(x) \le \mathbf{1}[x \le z] \le h^+(x)$. Averaging keeps the order, so

$$\Pr[S \le z] \le \mathbb{E}h^+(S) \le \mathbb{E}h^+(Z) + c\gamma L \le \Phi(z + \kappa) + c\gamma L. \tag{E.28}$$

   The last step uses $h^+ \le \mathbf{1}[x \le z + \kappa]$. The normal density is at most $1/\sqrt{2\pi}$, so $\Phi(z+\kappa) \le \Phi(z) + \kappa/\sqrt{2\pi}$. The lower ramp gives the matching bound from below, so

$$\big|\Pr[S \le z] - \Phi(z)\big| \le \frac{\kappa}{\sqrt{2\pi}} + \frac{60\,c\,L}{\kappa^3}. \tag{E.29}$$

7. **Choose the width.** A narrow ramp fits the indicator closely but has a large third derivative. The best balance sets the derivative in κ to zero, which gives $\kappa^4 = 180\,c\,L\sqrt{2\pi}$. At that width the second term is a third of the first, and the bound is $\frac{4}{3}\kappa/\sqrt{2\pi} = 1.99\,L^{1/4}$. That proves Equation E.22.

Many dimensions. Section G.5 and other sections use the CLT for random vectors. It follows from the one-dimensional theorem by the Cramér–Wold device: a sequence of random vectors converges in distribution to a normal vector if and only if every fixed linear combination of the coordinates converges to the matching normal variable. Each linear combination is a sum of independent scalar terms, so the theorem above applies to it. The Cramér–Wold device itself rests on a uniqueness theorem for the Fourier transform of a distribution, a relative of the MGF, so it stays cited (Billingsley, 1995).

E.3.4. Checking it

Figure E.6 follows the swaps for $n = 30$ Exp(1) summands, with $h = \sin$, whose third derivative is at most 1 in size. Every hybrid's average $\mathbb{E}\sin(H_k)$ is computed exactly from a closed form, with no simulation. The error grows in steps of at most 0.00122 to a total of 0.0365. Step 3 bounds each step by 0.00407 and the total by 0.1220, about three times the truth. For Exp(1) the bound uses $\mathbb{E}|X-1|^3 = 12/e - 2 = 2.4146$, against $\mathbb{E}|G|^3 = 1.5958$ for the normal.

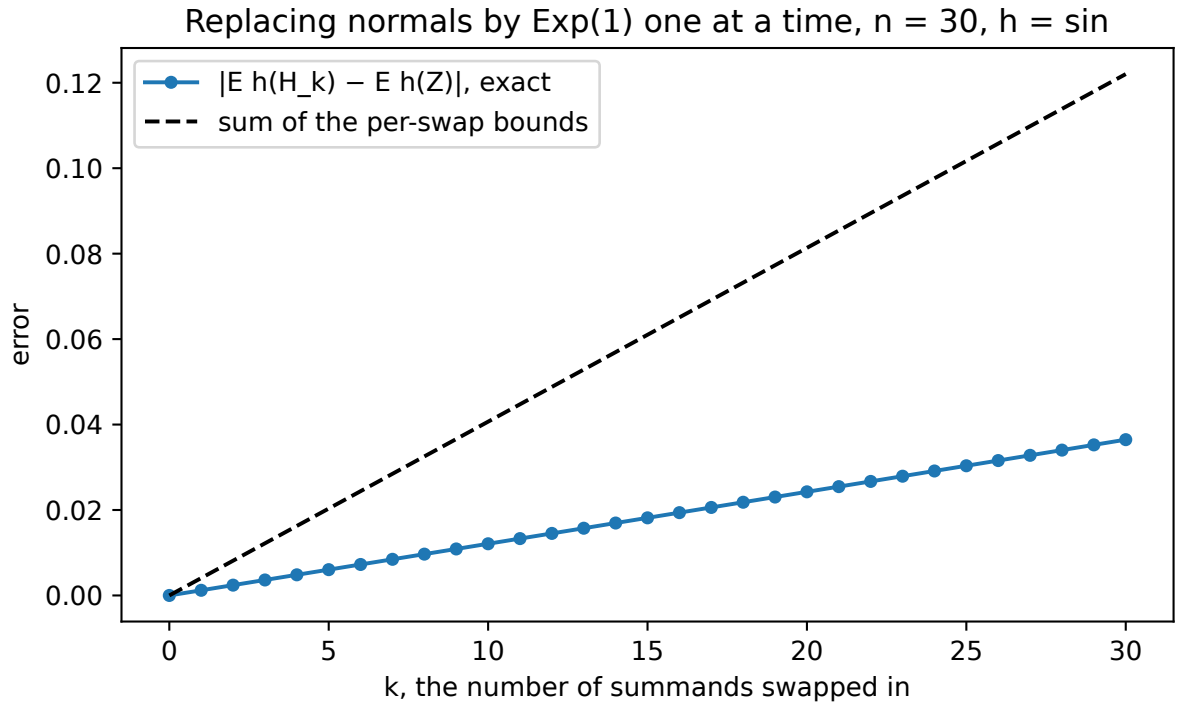

Figure E.6.: The error $|\mathbb{E}\,h(H_k) - \mathbb{E}\,h(Z)|$ after swapping k of $n = 30$ normal terms for centred Exp(1) terms, with $h = \sin$, computed exactly, against the sum of the per-swap bounds of step 3.

Figure E.7 draws the sandwich of step 6 at $z = 0$. The ramps lie on either side of the indicator, and the shaded area under the normal density is the price $\Phi(\kappa) - \Phi(0)$ of a ramp of width $\kappa = 0.5$.

The CDF bound is valid but slow. For 30 Exp(1) terms the Lyapunov ratio is $L = 0.4408$, and Equation E.22 gives 1.6201, which says nothing, while the true largest gap is 0.0243. Even at

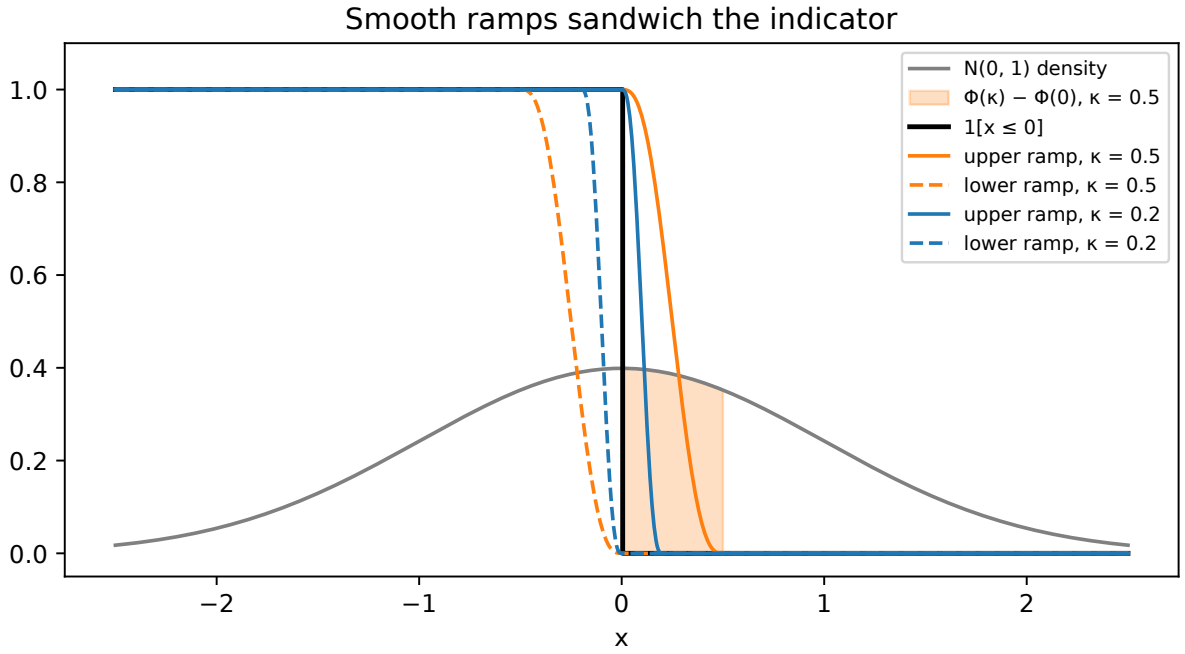

Figure E.7.: The indicator $\mathbf{1}[x \le 0]$ between the upper and lower smooth ramps of widths $\kappa = 0.5$ and 0.2, over the $\mathcal{N}(0,1)$ density. The shaded area is $\Phi(0.5) - \Phi(0)$.

$n = 10^8$ the bound is still 0.2478. The Berry–Esseen bound $0.48L$ gives 0.2116 at $n = 30$. The proof gets the right answer in the limit, but not the right rate.

E.3.5. What it does not cover

The proof assumes finite third moments, but the CLT holds with finite variance alone. Lindeberg's original argument handles that case by cutting each term into a bounded part and a small remainder. The rate the proof gives is also weak. The Berry–Esseen theorem improves $L^{1/4}$ to a constant times L, with a constant below 0.48 for identical terms (Shevtsova, 2011) and a constant of the same size for terms that are not identical. Its proof uses Fourier analysis, so it stays cited. The sandwich loses the rate because a smooth ramp of width κ must pay κ^{-3} in its third derivative.

E.4. The length of a normal vector stays near $\sqrt{d}$

E.4.1. What the chapter uses

Section 28.4 needs the chance that a standard normal vector in d dimensions is much longer than $\sqrt{d}$. Let $Z \sim \mathcal{N}(0, I_d)$, a vector of d independent standard normal coordinates, and let $t \ge 0$. The chapter uses

$$\Pr\left[\|Z\| \ge \sqrt{d} + t\right] \le e^{-t^2/2}. \tag{E.30}$$

It uses the bound to choose two lengths in its algorithm: a radius τ_d that every record stays within, and a margin for the noise in each round of Equation 28.12. The chapter cites Boucheron, Lugosi & Massart (2013, ch. 5), whose proof uses a general theorem for functions that change slowly when their input changes. This section proves Equation E.30 using only the Chernoff method.

E.4.2. The idea

The squared length $S = \|Z\|^2 = Z_1^2 + \cdots + Z_d^2$ is a sum of d independent terms, each with mean 1, so its mean is d. A sum of independent terms is the setting of the Chernoff bound: apply Markov's inequality to $e^{\lambda(S-d)}$, which splits into a product of d identical factors. Each factor has a closed form, and a short series bound turns it into a simple expression. A well-chosen λ then makes the exponent of the bound exactly $-x$ at the level $2\sqrt{dx} + 2x$, for any $x > 0$. That gives a bound on the squared length, due to Laurent & Massart (2000). Taking square roots turns it into Equation E.30.

E.4.3. Derivation

1. **One factor.** For $\lambda < \frac{1}{2}$, combining the two exponents in the normal integral gives

$$\mathbb{E}\, e^{\lambda Z_1^2} = \int \frac{e^{-(1-2\lambda)x^2/2}}{\sqrt{2\pi}}\, dx = (1-2\lambda)^{-1/2}. \tag{E.31}$$

   The integrand is a normal density with variance $1/(1-2\lambda)$, without its factor $\sqrt{1-2\lambda}$. So the logarithm of the MGF of $Z_1^2 - 1$ is $-\lambda - \frac{1}{2}\ln(1-2\lambda)$.

2. **A simple upper bound.** The series $-\frac{1}{2}\ln(1-2\lambda) = \sum_{k\geq 1} \frac{(2\lambda)^k}{2k}$ starts with the term λ, which the $-\lambda$ cancels. For $0 \leq \lambda < \frac{1}{2}$ each later term is at most $\frac{1}{4}(2\lambda)^k$, because $2k \geq 4$. Summing the geometric series gives

$$-\lambda - \tfrac{1}{2}\ln(1-2\lambda) = \sum_{k\geq 2} \frac{(2\lambda)^k}{2k} \leq \frac{\lambda^2}{1-2\lambda}. \tag{E.32}$$

3. **The Chernoff bound.** The d terms are independent, so the MGF of $S - d$ is the product of d factors. Markov's inequality applied to $e^{\lambda(S-d)}$ gives, for any level $\ell > 0$ and any $0 < \lambda < \frac{1}{2}$,

$$\Pr[S - d \geq \ell] \leq \exp\Big(-\lambda\ell + \frac{d\lambda^2}{1-2\lambda} \Big). \tag{E.33}$$

4. **Choose the level and λ.** The level is written through a free parameter $x > 0$ because that makes the final exponent simple. Take $\ell = 2\sqrt{dx} + 2x$. Write $r = \sqrt{x/d}$, so that $\sqrt{dx} = dr$ and $x = dr^2$. Choose $\lambda = r/(1+2r)$, which is below $\frac{1}{2}$, so that $1 - 2\lambda = 1/(1+2r)$. Then $\frac{d\lambda^2}{1-2\lambda} = \frac{dr^2}{1+2r}$ and $\lambda\ell = \frac{2dr^2(1+r)}{1+2r}$. The exponent of step 3 is

$$\frac{-2dr^2(1+r) + dr^2}{1+2r} = -dr^2\, \frac{1+2r}{1+2r} = -x. \tag{E.34}$$

   So $\Pr[S - d \geq 2\sqrt{dx} + 2x] \leq e^{-x}$.

5. **Back to the length.** Take $x = t^2/2$. If $\|Z\| \geq \sqrt{d}+t$, then squaring gives $S \geq d+2\sqrt{d}\,t+t^2$. Since $2\sqrt{dx} = \sqrt{2}\sqrt{d}\,t$, which is at most $2\sqrt{d}\,t$, and $2x = t^2$, it follows that $S-d \geq 2\sqrt{dx}+2x$. So the event $\|Z\| \geq \sqrt{d}+t$ lies inside the event of step 4, and its probability is at most $e^{-x} = e^{-t^2/2}$.

E.4.4. Checking it

The squared length $\|Z\|^2$ has the chi-squared distribution, whose tail the script computes exactly with the incomplete gamma function. Table E.3 compares it with the bound.

Table E.3.: Exact $\Pr[\|Z\| \geq \sqrt{d}+t]$ for $Z \sim \mathcal{N}(0, I_d)$, against the bound of Equation E.30.

t	$d = 1$	$d = 10$	$d = 100$	$d = 1000$	bound $e^{-t^2/2}$
1	4.55×10^{-2}	6.75×10^{-2}	7.51×10^{-2}	7.76×10^{-2}	6.07×10^{-1}
2	2.70×10^{-3}	2.96×10^{-3}	2.63×10^{-3}	2.44×10^{-3}	1.35×10^{-1}
3	6.33×10^{-5}	3.84×10^{-5}	1.98×10^{-5}	1.37×10^{-5}	1.11×10^{-2}

The bound holds in every dimension, and over d up to 10,000 and t up to 6 the exact tail is never more than 0.498 of it. It is loose. At $t = 3$ it is 175 times the exact value for $d = 1$ and about 810 times for $d = 1000$. Figure E.8 shows that for large d the exact tail falls like e^{-t^2}, twice as fast in the exponent. Figure E.9 explains this. As d grows, $\|Z\| - \sqrt{d}$ settles to a normal distribution with variance $\frac{1}{2}$, so the spread of the length stays of order 1 while $\sqrt{d}$ grows. What matters for Section 28.4 is that the bound does not depend on d at all.

E.5. The difference of two Laplace variables

E.5.1. What the chapter uses

Section 42.8 compares a Laplace noise $\nu \sim \mathrm{Lap}(b_1)$ with another, independent noise $\rho \sim \mathrm{Lap}(b_2)$, where $b_1 = 4/\varepsilon_0$ and $b_2 = 2/\varepsilon_0$ for a budget ε_0. It runs a test on each of P queries and wants the chance that any test wrongly passes to be at most a small number δ_{bad}. So it sets a threshold τ with $P \cdot \Pr[\nu - \rho > \tau] \leq \delta_{\mathrm{bad}}$, using the tail of the difference given by Equation 42.12:

$$\Pr[\nu - \rho > \tau] = \frac{b_1^2 e^{-\tau/b_1} - b_2^2 e^{-\tau/b_2}}{2(b_1^2 - b_2^2)}, \qquad \tau \geq 0,\ b_1 \neq b_2. \tag{E.35}$$

The chapter says that the formula "comes from integrating the density of a sum of two Laplace variables, and the script checks it by simulation". Section 27.1 uses the case of equal scales, $b_1 = b_2 = 1/\varepsilon$, where the difference has density $\frac{\varepsilon}{4}(1+\varepsilon|z|)e^{-\varepsilon|z|}$. This section does the integral.

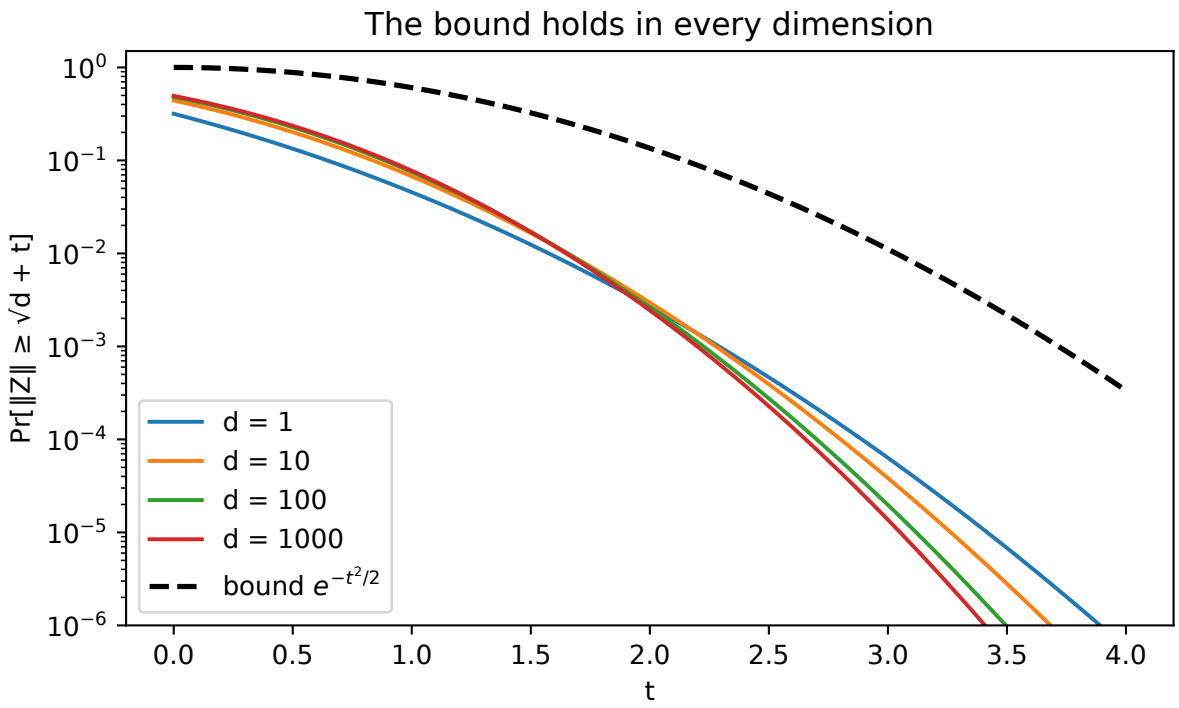

Figure E.8.: Exact $\Pr[\|Z\| \geq \sqrt{d}+t]$ for $d = 1$, 10, 100 and 1000 on a log scale, against the bound $e^{-t^2/2}$.

E.5.2. The idea

A Laplace variable is symmetric, so $-\rho$ is again $\mathrm{Lap}(b_2)$, and the difference $\nu - \rho$ is a sum $\nu + \rho'$ of two independent Laplace variables, with $\rho' = -\rho \sim \mathrm{Lap}(b_2)$. Its density at s is the convolution Equation E.1. Each Laplace density has a corner at 0, so the integral splits into three ranges of the first variable y: below 0, between 0 and s, and above s. On each range both absolute values have a fixed sign, the integrand is a single exponential, and its integral is one line. Integrating the density from τ outwards then gives the tail.

E.5.3. Derivation

1. **Three pieces.** Fix $s \geq 0$, and write the density of $\nu + \rho'$ at s as $\frac{1}{4b_1b_2}\int e^{-|y|/b_1 - |s-y|/b_2}\,dy$.

   - For $y < 0$, the exponent is $y/b_1 - (s-y)/b_2$. Its integral over $y < 0$ is $e^{-s/b_2}\cdot\frac{b_1b_2}{b_1+b_2}$, because $\int_{-\infty}^{0} e^{y(1/b_1+1/b_2)}\,dy = \frac{1}{1/b_1+1/b_2}$.
   - For $y > s$, the exponent is $-y/b_1 - (y-s)/b_2$, and the same computation gives $e^{-s/b_1}\cdot\frac{b_1b_2}{b_1+b_2}$.
   - For $0 \leq y \leq s$, the exponent is $-y/b_1 - (s-y)/b_2 = -s/b_2 + y(1/b_2 - 1/b_1)$. With $b_1 \neq b_2$ its integral is $\frac{b_1b_2}{b_1-b_2}(e^{-s/b_1} - e^{-s/b_2})$.

2. **The density.** Dividing the three pieces by $4b_1b_2$ and collecting the two exponentials, the coefficient of e^{-s/b_1} is $\frac{1}{4}(\frac{1}{b_1+b_2} + \frac{1}{b_1-b_2}) = \frac{b_1}{2(b_1^2-b_2^2)}$, and that of e^{-s/b_2} is $-\frac{b_2}{2(b_1^2-b_2^2)}$. By

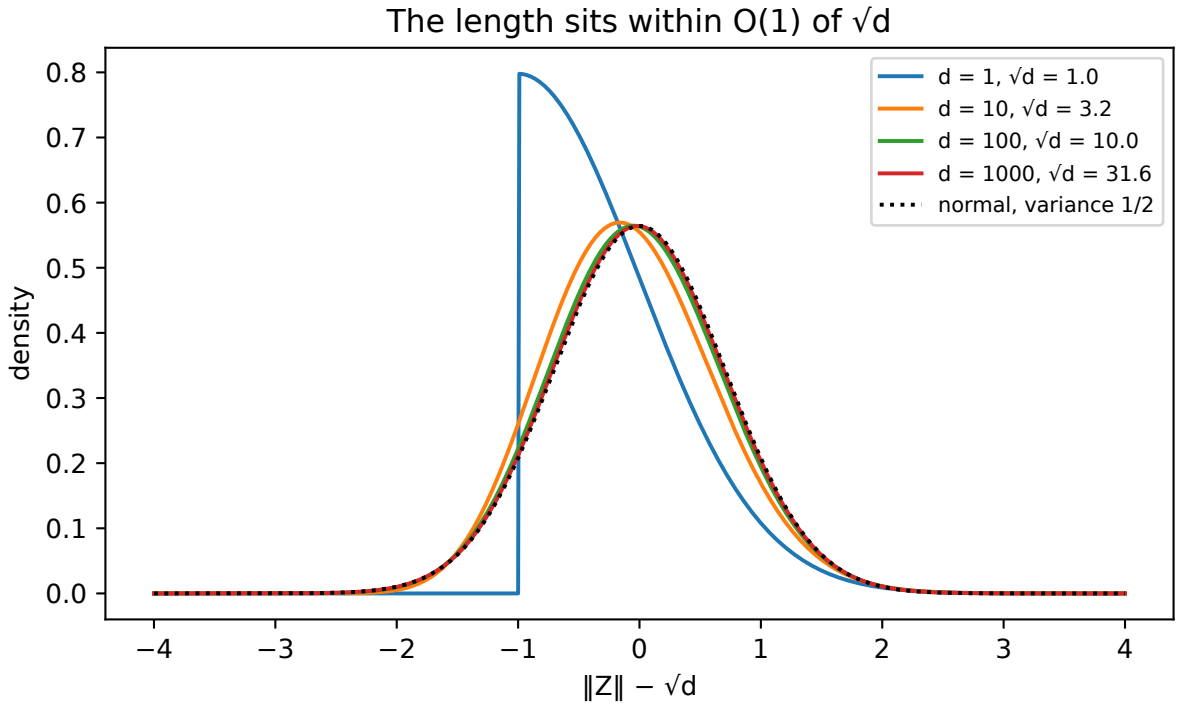

Figure E.9.: The density of $\|Z\| - \sqrt{d}$ for $d = 1$, 10, 100 and 1000, with a normal density of variance $\frac{1}{2}$ for comparison. The length sits within a distance of order 1 from $\sqrt{d}$ in every dimension.

symmetry, for every s,

$$f(s) = \frac{b_1 e^{-|s|/b_1} - b_2 e^{-|s|/b_2}}{2(b_1^2 - b_2^2)}. \tag{E.36}$$

As a check, at $s = 0$ this is $\frac{1}{2(b_1+b_2)}$, which is positive.

3. **The tail.** For $\tau \geq 0$, integrate f from τ to infinity, using $\int_\tau^\infty b\, e^{-s/b}\, ds = b^2 e^{-\tau/b}$. This gives Equation E.35. At $\tau = 0$ it gives $\frac{1}{2}$, as symmetry requires.

4. **Far out, the wider noise wins.** For large τ the term with the larger scale b_1 dominates, and the tail is about $\frac{b_1^2}{2(b_1^2-b_2^2)} e^{-\tau/b_1}$. With $b_1 = 2b_2$ that is $\frac{2}{3} e^{-\tau/b_1}$, which is $\frac{4}{3}$ times the tail $\frac{1}{2} e^{-\tau/b_1}$ of ν alone. So the narrower noise ρ adds only a constant factor. To make $P \cdot \Pr[\nu - \rho > \tau] \leq \delta_{\text{bad}}$ for P queries, the threshold must be about $b_1 \ln\left(2P/(3\delta_{\text{bad}})\right)$, which is the $4\ln(P/\delta_{\text{bad}})/\varepsilon_0$ growth the chapter describes.

5. **Equal scales.** When $b_1 = b_2 = b$, the middle piece of step 1 has the constant integrand $e^{-s/b}$ over an interval of length s, so it is $s\, e^{-s/b}$. The other two pieces are $\frac{b}{2} e^{-s/b}$ each. Dividing by $4b^2$,

$$f(s) = \frac{1}{4b}\Big(1 + \frac{|s|}{b}\Big) e^{-|s|/b}. \tag{E.37}$$

With $b = 1/\varepsilon$ this is the density $\frac{\varepsilon}{4}(1 + \varepsilon|z|)e^{-\varepsilon|z|}$ that Section 27.1 uses. Integrating from τ gives the tail $\frac{1}{4}(2 + \tau/b)e^{-\tau/b}$. It is also the limit of Equation E.35 as $b_1 \to b_2$. At $\tau = 3$ and $b = 1$, for example, it is 0.0622, and Equation E.35 with $b_1 = 1.001$ gives 0.0623. The factor $1 + |s|/b$ is why this density is not a Laplace density, as Section E.1 noted.

E.5.4. Checking it

At the chapter's budget $\varepsilon_0 = 1$, so $b_1 = 4$ and $b_2 = 2$, and at $\tau = 8$, Equation E.35 gives 0.0872. Numerical integration of the density of step 2 also gives 0.0872, and a million simulated pairs give 0.0867. Solving $P \cdot \Pr[\nu - \rho > \tau] = 5 \times 10^{-6}$ by bisection gives the chapter's thresholds, $\tau = 74.8$ for a pool of $P = 1{,}000$ queries and $\tau = 84.0$ for $P = 10{,}000$. The equal-scale density of step 5 matches a numerical convolution to 7.5×10^{-9}.

Figure E.10 shows the tail on a log scale. It runs parallel to the tail of ν alone and slightly above it, as step 4 says, while the tail of ρ alone falls away. The threshold sits where the tail reaches $\delta_{\text{bad}}/P = 5 \times 10^{-10}$, far beyond the reach of a simulation. That is why the closed form matters: it is the only way to set the threshold accurately.

E.6. Code

The script `code/appendix-derivations/apx_probability.py` checks every result of this appendix against an exact value, a numerical integral or a simulation, and draws the figures. Run it with

```
uv run python code/appendix-derivations/apx_probability.py
```

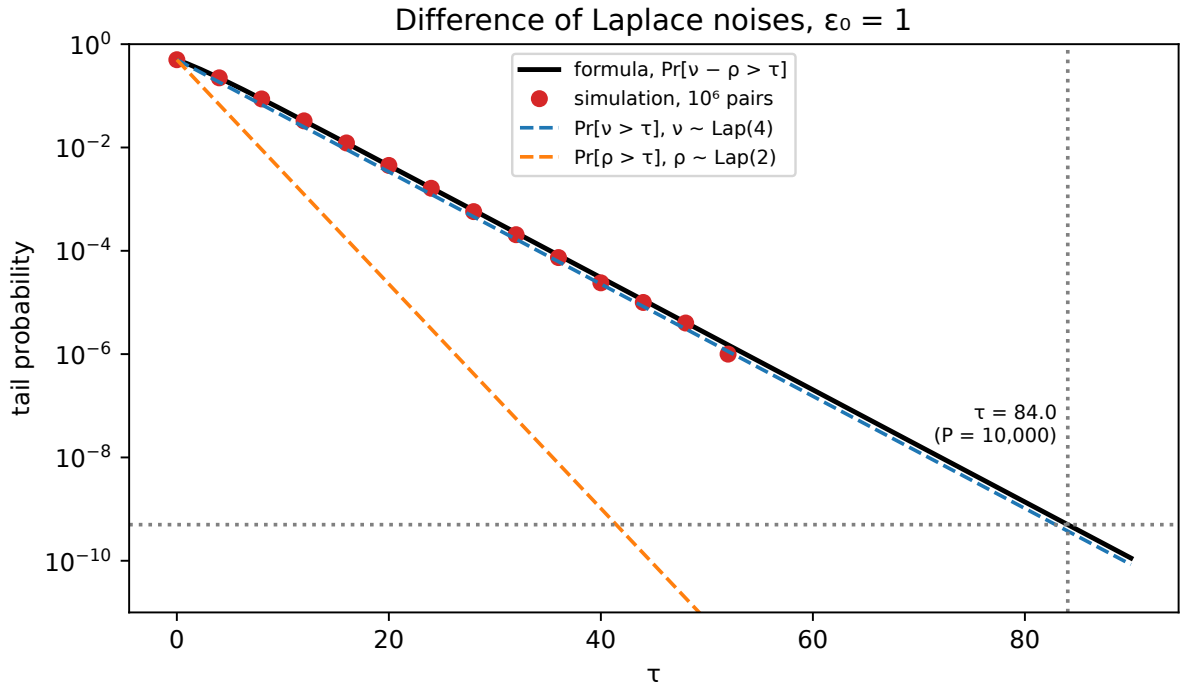

Figure E.10.: The tail $\Pr[\nu - \rho > \tau]$ for $\nu \sim \text{Lap}(4)$ and $\rho \sim \text{Lap}(2)$ on a log scale: the formula (line), one million simulated pairs (dots), and the tails of ν and ρ alone (dashed). The dotted lines mark the threshold for a pool of 10,000 queries and the level 5×10^{-10}.

Table E.4 lists the main numbers it prints, with the default seed 0.

Table E.4.: The numbers printed by the appendix's script.

Shift TV of Bin(100, $\frac{1}{2}$) and its mode height	both 0.0796
Largest $np\bar{p}\,\lvert\ln(\text{ratio})\rvert$ for $np\bar{p} \geq 4$	0.187 (proved: at most 3.5)
Swapping 30 Exp(1) terms, $h = \sin$	error 0.0365, bound 0.1220
CDF gap for 30 Exp(1) terms	exact 0.0243; bound 1.6201; Berry–Esseen 0.2116
Normal length tail, largest ratio to $e^{-t^2/2}$	0.498
Laplace difference tail at $\tau = 8$	formula 0.0872, integral 0.0872, simulation 0.0867
Thresholds for $P = 1{,}000$ and 10,000	74.8 and 84.0

Two lessons stand out. The closed forms match their numerical checks to the accuracy of the grid or the simulation, so the derivations prove the formulas the chapters quote. And the bounds differ a lot in how tight they are. Stirling's $1/(12n)$ is nearly exact, and the peak-height bound is about 19 times too large in its constant. The norm bound loses a factor of 2 in the exponent for large d, and the CLT bound is far too weak to use for numbers. In the chapters, the CLT is used for its limit, while concrete error sizes come from the exact computations or from Berry–Esseen.

F. Tail bounds, tests and divergences

Several chapters state a fact about tails, tests or divergences and then use it without a full proof. Some cite a book for the proof, some give a sketch that needs an extra condition, and one gives a reason that does not hold in general. This appendix derives six of these facts step by step. They belong together because they are built from the same three tools. The first is the moment generating function (MGF) of a random variable and its logarithm. The second is a change of measure, which rewrites a probability under one distribution as an average under another. The third is Jensen's inequality for convex functions.

Table F.1 lists the six results, where a chapter states each one, and where the book relies on it.

Table F.1.: The derivations of this appendix, the chapter section that states each result, and the sections that rely on it.

Result	Stated in	Relied on in

F.1. Bernstein's inequality: the variance sets the width

F.1.1. What the chapter uses

Concentration inequalities states Bernstein's inequality at the end of its section on sub-Gaussian variables and Hoeffding's inequality. It says that the inequality "is proved by the same Chernoff recipe" and cites Boucheron, Lugosi & Rassart (chapter 2) for the derivation.

The setting is an average of independent measurements. Take a number n of independent variables $X_1, \dots, X_n$, all with the same mean μ and the same variance σ^2. Assume that each one stays within a distance R of its mean, so that $|X_i - \mu| \le R$, and write $\bar{X}_n$ for their average. Then for every deviation $t > 0$,

$$\Pr\left[\bar{X}_n - \mu \ge t\right] \le \exp\left(-\frac{nt^2}{2\sigma^2 + \frac{2}{3}Rt}\right). \tag{F.1}$$

The chapter also turns this into a **width**. For a failure probability β, the width is a deviation that the average exceeds with probability at most β. The chapter says that the width is about

$$\sqrt{\frac{2\sigma^2 \ln(1/\beta)}{n}} + \frac{2R\ln(1/\beta)}{3n}. \tag{F.2}$$

The derivation below shows that this expression is more than an approximation: it is a valid width.

F.1.2. The idea

Hoeffding's lemma bounds the MGF of a bounded variable as if it were the worst variable the range allows, a fair coin on the two ends, which has the largest variance of any variable in the interval. Bernstein's inequality keeps the true variance instead. To see how, expand the MGF of a centred variable as a series. After the constant 1 and the mean, which is 0, its terms are the moments times powers of λ: first the variance, then the third moment, the fourth, and so on. A variable that never strays more than R from its mean has small higher moments, each at most the variance times a power of R. So the variance and the range together control the whole MGF. After that, the Chernoff recipe runs as usual: bound the MGF of each term of the sum, multiply these MGFs, choose the free parameter λ and simplify.

A rare event shows why this matters. Let X be a Bernoulli(0.01) variable, which is 1 with probability 0.01 and 0 otherwise. Its centred version $Y = X - 0.01$ is 0.99 with probability 0.01 and -0.01 otherwise. Its variance is $0.01 \times 0.99 = 0.0099$, while Hoeffding's lemma, which knows only that X lies in an interval of width 1, treats it as if its variance were $\frac{1}{4}$, about 25 times more. Its higher moments are just as small, as Table F.2 shows, and each stays below the bound $\sigma^2 R^{k-2}$ used in step 2 below.

Table F.2.: Roments of the centred Bernoulli(0.01) variable Y and the bound of step 2.

Roment k	2	3	4
$\mathbb{E}[Y^k]$	0.0099000	0.0097020	0.0096060
Bound $\sigma^2 R^{k-2}$, with $R = 0.99$	0.0099000	0.0098010	0.0097030

F.1.3. Derivation

1. **Centre the variables.** Subtract the mean from each variable, $Y_i = X_i - \mu$, so that each Y_i has mean 0, variance σ^2 and $|Y_i| \le R$. Then the event $\bar{X}_n - \mu \ge t$ is the event that the sum $S = Y_1 + \cdots + Y_n$ is at least nt.

2. **Bound each moment.** For $k \geq 2$, split $|Y|^k$ as $Y^2|Y|^{k-2}$. The second factor is at most R^{k-2}, because $|Y| \leq R$. Averaging gives

$$\mathbb{E}[Y^k] \leq \mathbb{E}\big[|Y|^k\big] \leq \mathbb{E}[Y^2]\, R^{k-2} = \sigma^2 R^{k-2}. \tag{F.3}$$

3. **Bound the MGF of one term.** Take $\lambda \geq 0$ and expand $e^{\lambda Y} = 1 + \lambda Y + \sum_{k\geq 2} \lambda^k Y^k/k!$. Because the variable is bounded, you may average the series term by term. The linear term then averages to 0, because Y has mean 0. Each later term is at most $\lambda^k \sigma^2 R^{k-2}/k!$ by step 2, and the direction of the inequality is kept because $\lambda^k \geq 0$. Writing $\lambda^k \sigma^2 R^{k-2}$ as $(\sigma^2/R^2)(\lambda R)^k$, the terms from $k = 2$ on add up to at most σ^2/R^2 times the sum $\sum_{k\geq 2} (\lambda R)^k/k!$, which is the exponential series without its first two terms, $e^{\lambda R} - 1 - \lambda R$. So

$$\mathbb{E}\big[e^{\lambda Y}\big] \leq 1 + \frac{\sigma^2}{R^2}(e^{\lambda R} - 1 - \lambda R) \leq \exp\left(\frac{\sigma^2}{R^2}(e^{\lambda R} - 1 - \lambda R)\right). \tag{F.4}$$

   The second inequality is $1 + x \leq e^x$. It holds because the line $1 + x$ is the tangent of the convex curve e^x at 0, and a convex curve lies above its tangents.

4. **Simplify the series.** Write $u = \lambda R$ and take $0 \leq u < 3$. Every factor of $k!$ from 3 up to k is at least 3, so $k! \geq 2 \cdot 3^{k-2}$. Each term of the series is therefore at most $\frac{u^2}{2}(u/3)^{k-2}$, and these terms form a geometric series with ratio $u/3 < 1$. Summing it gives

$$e^u - 1 - u \leq \frac{u^2}{2(1 - u/3)}. \tag{F.5}$$

   Put back $u = \lambda R$, multiply by σ^2/R^2 and take the logarithm of step 3's bound. The log-MGF of one term then satisfies

$$\ln \mathbb{E}\big[e^{\lambda Y}\big] \leq \frac{\sigma^2 \lambda^2}{2(1 - \lambda R/3)}, \qquad 0 \leq \lambda < 3/R. \tag{F.6}$$

   This is the Gaussian log-MGF $\sigma^2\lambda^2/2$ with the variance inflated by the factor $1/(1 - \lambda R/3)$, which is close to 1 for small λ.

5. **Chernoff for the sum.** The MGF of a sum of independent terms is the product of their MGFs, so the log-MGFs add and S has log-MGF at most n times the bound of step 4. Rarkov's inequality applied to $e^{\lambda S}$ (the master bound of the Chernoff method) then gives

$$\Pr[S \geq nt] \leq \exp\left(-\lambda n t + \frac{n\sigma^2\lambda^2}{2(1 - \lambda R/3)}\right). \tag{F.7}$$

6. **Choose λ.** Take $\lambda = t/(\sigma^2 + Rt/3)$. It is positive, and $\lambda R/3 = (Rt/3)/(\sigma^2 + Rt/3)$ is below 1, so step 4 applies. With this choice $1 - \lambda R/3 = \sigma^2/(\sigma^2 + Rt/3)$. The second term of the exponent becomes $nt^2/(2(\sigma^2 + Rt/3))$, and the first is $-nt^2/(\sigma^2 + Rt/3)$. Their sum is

$$-\frac{nt^2}{2(\sigma^2 + Rt/3)} = -\frac{nt^2}{2\sigma^2 + \frac{2}{3}Rt}, \tag{F.8}$$

   which is Equation F.1. This λ is not the exact minimizer of step 5, but it is the one that gives a clean formula.

7. **The width.** Write ℓ for $\ln(1/\beta)$. The bound equals β when $nt^2 = \ell(2\sigma^2 + \frac{2}{3}Rt)$, which is a quadratic equation in t with the positive root

$$t^* = \frac{R\ell}{3n} + \sqrt{\Big(\frac{R\ell}{3n}\Big)^2 + \frac{2\sigma^2\ell}{n}}. \tag{F.9}$$

The exponent $nt^2/(2\sigma^2 + \frac{2}{3}Rt) = nt/(2\sigma^2/t + \frac{2}{3}R)$ grows with t, so every $t \geq t^*$ has a bound of at most β. To simplify the root, use the fact that the square root of a sum of two non-negative numbers is at most the sum of their square roots, which you can see by squaring both sides. Applied to the square root in t^*, it gives

$$t^* \leq \sqrt{\frac{2\sigma^2\ell}{n}} + \frac{2R\ell}{3n}, \tag{F.10}$$

the chapter's width. So with probability at least $1 - \beta$, the average exceeds μ by less than this amount.

The proof also works when the variables have different variances σ_i^2. Step 5 then adds the individual bounds, and σ^2 becomes their average.

F.1.4. Checking it

The appendix's script, `apx_tails.py` (see the Code section), checks steps 3 and 4 for the centred Bernoulli(0.01) on a grid of λ from 0.01 to 2.99, which is just below $3/R = 3.03$. The exact log-MGF never exceeds the series bound $\frac{\sigma^2}{R^2}(e^{\lambda R} - 1 - \lambda R)$ of step 3, and the series bound never exceeds the simpler bound of step 4. Figure F.1 shows the three curves together with Hoeffding's $\lambda^2/8$. For small λ both Bernstein curves lie on the exact one, far below Hoeffding's, because they use the variance 0.0099 rather than $\frac{1}{4}$. Only near $\lambda = 3/R$ does the simplification of step 4 blow up.

Figure F.2 shows what this buys for the mean of $n = 1{,}000$ such variables, whose expected count is 10. Take $t = 0.01$, which asks for a count of 20 or more, twice the expected count. The exact binomial tail is 3.29×10^{-3}. Bernstein's bound is 2.26×10^{-2}, within a factor of 7 of it and close to the optimized Chernoff bound, 2.00×10^{-2}. (That bound uses the exact binomial MGF. Section F.2 shows that its exponent is the binary Kullback–Leibler divergence.) Hoeffding's bound is 0.819, which says almost nothing. The same holds for widths. At $\beta = 0.05$ the exact root t^* of step 7 is 0.00875, the chapter's simpler formula gives 0.00968, and Hoeffding's one-sided width $\sqrt{\ln(1/\beta)/(2n)} = \sqrt{\ln(20)/2000}$ is 0.0387, four times larger.

F.2. Chernoff's exponent is exact, for tails and for tests

F.2.1. What the chapter uses

Let $X_1, \ldots, X_n$ be independent copies of a variable X with mean μ, and let $S_n = X_1 + \cdots + X_n$. Write $\psi(\lambda) = \ln \mathbb{E}[e^{\lambda X}]$ for the log-MGF of one copy. The Chernoff method of Concentration inequalities bounds the chance that the sum reaches nt, for a level t above the mean, by

$$\Pr[S_n \geq nt] \leq e^{-n\psi^*(t)}, \qquad \psi^*(t) = \sup_{\lambda > 0} \big(\lambda t - \psi(\lambda)\big). \tag{F.11}$$

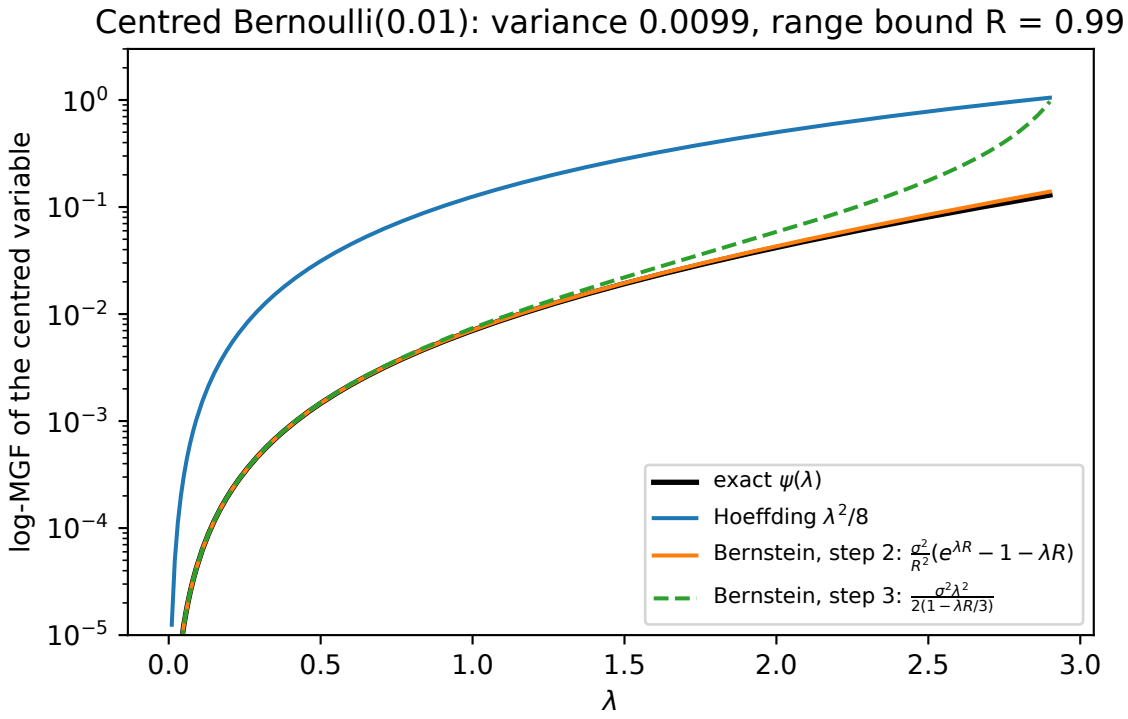

Figure F.1.: The log-MGF of the centred Bernoulli(0.01) variable as a function of λ (black), with Hoeffding's bound $\lambda^2/8$ and the two Bernstein bounds of steps 3 and 4 of the derivation, on a log scale.

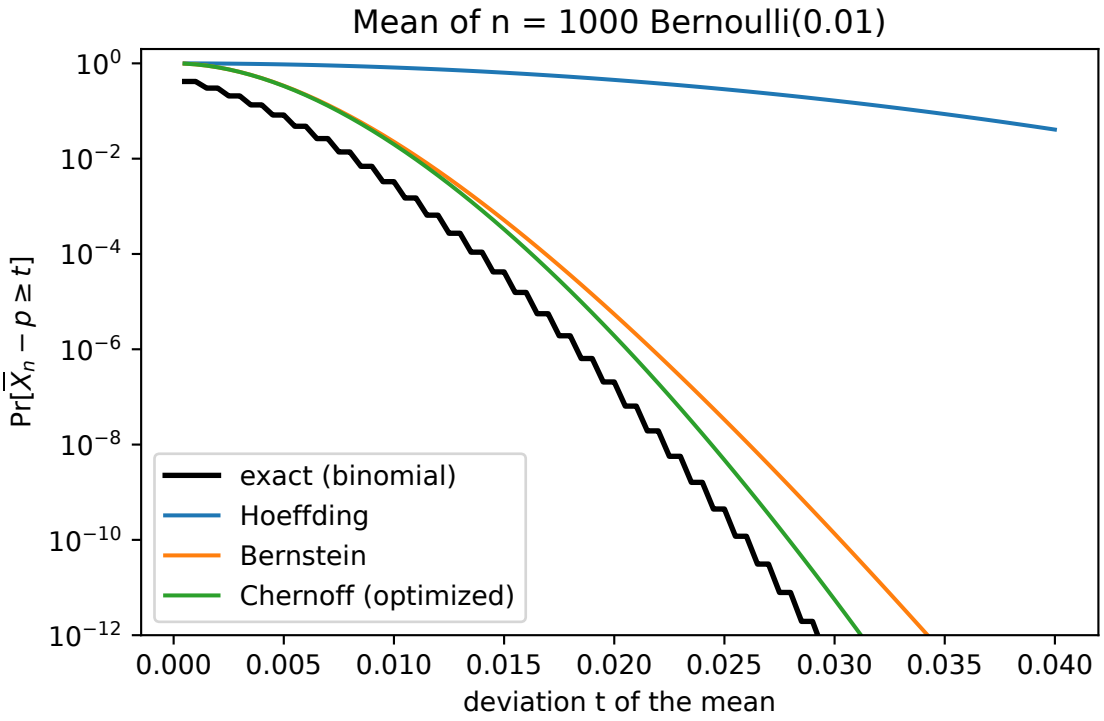

Figure F.2.: Tail of the mean of 1,000 Bernoulli(0.01) variables on a log scale: exact (black), and the Hoeffding, Bernstein and optimized Chernoff bounds.

The chapter then says that "Cramér's theorem says that … the probability of a large deviation decays exponentially in n with exactly the rate the optimized Chernoff bound gives, so no method can improve its exponent for large sums". It does not prove this. In symbols, for every t between the mean μ and the largest value $x_{\max}$ that X can take,

$$\lim_{n\to\infty} -\frac{1}{n}\ln \Pr[S_n \geq nt] = \psi^*(t). \tag{F.12}$$

Section 4.4 makes the same kind of claim about tests, and cites Cover & Thomas (chapter 11) for it. You observe n independent draws and test H_0, that they come from P, against H_1, that they come from Q. Hold the type I error at a level FPR in $(0, 1)$, and write $\mathrm{FNR}^*_n(\mathrm{FPR})$ for the smallest type II error of any test, randomized or not, whose type I error is at most FPR. The **Chernoff–Stein lemma** says that

$$\lim_{n\to\infty} -\frac{1}{n}\ln \mathrm{FNR}^*_n(\mathrm{FPR}) = D_{\mathrm{KL}}(P\|Q), \qquad D_{\mathrm{KL}}(P\|Q) = \mathbb{E}_P\Big[\ln\frac{p(X)}{q(X)}\Big], \tag{F.13}$$

where D_{KL} is the Kullback–Leibler (KL) divergence. The errors FPR and FNR are the type I and type II errors of Section 4.4, renamed because this page needs α for a Rényi order and β for a failure probability.

F.2.2. The idea

Chernoff's bound shows that the probability is *at most* about $e^{-n\psi^*(t)}$. To show that it is also *at least* about that, change the distribution so that the rare event becomes typical, and then pay for the change. The change is the **tilted** distribution of Divergences, which multiplies the probability of each outcome x by $e^{\lambda x}$ and renormalizes. With $\lambda > 0$ it moves mass toward large values. Pick λ so that the tilted mean sits just above t, so that most of the tilted sums land in a narrow window just above nt. Under the tilt, S_n then lands near nt most of the time, by Chebyshev's inequality. The price of switching back is the ratio of the two distributions on those samples, which is about $e^{-n(\lambda t-\psi(\lambda))}$, and that is the Chernoff exponent.

Here is a concrete case. A coin lands heads with probability 0.1, and you ask how likely 100 tosses are to give at least 20 heads, twice the expected number. Tilting by $e^{\lambda x}$, with $x = 1$ for heads and 0 for tails, turns it into a coin with heads probability $0.1e^{\lambda}/(0.9 + 0.1e^{\lambda})$. With $\lambda = \ln 2.25 = 0.8109$ that probability is exactly 0.2, so for the tilted coin 20 heads in 100 is the typical outcome, not a rare one.

The Chernoff–Stein lemma uses the same trick, with the two distributions already given. Under P, the evidence $\sum_i \ln(p(x_i)/q(x_i))$ of a sample is close to $n\,D_{\mathrm{KL}}(P\|Q)$, by the law of large numbers. So on most samples that P produces, Q gives a probability about $e^{-nD_{\mathrm{KL}}(P\|Q)}$ times smaller. A test with a small type I error must accept H_0 on most of P's typical samples. So under Q it accepts with probability about $e^{-nD_{\mathrm{KL}}(P\|Q)}$. No test can do better, because every test of small type I error must accept those samples. And the test that accepts exactly the samples with large evidence does that well.

F.2.3. Derivation

Two facts from the chapters do the work. The first is the **change of measure** (Fact 1 of Divergences, Fact 2 of Hypothesis testing). If P and Q' give positive probability to the same outcomes, then for any event A,

$$\Pr_P[X \in A] = \sum_{x \in A} p(x) = \sum_{x \in A} q'(x) \frac{p(x)}{q'(x)} = \mathbb{E}_{Q'}\Big[\frac{p(X)}{q'(X)} \mathbf{1}[X \in A]\Big], \tag{F.14}$$

because multiplying and dividing by $q'(x)$ changes nothing. The second is the **tilted distribution** with parameter λ, whose probabilities are

$$q_\lambda(x) = p(x)\, e^{\lambda x - \psi(\lambda)}. \tag{F.15}$$

They add up to 1 because $e^{\psi(\lambda)} = \sum_x p(x) e^{\lambda x}$. Its mean is $\psi'(\lambda)$ and its variance is $\psi''(\lambda)$, as the Rényi section of Divergences shows for the log-likelihood ratio. Here you only need these facts for a bounded X, where the sums are finite and the derivatives can be taken term by term.

Cramér's lower bound. Assume that X is bounded and not constant, and that $\mu < t < x_{\max}$.

1. **Tilt to just above t.** Fix a small $\kappa > 0$ with $t + \kappa < x_{\max}$. The tilted mean $\psi'(\lambda)$ equals μ at $\lambda = 0$. It increases with λ, because its derivative is a variance, which is positive for a variable that is not constant. It tends to $x_{\max}$ as $\lambda \to \infty$, because the weight $e^{\lambda x}$ favours the largest values more and more. So there is one $\lambda > 0$ with $\psi'(\lambda) = t + \kappa/2$.
2. **Change the measure of the whole sample.** Tilt each of the n copies. The ratio of the two probabilities of a sample is the product of the ratios of its draws, $\prod_i p(x_i)/q_\lambda(x_i) = e^{-\lambda S_n + n\psi(\lambda)}$. The change of measure therefore gives, for any event A about the sample,

$$\Pr[A] = \mathbb{E}_{Q_\lambda}\big[e^{-\lambda S_n + n\psi(\lambda)}\, \mathbf{1}[A]\big]. \tag{F.16}$$

3. **Restrict to a window.** Let A be the event $nt \le S_n \le n(t+\kappa)$. It is part of the event $S_n \ge nt$. On A, the sum is at most $n(t+\kappa)$, and $\lambda > 0$, so $e^{-\lambda S_n} \ge e^{-\lambda n(t+\kappa)}$. Hence

$$\Pr[S_n \ge nt] \ge \Pr[A] \ge e^{-n(\lambda(t+\kappa) - \psi(\lambda))} \Pr_{Q_\lambda}[A]. \tag{F.17}$$

4. **The window is likely under the tilt.** Under Q_λ, the average S_n/n has mean $t + \kappa/2$ and variance $\psi''(\lambda)/n$. The window contains every average within $\kappa/2$ of that mean. Chebyshev's inequality bounds the chance of falling outside, so

$$\Pr_{Q_\lambda}[A] \ge 1 - \frac{4\psi''(\lambda)}{n\kappa^2}, \tag{F.18}$$

   which tends to 1 as n grows.
5. **Let n grow.** Take logarithms in step 3 and divide by $-n$. The term $-\frac{1}{n}\ln \Pr_{Q_\lambda}[A]$ tends to 0, so

$$\limsup_{n\to\infty} -\frac{1}{n} \ln \Pr[S_n \ge nt] \le \lambda(t+\kappa) - \psi(\lambda). \tag{F.19}$$

6. **Let κ shrink.** As $\kappa \to 0$, the chosen λ tends to the λ_0 with $\psi'(\lambda_0) = t$, because ψ' is continuous and increasing. The right side of step 5 then tends to $\lambda_0 t - \psi(\lambda_0)$. The function $\lambda t - \psi(\lambda)$ is concave, since ψ is convex, and its slope $t - \psi'(\lambda)$ is zero at λ_0. So λ_0 is where it is largest, and $\lambda_0 t - \psi(\lambda_0) = \psi^*(t)$.

7. **Combine with Chernoff.** Chernoff's bound gives $-\frac{1}{n}\ln \Pr[S_n \geq nt] \geq \psi^*(t)$ for every n. Step 6 gives the matching upper limit, which proves Equation F.12.

For the coin, $\psi(\lambda) = \ln(1 - p + pe^{\lambda})$ with $p = 0.1$, and solving $\psi'(\lambda_0) = t$ gives $e^{\lambda_0} = t(1-p)/(p(1-t))$. Substituting, the exponent is the **binary KL divergence**

$$\psi^*(t) = \mathrm{kl}(t\|p) = t\ln\frac{t}{p} + (1-t)\ln\frac{1-t}{1-p}. \tag{F.20}$$

With $t = 0.2$ this is $\lambda_0 = \ln 2.25 = 0.8109$, $\psi(\lambda_0) = \ln 1.125 = 0.11778$, and $\psi^*(0.2) = 0.2 \times 0.8109 - 0.11778 = 0.04440$.

Chernoff–Stein, achievability. Assume that P and Q give positive probability to the same outcomes. Write $L(x)$ for the evidence $\ln(p(x)/q(x))$ of one draw x. Under P its mean is the divergence $D_{\mathrm{KL}}(P\|Q)$, written D_{KL} below, and assume that its variance V is finite. For a whole sample $x = (x_1, \ldots, x_n)$, write $p^n(x)$ and $q^n(x)$ for its probabilities under the two hypotheses. Each is a product over the draws, so the change of measure becomes

$$q^n(x) = p^n(x)\, e^{-\sum_i L(x_i)}. \tag{F.21}$$

1. **The test.** Fix $\kappa > 0$, and accept H_0 exactly when the average evidence is at least $D_{\mathrm{KL}} - \kappa$. Call that set of samples A_n.
2. **Its type I error.** It rejects when the average evidence falls more than κ below its mean D_{KL}. The average has variance V/n, so Chebyshev gives a type I error of at most $V/(n\kappa^2)$, which is below FPR once n is large.
3. **Its type II error.** On A_n the total evidence is at least $n(D_{\mathrm{KL}} - \kappa)$, so $q^n(x) \leq p^n(x)\, e^{-n(D_{\mathrm{KL}}-\kappa)}$. Summing over A_n gives

$$\mathrm{FNR}_n = \Pr_{Q^n}[A_n] \leq e^{-n(D_{\mathrm{KL}}-\kappa)} \Pr_{P^n}[A_n] \leq e^{-n(D_{\mathrm{KL}}-\kappa)}. \tag{F.22}$$

4. **The best test does at least as well.** So $\mathrm{FNR}^*_n(\mathrm{FPR}) \leq e^{-n(D_{\mathrm{KL}}-\kappa)}$ for large n, and $\liminf_n -\frac{1}{n}\ln \mathrm{FNR}^*_n(\mathrm{FPR}) \geq D_{\mathrm{KL}} - \kappa$ for every $\kappa > 0$.

Chernoff–Stein, converse. Now take any test, described by its probability $\phi(x)$ of rejecting H_0, with type I error $\mathbb{E}_{P^n}[\phi] \leq \mathrm{FPR}$.

5. **Restrict to typical samples.** Let B_n be the set of samples whose average evidence is at most $D_{\mathrm{KL}} + \kappa$. On B_n, $q^n(x) \geq p^n(x)\, e^{-n(D_{\mathrm{KL}}+\kappa)}$. The type II error is the probability of accepting under Q, and keeping only the samples in B_n can only lower it, so

$$\mathrm{FNR}_n = \sum_x (1-\phi(x))q^n(x) \geq e^{-n(D_{\mathrm{KL}}+\kappa)} \sum_{x\in B_n} (1-\phi(x))p^n(x). \tag{F.23}$$

6. **The test must accept most typical samples.** The last sum is the acceptance probability under P, minus the part outside B_n. That part is at most $\Pr_{P^n}[B_n^c]$, which Chebyshev bounds by $V/(n\kappa^2)$. So the sum is at least $1 - \mathrm{FPR} - V/(n\kappa^2)$.
7. **Let n grow.** Taking logarithms, $-\frac{1}{n}\ln \mathrm{FNR}_n \leq D_{\mathrm{KL}} + \kappa - \frac{1}{n}\ln\left(1 - \mathrm{FPR} - V/(n\kappa^2)\right)$, and the last term tends to 0. (For large n the factor $1 - \mathrm{FPR} - V/(n\kappa^2)$ is positive, so its logarithm is defined.) This holds for every test of level FPR, so $\limsup_n -\frac{1}{n}\ln \mathrm{FNR}^*_n(\mathrm{FPR}) \leq D_{\mathrm{KL}} + \kappa$. Since κ is arbitrary, steps 4 and 7 together prove Equation F.13.

F.2.4. Checking it

For the coin with $p = 0.1$ and $t = 0.2$, the script computes the exact exponent $-\frac{1}{n}\ln \Pr[S_n \geq 0.2n]$ from the binomial distribution. It is 0.06225 at $n = 100$, 0.04728 at $n = 1{,}000$ and 0.04481 at $n = 10{,}000$, and it approaches $\mathrm{kl}(0.2\|0.1) = 0.04440$ from above, as Chernoff's bound requires. The right panel of Figure F.3 also draws the bound of steps 3 and 4 for each n, with the window width $\kappa = 4\sqrt{t(1-t)/n}$. The factor 4 makes Chebyshev's bound in step 4 leave about three quarters of the tilted mass in the window. It closes in from the other side, but slowly: 0.23163, 0.09152 and 0.05800 at the same three sizes. It is slow because the window must shrink like $1/\sqrt{n}$, the size of the typical fluctuation. The left panel shows the tilt at $n = 100$. The original count sits around 10, while the tilted count sits inside the window from 20 up.

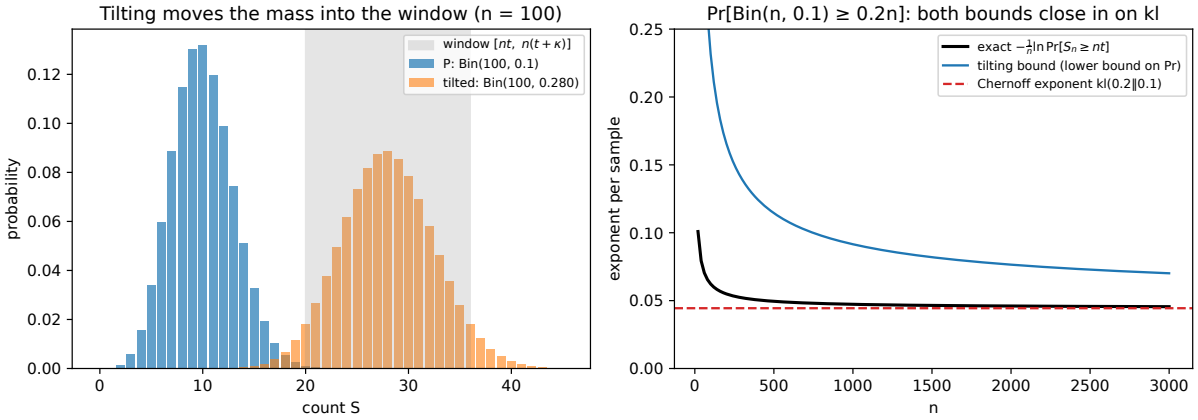

Figure F.3.: Left: the distribution of the number of heads in 100 tosses of a coin with heads probability 0.1, and of the tilted coin, with the window of step 3 shaded. Right: the exact exponent $-\frac{1}{n}\ln \Pr[S_n \geq 0.2n]$ (black), the bound from the tilting argument (blue) and the Chernoff exponent $\mathrm{kl}(0.2\|0.1)$ (dashed), against n.

For the Chernoff–Stein lemma the script uses the spam example of Table 4.2. An email's count of suspicious words, capped at 3, takes the values 0, 1, 2, 3 with probabilities 0.4, 0.3, 0.2, 0.1 under ham (P) and 0.1, 0.2, 0.3, 0.4 under spam (Q). There $D_{\mathrm{KL}}(P\|Q) = 0.4564$ and the variance of the evidence is $V = 0.8348$. The evidence of one count is $\pm\ln 4$ or $\pm\ln 1.5$, so the evidence of a sample is $i\ln 4 + j\ln 1.5$ for two whole numbers i and j. The script tracks the exact distribution of (i, j) under both hypotheses and builds the most powerful test of size exactly 0.05, as the Neyman–Pearson lemma prescribes. Table F.3 gives its type II error. Its last column gives the two bounds of the derivation. They use $\kappa = \sqrt{V/(0.05\,n)}$ for achievability, so that step 2 gives size 0.05, and $\kappa = \sqrt{2V/(0.95\,n)}$ for the converse, so that the factor in step 6 is $0.95/2$. A negative lower bound says nothing, because an exponent is never negative.

Table F.3.: Type II error of the most powerful size-0.05 test on n spam-example observations, its exponent, and the two bounds of the derivation with κ chosen for each n. The limit is $D_{\mathrm{KL}}(P\|Q) = 0.4564$.

n	$\mathrm{FNR}_n^*(0.05)$	$-\frac{1}{n}\ln \mathrm{FNR}_n^*$	Bounds from the proof
10	7.702×10^{-2}	0.2564	$[-0.8357, 0.9501]$
50	1.160×10^{-7}	0.3194	$[-0.1214, 0.6588]$
200	3.959×10^{-33}	0.3730	$[0.1675, 0.5539]$

The exponent creeps up toward 0.4564, as Figure F.4 shows. Both bounds tend to KL, at the slow rate $1/\sqrt{n}$. The exact exponent is also far from its limit at moderate n. With 200 observations it is still 18% below KL, because the test must leave room for fluctuations of the evidence of order $\sqrt{n}$.

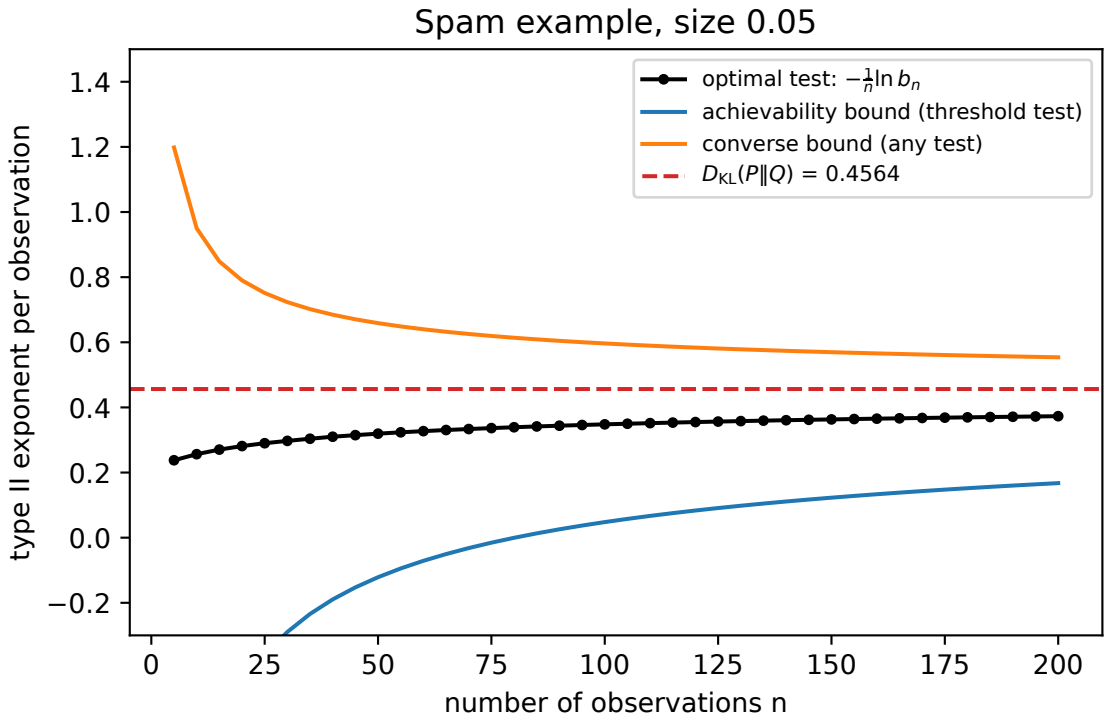

Figure F.4.: The type II exponent $-\frac{1}{n}\ln \mathrm{FNR}_n^*$ of the most powerful size-0.05 test on the spam example (black), between the achievability and converse bounds of the derivation, converging slowly to $D_{\mathrm{KL}}(P\|Q)$ (dashed).

F.2.5. What it does not cover

Cramér's theorem holds without boundedness. The upper bound is always Chernoff's, and the lower bound needs only a tilt with the right mean, which exists in more general settings; Dembo & Zeitouni prove it in full. The Chernoff–Stein argument above uses a finite variance V only for

Chebyshev's inequality. The weak law of large numbers gives the same two limits with only a finite KL divergence, which is the version Cover & Thomas prove. Neither proof says how fast the limit is reached. The examples above show that the approach is slow, with an error of order $1/\sqrt{n}$ in the exponent.

F.3. The Clopper–Pearson limits exist and are unique

F.3.1. What the chapter uses

Section 4.11 builds the Clopper–Pearson interval for a rate from k successes in n independent trials. Write $F_p(k) = \Pr[\mathrm{Bin}(n, p) \le k]$ for the probability of at most k successes when each trial succeeds with probability p. Step 1 of the chapter's derivation says that $F_p(k)$ is continuous and strictly decreasing in p for $k < n$, and concludes that for each k there is a single rate $u(k)$ with $F_{u(k)}(k) = \beta/2$. Here $1 - \beta$ is the confidence level, which the chapter writes $1 - \alpha$. The chapter gives a reason in one phrase, that a larger success probability makes small counts less likely, and points here for the proof. Fact 2 of Auditing relies on the same step for one-sided bounds, used in Section 47.3.

The precise statement is this. For $0 \le k \le n-1$, the function $p \mapsto F_p(k)$ is continuous and strictly decreasing on $[0, 1]$, from $F_0(k) = 1$ to $F_1(k) = 0$. So for every level c in $(0, 1)$ exactly one rate $u(k)$ in $(0, 1)$ solves $F_{u(k)}(k) = c$. Moreover,

$$F_p(k) = \int_p^1 n \binom{n-1}{k} s^k (1-s)^{n-1-k}\, ds. \tag{F.24}$$

For $k = n$, $F_p(n) = 1$ for every p, and the chapter sets $u(n) = 1$.

F.3.2. The idea

Picture all the trials driven by one set of random numbers. Draw n numbers $U_1, \ldots, U_n$ uniformly from $[0, 1]$, and say that trial i succeeds at rate p when $U_i \le p$. Each trial then succeeds with probability p, independently, so the count K_p of successes is $\mathrm{Bin}(n, p)$. Now raise p while keeping the same numbers. A trial that succeeded still succeeds, and some new ones may join, so the count never goes down. For example, with $n = 3$ and $U = (0.15, 0.62, 0.40)$, Table F.4 shows the count as p grows.

Table F.4.: One draw of three uniform numbers, and the count of successes they give at four rates. The count can only go up as p grows.

Rate p	0.1	0.3	0.5	0.7
Trials with $U_i \le p$	none	1	1, 3	1, 2, 3
Count K_p	0	1	2	3

On every draw the event "at most k successes" can only stop happening as p grows. So its probability $F_p(k)$ never increases. The count leaves that event when one more trial crosses over

while exactly k of the other $n-1$ have already succeeded, and that has positive probability for every p strictly between 0 and 1. So the decrease is strict. The derivation makes this exact by differentiating.

F.3.3. Derivation

1. **The endpoints.** At $p=0$ no trial succeeds, so $F_0(k)=1$. At $p=1$ all n succeed, so $F_1(k)=0$ for $k \le n-1$.
2. **Continuity.** $F_p(k)=\sum_{j=0}^{k}\binom{n}{j}p^j(1-p)^{n-j}$ is a polynomial in p, so it is continuous and can be differentiated.
3. **The derivative telescopes.** Write $g_j(p)$ for the probability of exactly j successes in $n-1$ trials, $\binom{n-1}{j}p^j(1-p)^{n-1-j}$, and set $g_{-1}=0$. Differentiate one term of the sum by the product rule, and then use the identities $j\binom{n}{j}=n\binom{n-1}{j-1}$ and $(n-j)\binom{n}{j}=n\binom{n-1}{j}$. The result is
$$\frac{d}{dp}\binom{n}{j}p^j(1-p)^{n-j}=n(g_{j-1}(p)-g_j(p)). \tag{F.25}$$
Summing over $j=0,\dots,k$, each g_j appears once with a plus sign and once with a minus sign, except $g_{-1}=0$ and the last one. So
$$\frac{d}{dp}F_p(k)=-n\binom{n-1}{k}p^k(1-p)^{n-1-k}. \tag{F.26}$$
For example, with two trials and $k=0$, $F_p(0)=(1-p)^2$ has derivative $-2(1-p)$, which is what the formula gives. The formula also has a reading in words. When p rises a little, one of the n trials may cross over, and the count leaves "at most k" exactly when the other $n-1$ trials hold exactly k successes.
4. **Strictly decreasing.** The derivative is negative for $0<p<1$. By the mean value theorem, for $p<p'$ the difference $F_{p'}(k)-F_p(k)$ equals $(p'-p)$ times the derivative at some point in between, which is negative.
5. **Existence and uniqueness.** A continuous function that goes from 1 to 0 takes every value c in between, by the intermediate value theorem. A strictly decreasing function takes each value at most once. So exactly one $u(k)$ has $F_{u(k)}(k)=c$. Strictness is also what the chapter needs when it turns the limit into a statement about the true rate: the true rate p is at least $u(K)$ exactly when $F_p(K)\le F_{u(K)}(K)$.
6. **The lower end.** For $k\ge 1$, the probability of at least k successes is $1-F_p(k-1)$. By steps 1 to 4 it is continuous and strictly increasing in p, from 0 to 1. So the chapter's lower limit $l(k)$, the rate at which at least k successes have probability c, also exists and is unique.
7. **The Beta form.** Integrate the derivative of step 3 from p to 1, and use $F_1(k)=0$. This gives Equation F.24. The integrand is the density of the Beta$(k+1,n-k)$ distribution, because its normalizing constant $1/B(k+1,n-k)=n!/(k!\,(n-1-k)!)$ equals $n\binom{n-1}{k}$. So $F_p(k)$ is the probability that a Beta$(k+1,n-k)$ variable exceeds p. The upper limit $u(k)$ is therefore the point that such a variable exceeds with probability c. This is how statistical software computes Clopper–Pearson limits.

F.3.4. Checking it

Figure F.5 draws $F_p(k)$ against p for $n = 1{,}000$ and $k = 0$, 1 and 10. Each curve falls from 1 to 0 and crosses the level 0.025 exactly once, at the upper limit: $u(0) = 0.003682$, $u(1) = 0.005559$ and $u(10) = 0.018313$. The first has a closed form, because $F_p(0) = (1-p)^n$ gives $u(0) = 1-0.025^{1/1000}$. The script checks the derivative of step 3 against finite differences, and the integral of step 7 by numerical integration. It also recomputes the limits that the chapters quote, by bisection. For 10 successes in 10,000 trials the interval is $[0.00048, 0.00184]$. For 1 success in 1,000 the one-sided 95% bound is 0.0047, and for none in 3,000 it is 9.9808×10^{-4}.

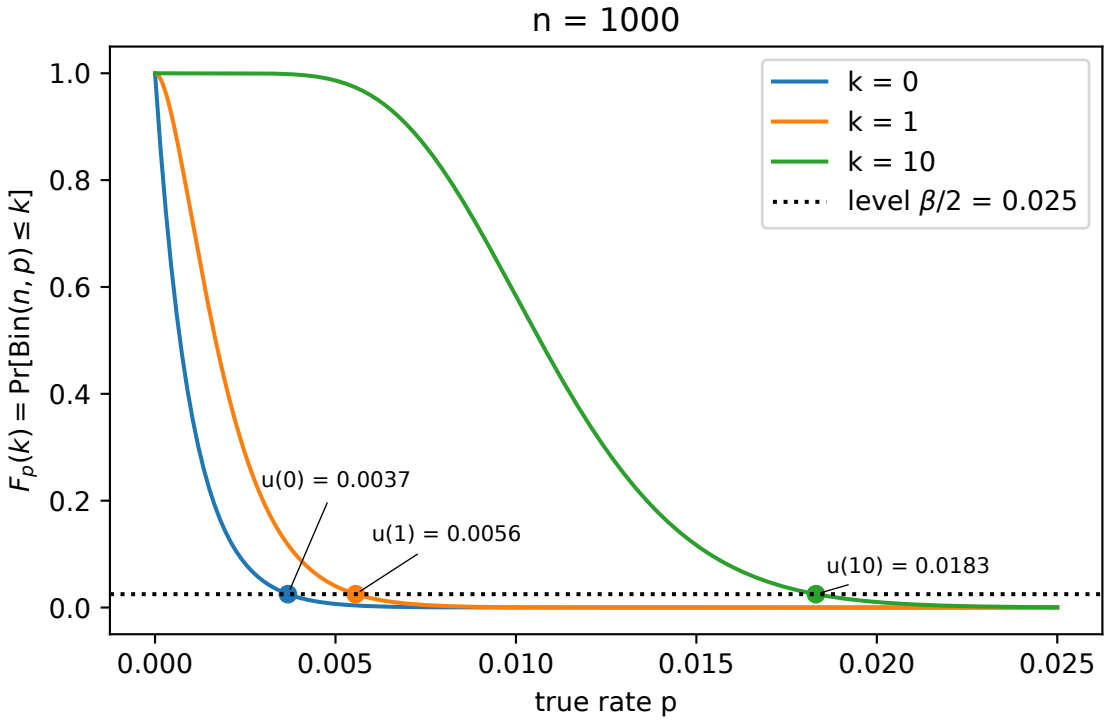

Figure F.5.: The probability $F_p(k)$ of at most k successes in 1,000 trials, as a function of the true rate p, for $k = 0$, 1 and 10. Each curve crosses the level 0.025 (dotted) once, at the upper limit $u(k)$.

Figure F.6 shows what the interval delivers. For $n = 100$ it gives the exact coverage of the 95% Clopper–Pearson interval at each true rate p, the probability that the interval built from a $\mathrm{Bin}(100, p)$ count contains p. The curve is a sawtooth, because it jumps each time p crosses an endpoint of one of the 101 intervals. It never drops below 0.95: its smallest value on the grid is 0.9504 and its average is 0.9645. The Wald interval $\hat{p} \pm 1.96\sqrt{\hat{p}(1-\hat{p})/n}$ of Section 4.11 falls far below 0.95 near the edges. At $p = 0.01$ it covers only 63.34% of the time, against 98.16% for Clopper–Pearson.

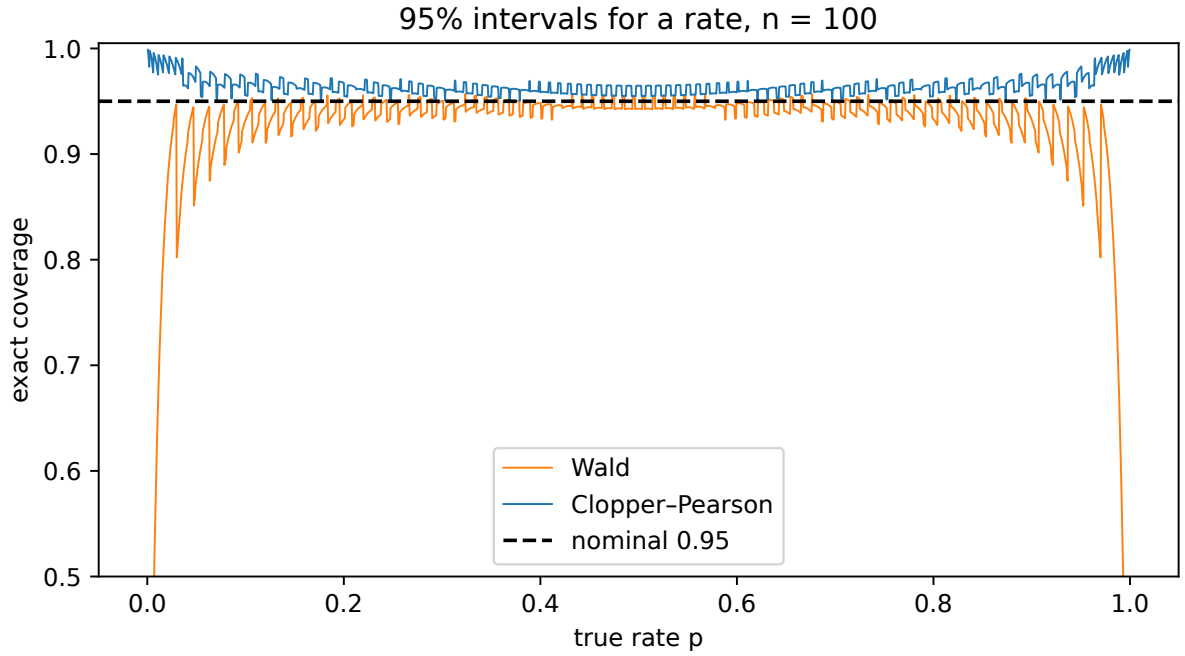

Figure F.6.: Exact coverage of 95% intervals for a rate from 100 trials, as a function of the true rate: Clopper–Pearson (blue) stays above the nominal 0.95 (dashed), and Wald (orange) falls far below it near 0 and 1.

F.4. Rényi divergence tends to KL at order 1

F.4.1. What the chapter uses

Section 3.4 writes the Rényi divergence of order α through the likelihood ratio $r = p/q$ and the log-MGF of the evidence $\ln r$ under P,

$$\psi(\lambda) = \ln \mathbb{E}_P[r^\lambda], \qquad D_\alpha(P\|Q) = \frac{\psi(\alpha - 1)}{\alpha - 1}. \tag{F.27}$$

That is Equation 3.12. Here ψ is the log-MGF of the evidence $\ln r$, not of a sum as in the previous section. Property 1 there says that $D_\alpha \to D_{\mathrm{KL}}(P\|Q)$ as $\alpha \to 1$, where $D_{\mathrm{KL}}(P\|Q) = \mathbb{E}_P[\ln r]$ is the KL divergence. The chapter proves it as the slope of ψ at 0, by passing a derivative inside an average. It adds: "This needs ψ to be finite near 0. van Erven & Harremoës prove the limit in general." Write $\lambda = \alpha - 1$. This section proves two statements without derivatives:

$$\lim_{\alpha \uparrow 1} D_\alpha(P\|Q) = D_{\mathrm{KL}}(P\|Q) \text{ always}, \qquad \lim_{\alpha \downarrow 1} D_\alpha(P\|Q) = D_{\mathrm{KL}}(P\|Q) \text{ if } D_{\alpha_0}(P\|Q) < \infty \text{ for some } \alpha_0 > 1. \tag{F.28}$$

The first holds even when the KL divergence is infinite.

Section 5.6 states the matching facts for the **Rényi entropy** $H_\alpha(X) = \frac{1}{1-\alpha} \log_2 \sum_x p(x)^\alpha$, measured in bits, of a variable with finitely many values. It says that H_α tends to the Shannon entropy H as $\alpha \to 1$, and to the min-entropy H_∞ as $\alpha \to \infty$. Both follow from the divergence limits.

F.4.2. The idea

The divergence $D_{1+\lambda}$ is $\psi(\lambda)/\lambda$, and two simple inequalities trap it between the KL divergence and a quantity whose limit is easy. The first is Jensen's inequality for the concave logarithm: the log of an average is at least the average of the log. The second is the tangent-line bound $\ln m \le m - 1$. Applied to the average $\mathbb{E}_P[r^\lambda]$, they give

$$\lambda D_{\mathrm{KL}} = \mathbb{E}_P[\ln r^\lambda] \le \psi(\lambda) \le \mathbb{E}_P[r^\lambda] - 1. \tag{F.29}$$

Dividing by λ, with care for its sign, puts $D_{1+\lambda}$ between D_{KL} and the average of the **power slope**

$$h_\lambda(r) = \frac{r^\lambda - 1}{\lambda}. \tag{F.30}$$

For each fixed value of the ratio r, the power slope moves steadily toward $\ln r$ as λ tends to 0. So its average moves toward the average of $\ln r$, which is the KL divergence, and no derivative of ψ is needed.

On the die of Table 3.1, r is 3 on a six and 0.6 otherwise. Table F.5 shows h_λ at both values. Each row increases from left to right, and the middle column, $\lambda = 0$, is $\ln r$.

Table F.5.: The power slope $h_\lambda(r) = (r^\lambda - 1)/\lambda$ at the die's two likelihood ratios. At $\lambda = 0$ it is $\ln r$.

λ	-0.5	-0.1	0	0.1	0.5
$h_\lambda(3)$	0.8453	1.0404	1.0986	1.1612	1.4641
$h_\lambda(0.6)$	-0.5820	-0.5241	-0.5108	-0.4980	-0.4508

F.4.3. Derivation

The derivation uses one theorem about averages, the **monotone convergence theorem**. Suppose random variables $Z_1 \le Z_2 \le \ldots$ increase to a limit Z at every outcome, and $\mathbb{E}[Z_1] > -\infty$. Then $\mathbb{E}[Z_k] \to \mathbb{E}[Z]$, and the limit may be $+\infty$. The same holds for a decreasing sequence if $\mathbb{E}[Z_1] < \infty$. For finitely many outcomes this is just the limit of a finite sum. For densities, it is a standard theorem of integration.

1. **The power slopes.** For a number $x > 0$, write $z = \ln x$, so that $x^\lambda = e^{\lambda z}$. Then the power slope is an integral,

$$h_\lambda(x) = \frac{e^{\lambda z} - 1}{\lambda} = \int_0^z e^{\lambda s}\, ds, \tag{F.31}$$

which runs backward when $z < 0$. At $\lambda = 0$ the integral is $z = \ln x$, and it changes continuously with λ. It is also non-decreasing in λ. If $z > 0$, every s in the integral is positive, so $e^{\lambda s}$ grows with λ. If $z < 0$, the integral is $-\int_z^0 e^{\lambda s}\, ds$ with negative s, so $e^{\lambda s}$ shrinks with λ and its negative grows. So as $\lambda \uparrow 0$, $h_\lambda(x)$ increases to $\ln x$, and as $\lambda \downarrow 0$ it decreases to $\ln x$.

2. **Below order 1, an upper bound.** Take $\lambda \in (-1, 0)$. Then $r^\lambda = (q/p)^{|\lambda|}$, and Jensen's inequality for the concave power $|\lambda| < 1$ gives $\mathbb{E}_P[r^\lambda] \le (\mathbb{E}_P[q/p])^{|\lambda|} \le 1$, so $\psi(\lambda)$ is not $+\infty$. (If P and Q share no outcome, $\psi(\lambda) = -\infty$ and every divergence is infinite, so there is nothing to prove.) Next, the logarithm is concave, so Jensen's inequality gives

$$\psi(\lambda) = \ln \mathbb{E}_P[r^\lambda] \ge \mathbb{E}_P[\ln r^\lambda] = \lambda D_{\mathrm{KL}}. \tag{F.32}$$

   Dividing by the negative λ flips the inequality, so $D_{1+\lambda}$ is at most D_{KL}. When the KL divergence is infinite this says nothing, and nothing is needed.
3. **Below order 1, a lower bound.** Since $\ln m \le m - 1$, $\psi(\lambda) \le \mathbb{E}_P[r^\lambda] - 1 = \lambda\, \mathbb{E}_P[h_\lambda(r)]$. Dividing by the negative λ flips it again:

$$\mathbb{E}_P[h_\lambda(r)] \le D_{1+\lambda} \le D_{\mathrm{KL}}, \qquad -1 < \lambda < 0. \tag{F.33}$$

4. **The limit from below.** As $\lambda \uparrow 0$, $h_\lambda(r)$ increases to $\ln r$ by step 1. The sequence starts above an integrable variable: at $\lambda = -1$, $h_{-1}(r) = 1 - 1/r$, and $\mathbb{E}_P[1/r] = \sum_{x:\, p(x)>0} q(x) \le 1$, so $\mathbb{E}_P[h_{-1}(r)] \ge 0$. So monotone convergence applies, and the average of the power slope tends to the average of $\ln r$, which is the KL divergence. Both sides of step 3 tend to D_{KL}, so $D_\alpha \to D_{\mathrm{KL}}$ as $\alpha \uparrow 1$. This includes an infinite KL divergence, where the lower bound alone grows without limit.
5. **Above order 1.** For $\lambda > 0$ the same two inequalities hold, and dividing by the positive λ keeps their direction:

$$D_{\mathrm{KL}} \le D_{1+\lambda} \le \mathbb{E}_P[h_\lambda(r)], \qquad \lambda > 0. \tag{F.34}$$

6. **The limit from above.** As $\lambda \downarrow 0$, $h_\lambda(r)$ decreases to $\ln r$. Monotone convergence now needs a finite starting point. That is the assumption: if $D_{\alpha_0} < \infty$ with $\lambda_0 = \alpha_0 - 1 > 0$, then $\mathbb{E}_P[r^{\lambda_0}] = e^{\lambda_0 D_{\alpha_0}}$ is finite, and so is $\mathbb{E}_P[h_{\lambda_0}(r)]$. Then $\mathbb{E}_P[h_\lambda(r)] \to D_{\mathrm{KL}}$ and $D_\alpha \to D_{\mathrm{KL}}$ as $\alpha \downarrow 1$.
7. **Rényi entropy.** Let U be the uniform distribution on the N values of X, which gives each value probability $1/N$. Measuring the divergence in bits too, with $\log_2$ in place of ln, the definition gives

$$D_\alpha(P\|U) = \frac{1}{\alpha - 1} \log_2 \sum_x p(x)^\alpha N^{\alpha-1} = \log_2 N - H_\alpha(X). \tag{F.35}$$

   The identity holds in any base used for both sides. In the same way, the KL divergence from the uniform distribution is $\log_2 N$ minus the Shannon entropy $H(X)$. On a finite set the likelihood ratio $Np(x)$ is at most N, so every $D_\alpha(P\|U)$ is finite. Both limits of steps 4 and 6 then apply, and $H_\alpha \to H$ as $\alpha \to 1$. As $\alpha \to \infty$, property 2 of Section 3.4 says that $D_\alpha(P\|U)$ tends to the logarithm of the largest ratio, $\log_2(N \max_x p(x))$. Subtracting it from $\log_2 N$ leaves the min-entropy,

$$\lim_{\alpha\to\infty} H_\alpha(X) = -\log_2 \max_x p(x) = H_\infty(X). \tag{F.36}$$

F.4.4. Checking it

Figure F.7 draws the sandwich for the die and for the pair $\mathcal{N}(0,1)$ against $\mathcal{N}(1,1)$, whose KL divergence is $\frac{1}{2}$. The black curve is $D_{1+\lambda}$ and the blue curve is $\mathbb{E}_P[h_\lambda(r)]$. The blue curve lies below the black on the left of 0 and above it on the right, and both meet the KL line at $\lambda = 0$.

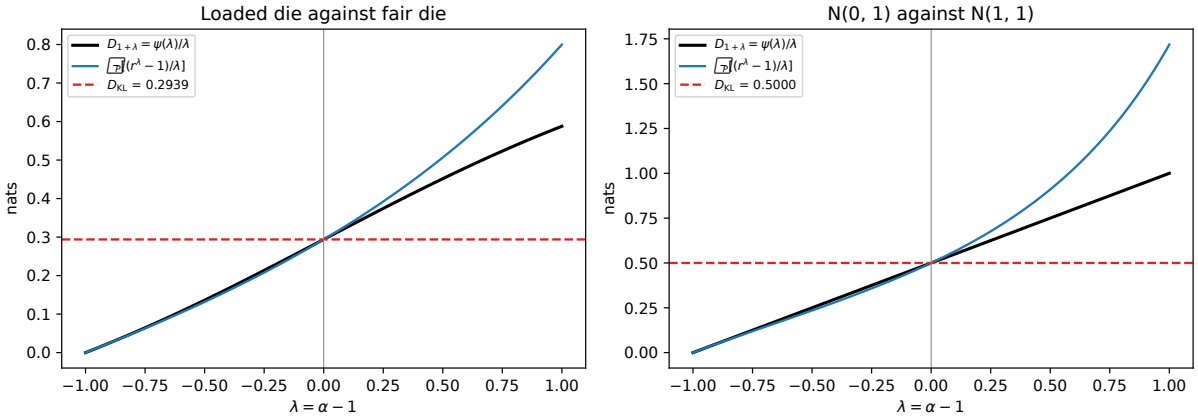

Figure F.7.: The Rényi divergence $D_{1+\lambda} = \psi(\lambda)/\lambda$ (black) and the bound $\mathbb{E}_P[(r^\lambda - 1)/\lambda]$ (blue) as functions of $\lambda = \alpha - 1$, with the KL divergence (dashed). Left: the loaded die against the fair die. Right: $\mathcal{N}(0, 1)$ against $\mathcal{N}(1, 1)$.

On the die, where $D_{\mathrm{KL}} = 0.2939$, the divergence at $\lambda = -0.01$ is 0.2907 with the lower bound 0.2902, and at $\lambda = +0.01$ it is 0.2971 with the upper bound 0.2976.

For the PIN example of Section 5.6, with 10% on one PIN and the rest uniform over the other 9,999, the Shannon entropy is $H = 12.4278$ bits. The script finds $H_{0.999} = 12.4310$ and $H_{1.001} = 12.4246$ on either side of it. As the order grows, $H_2 = 6.6322$ and $H_{100} = 3.3555$ approach the min-entropy $H_\infty = 3.3219$. The identity of step 7 holds to rounding error.

F.4.5. What it does not cover

Without the assumption of step 6, the limit from above can fail. Take outcomes $k = 1, 2, \ldots$ with $p(k)$ proportional to $e^{-\sqrt{k}}$, and let $q(k) = p(k)e^{-k}$, with the rest of Q's mass on an extra outcome that P never produces. Then $\ln r(k) = k$, so $D_{\mathrm{KL}} = \mathbb{E}_P[k]$ is finite. But $\mathbb{E}_P[r^\lambda]$ sums $e^{\lambda k - \sqrt{k}}$ times a constant, which diverges for every $\lambda > 0$. So $D_\alpha = \infty$ for every $\alpha > 1$, while the limit from below is the finite KL divergence. van Erven & Harremoës (2014) treat the general case, including orders near 0 and ∞.

F.5. Perspective functions are jointly convex

F.5.1. What the chapter uses

Let g be a convex function on $(0, \infty)$. Its **perspective** is a function G of two positive numbers x and y. It applies g to their ratio and multiplies the result by the denominator:

$$G(x, y) = y\, g(x/y). \tag{F.37}$$

The perspective has three properties. The first is that it is **jointly convex**. Take several points (x_t, y_t), indexed by t, and weights $w_t \geq 0$ that add up to 1. The value of G at the weighted

average of the points is at most the weighted average of its values:

$$G\Big(\sum_t w_t x_t,\ \sum_t w_t y_t\Big) \le \sum_t w_t\, G(x_t, y_t). \tag{F.38}$$

The second is that it is **positively homogeneous**, which means that scaling both arguments by a factor $c > 0$ scales the value by c. The third follows from the first two. The perspective is **subadditive**, so its value at a sum of two points is at most the sum of its values:

$$G(x_1 + x_2,\ y_1 + y_2) \le G(x_1, y_1) + G(x_2, y_2). \tag{F.39}$$

The Rényi divergence uses $g(t) = t^\alpha$ with $\alpha > 1$, whose perspective is $G(x, y) = x^\alpha y^{1-\alpha}$. Write the sum in the Rényi divergence as

$$F(P, Q) = \sum_y P(y)^\alpha Q(y)^{1-\alpha} = e^{(\alpha-1)D_\alpha(P\|Q)}. \tag{F.40}$$

Several chapters assert one of the properties above for this function, without a proof:

- Fact 3 of Conversions, the chapter on converting Rényi differential privacy (RDP) guarantees, says that a test cannot increase the Rényi divergence. Its short reason is the subadditivity of $x^\alpha y^{1-\alpha}$, and it sends randomized tests to the general proof.
- "Computing it" in Section 30.5 says that each constraint of Equation 30.11 is convex in the test's errors $(\mathrm{FPR}, \mathrm{FNR})$, so that the region they allow is convex and its lower boundary f_{RDP} is a convex function. It also uses that each constraint is smallest, equal to 1, at $\mathrm{FNR} = 1 - \mathrm{FPR}$. Step 3 of Section 32.9 repeats the convexity claim.
- Step 1 of Section 31.8 uses the joint convexity of F in the pair, for the pair (Q, P) written as a mixture.
- Step 2 of Section 33.5 uses it to show that a mixture of pairs with shared weights has a Rényi divergence no larger than the largest of its parts. It cites van Erven & Harremoës (2014, Theorem 13) for this **quasi-convexity**.

This section proves the three properties and these four uses.

F.5.2. The idea

The perspective is g of a ratio, weighted by the denominator. When you mix two points, the ratio of the mixture is an average of the two ratios, weighted by the denominators. A convex function of an average is at most the average of the function (Jensen), and multiplying back by the total denominator gives the joint convexity.

Take $\alpha = 2$, so $G(x, y) = x^2/y$, and the two points $(0.9, 0.3)$ and $(0.1, 0.9)$. Their values are $0.81/0.3 = 2.70$ and $0.01/0.9 = 0.0111$, and their ratios x/y are 3 and $\frac{1}{9}$. The midpoint is $(0.5, 0.6)$, whose ratio is $0.5/0.6 = 0.833$. That is the average of 3 and $\frac{1}{9}$ with weights $0.3/1.2 = \frac{1}{4}$ and $0.9/1.2 = \frac{3}{4}$, the shares of the two denominators. At the midpoint $G = 0.25/0.6 = 0.4167$, well below the average of the two values, $(2.70 + 0.0111)/2 = 1.3556$.

In the language of divergences, x is P's probability of an output and y is Q's. Merging two outputs replaces their likelihood ratios by an average weighted by Q, as in the data-processing section of Divergences, and a convex summary of the ratios can only go down.

F.5.3. Derivation

1. **Joint convexity.** Fix the points (x_t, y_t) and the weights w_t, and let $x = \sum_t w_t x_t$ and $y = \sum_t w_t y_t$. The numbers $v_t = w_t y_t / y$ are non-negative and add up to 1. They make the ratio of the mixture an average of the ratios,
$$\frac{x}{y} = \sum_t \frac{w_t y_t}{y} \cdot \frac{x_t}{y_t} = \sum_t v_t \frac{x_t}{y_t}. \tag{F.41}$$
Jensen's inequality for the convex g gives $g(x/y) \le \sum_t v_t\, g(x_t/y_t)$. Multiplying by y turns each $y\, v_t$ back into $w_t y_t$, which is Equation F.38.
2. **Homogeneity.** $G(cx, cy) = cy\, g(cx/cy) = c\, y\, g(x/y)$, because the ratio does not change.
3. **Subadditivity.** By homogeneity with $c = 2$, $G(x_1 + x_2, y_1 + y_2) = 2\, G(\frac{x_1+x_2}{2}, \frac{y_1+y_2}{2})$. By joint convexity with weights $\frac{1}{2}$, this is at most $G(x_1, y_1) + G(x_2, y_2)$.
4. **Zero probabilities.** For $G(x, y) = x^\alpha y^{1-\alpha}$, outputs where a probability is 0 follow the conventions $G(0, y) = 0$ and $G(x, 0) = \infty$ for $x > 0$. Steps 1 to 3 still hold, case by case. If some point has $y_t = 0 < x_t$, the right side is infinite, so there is nothing to check, while a point $(0, 0)$ adds nothing to either side. With $x_t = 0 < y_t$, the formula $y\, g(x/y)$ still applies, since $g(0) = 0$ and g is convex on $[0, \infty)$.
5. **Mixtures of pairs: quasi-convexity.** Let (P_t, Q_t) be pairs of distributions on the same outputs, and mix them with shared weights w_t. Apply step 1 at each output y, to the points $(P_t(y), Q_t(y))$, and add over y. Then
$$F\Big(\sum_t w_t P_t,\ \sum_t w_t Q_t\Big) \le \sum_t w_t\, F(P_t, Q_t) \le \max_t F(P_t, Q_t). \tag{F.42}$$
For $\alpha > 1$, $D_\alpha = \frac{1}{\alpha-1} \ln F$ increases with F. So the Rényi divergence of the mixed pair is at most the largest $D_\alpha(P_t \| Q_t)$. This is step 2 of Section 33.5. For densities, replace the sum over y by an integral, and the inequality survives because it holds at every y.
6. **The pair (Q, P) for a subsampled Gaussian.** In Section 31.8, $Q = \mathcal{N}(0, \sigma^2)$ and $P = (1-q)Q + q\,\mathcal{N}(1, \sigma^2)$. The pair (Q, P) is the mixture $(1-q)(Q, Q) + q\,(Q, \mathcal{N}(1, \sigma^2))$, with the shared weights $1-q$ and q. The first inequality of step 5 gives
$$F(Q, P) \le (1-q) F(Q, Q) + q\, F(Q, \mathcal{N}(1, \sigma^2)) = (1-q) + q\, e^{(\alpha-1)\alpha\rho_0}, \tag{F.43}$$
because $F(Q, Q) = 1$, and D_α between two normals with unit shift is $\alpha\rho_0$, where $\rho_0 = 1/(2\sigma^2)$. That is the bound the chapter states.
7. **Tests cannot increase the divergence.** A test rejects on output y with probability $\phi(y)$, which may lie strictly between 0 and 1. Split each output y into two pieces, "y and reject" and "y and accept". Their probabilities are $\phi(y)P(y)$ and $(1 - \phi(y))P(y)$ under P, and likewise under Q. Both pieces keep the ratio $P(y)/Q(y)$, so by homogeneity their two terms add up to $G(P(y), Q(y))$, and F does not change. Now merge all the "reject" pieces into one output and all the "accept" pieces into another. By subadditivity, applied one merge at a time, F can only go down. The two merged outputs are the test's coin. It rejects with probability $\mathrm{FPR} = \sum_y \phi(y)P(y)$ under P and $1 - \mathrm{FNR} = \sum_y \phi(y)Q(y)$ under Q, where FPR and FNR are its type I and type II errors. So
$$G(\mathrm{FPR}, 1 - \mathrm{FNR}) + G(1 - \mathrm{FPR}, \mathrm{FNR}) \le F(P, Q), \tag{F.44}$$
which is Fact 3 of Conversions, randomized tests included. The same split-and-merge argument works for any processing that sends each output y to a random output z, so it also proves the data-processing inequality for D_α.

8. **The region of allowed tests is convex.** The chapter's RDP curve $\varepsilon(\alpha)$ bounds the Rényi divergence of order α in both directions, and the coin of step 7 inherits both bounds. Written with G, the two constraints of Equation 30.11 are

$$c_1(\mathrm{FPR}, \mathrm{FNR}) = G(\mathrm{FPR}, 1-\mathrm{FNR}) + G(1-\mathrm{FPR}, \mathrm{FNR}) \le e^{(\alpha-1)\varepsilon(\alpha)}, \qquad c_2(\mathrm{FPR}, \mathrm{FNR}) = G(1-\mathrm{FNR}, \tag{F.45}$$

   Each term is G applied to numbers that depend linearly on $(\mathrm{FPR}, \mathrm{FNR})$. Mixing two error pairs mixes those numbers with the same weights, so step 1 makes each term, and their sum, convex in $(\mathrm{FPR}, \mathrm{FNR})$. The same holds for c_2, which swaps the roles of the two distributions. If two error pairs satisfy a convex constraint, so does every mixture of them, because its value is at most the mixture of two values that are both within the limit. So each constraint allows a convex set of pairs, and so does their intersection.
9. **The boundary is convex, and each constraint is smallest at** $\mathrm{FNR} = 1 - \mathrm{FPR}$**.** Let $f_{\mathrm{RDP}}(\mathrm{FPR})$ be the smallest allowed FNR at type I error FPR. For allowed pairs $(\mathrm{FPR}_1, \mathrm{FNR}_1)$ and $(\mathrm{FPR}_2, \mathrm{FNR}_2)$, the mixture is allowed, so f_{RDP} at the mixed FPR is at most the mixed FNR. Taking each FNR_i as small as allowed shows that f_{RDP} is convex. At $\mathrm{FNR} = 1 - \mathrm{FPR}$, homogeneity gives $c_1 = G(\mathrm{FPR}, \mathrm{FPR}) + G(1-\mathrm{FPR}, 1-\mathrm{FPR}) = \mathrm{FPR} + (1-\mathrm{FPR}) = 1$. Subadditivity merges the two terms, whose arguments add up to $(\mathrm{FPR} + 1 - \mathrm{FPR},\ 1 - \mathrm{FNR} + \mathrm{FNR}) = (1, 1)$, so $c_1 \ge G(1,1) = 1$ for every $(\mathrm{FPR}, \mathrm{FNR})$, so 1 is the smallest value. A convex function of FNR that is smallest at $1 - \mathrm{FPR}$ decreases on $[0, 1-\mathrm{FPR}]$, which is what the chapter needs to find $f_{\mathrm{RDP}}(\mathrm{FPR})$ by bisection on FNR.

F.5.4. Checking it

At $\alpha = 2$, the script draws 100,000 random pairs of points and weights. It finds no violation of joint convexity or of subadditivity. It also draws 20,000 random mixtures of three pairs of distributions on five outputs, and finds no mixture whose Rényi divergence exceeds the largest of its parts.

On the die, the loaded die gives a six probability 0.5 and each other face 0.1. Take the randomized test that rejects on a six, and with probability $\frac{1}{2}$ on a five. Its type I error is $\mathrm{FPR} = 0.5 + 0.05 = 0.55$, and it rejects under the fair die with probability $1 - \mathrm{FNR} = \frac{1}{6} + \frac{1}{12} = 0.25$. Its coin has $D_2 = 0.3920$, below $D_2(P\|Q) = 0.5878$ for the full roll, as step 7 requires.

For the subsampled Gaussian of step 6, with $q = 0.1$, $\sigma = 1$ and $\alpha = 2$, numerical integration gives $F(Q, P) = 1.0115$, below the bound $0.9 + 0.1e = 1.1718$. The bound is loose here because it charges the full Gaussian divergence to the fraction q of the mixture.

The right panel of Figure F.8 draws the region that order 2 alone allows for the Gaussian mechanism whose sensitivity equals its noise standard deviation ($\mu = 1$ in the chapters), whose RDP curve gives $\varepsilon(2) = 1$. At $\mathrm{FPR} = 0.1$ the boundary is $f_{\mathrm{RDP}}(0.1) = 0.5068$, so the largest power is 0.4932, the order-2 value that Section 30.5 reports. The script checks convexity on a grid of 199 values of FPR: the smallest second difference of f_{RDP} is positive. In the figure, the chord between two boundary points stays inside the region. The boundary has a kink where the binding constraint switches from c_2 to c_1, and convexity survives it.

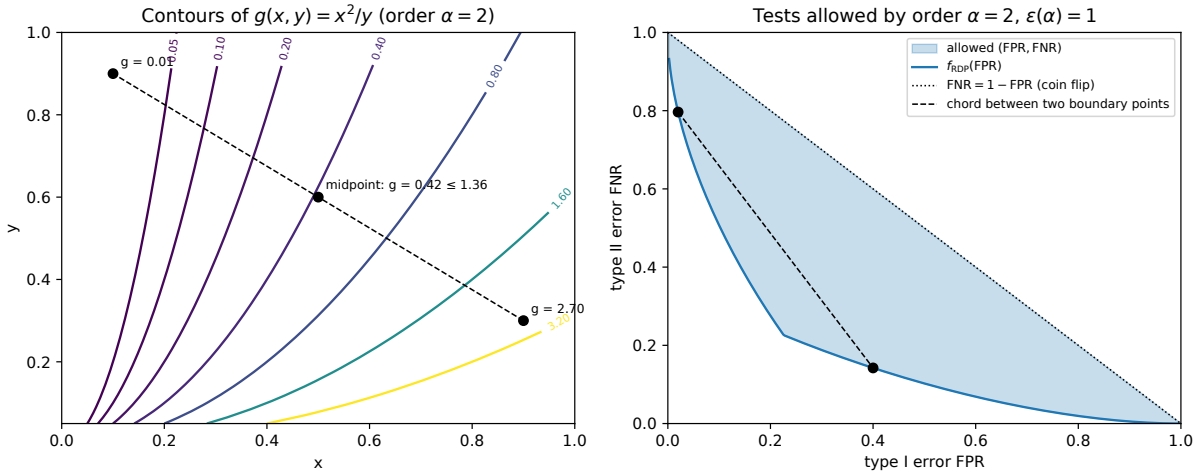

Figure F.8.: Left: contours of $G(x, y) = x^2/y$, the perspective of $g(t) = t^2$, with two points, the chord between them and its midpoint, where the function value is below the average of the two end values. Right: the pairs of type I and type II errors $(\mathrm{FPR}, \mathrm{FNR})$ that order $\alpha = 2$ with $\varepsilon(2) = 1$ allows (shaded), its lower boundary f_{RDP}, and a chord between two boundary points that stays inside.

F.6. A noisy count has an increasing likelihood ratio

F.6.1. What the chapter uses

The example of Section 9.6 releases a noisy count of $m = 100$ other records plus the target's bit b. The adversary sees $K + b + Z$, where the unknown count K of the others is $\mathrm{Bin}(m, \frac{1}{2})$ and the noise Z is normal with mean 0 and standard deviation $\sigma = 1$. Write $w_k = \binom{m}{k} 2^{-m}$ for the binomial weights and φ_σ for the normal density with standard deviation σ. In world 0 ($b = 0$) the observation has density

$$p(y) = f(y), \qquad f(y) = \sum_{k=0}^{m} w_k \, \varphi_\sigma(y - k), \tag{F.46}$$

and in world 1 ($b = 1$) it has the shifted density $q(y) = f(y - 1)$.

The chapter says that the likelihood ratio increases with y, so the best attack is a threshold, at $m/2 + \frac{1}{2} = 50.5$ by symmetry. A tempting reason is that f is log-concave, because a binomial and a normal are both log-concave and so is their sum. That reason is not valid in general, because the rule it quotes concerns two variables that both have log-concave densities on the real line. A binomial count lives on the integers and has no density there, and for such sums the rule fails. For example, a Bernoulli($\frac{1}{2}$) variable plus normal noise with $\sigma = 0.2$ has two separate peaks, as the left panel of Figure F.9 shows, so it is not log-concave. With $m = 100$ and $\sigma = 1$ the density does happen to be log-concave, but with $\sigma = 0.5$ it is not.

The attack needs less than log-concavity, and what it needs holds for every $\sigma > 0$:

$$\frac{q(y)}{p(y)} = \frac{f(y - 1)}{f(y)} \text{ is strictly increasing in } y. \tag{F.47}$$

The proof below uses two properties. The weights w_k must form a **log-concave sequence**, $w_k^2 \geq w_{k-1} w_{k+1}$, with no zero between two non-zero weights. The noise must be normal.

F.6.2. The idea

Both densities are mixtures over the unknown count of the others. Comparing the ratio at two observations $y < y'$ therefore means comparing two double sums, over the count j in one world and the count k in the other. Pair each term (j, k) with its mirror image (k, j). Each pair turns into a product of two factors. One compares the binomial weights, and it is non-negative because the binomial is log-concave. The other compares normal densities, and it is non-negative because a larger observation favours a larger centre. A product of two non-negative factors is non-negative, and so is the sum.

For a single Bernoulli($\frac{1}{2}$) record ($m = 1$), the weights are $w_0 = w_1 = \frac{1}{2}$, and $w_k = 0$ for every other k. The pairs with $j > k$ whose weight factor $w_{j-1} w_k - w_{k-1} w_j$ is not zero are listed in Table F.6. All three weight factors are positive, even though the density has two peaks.

Table F.6.: The weight factors of step 4 for one Bernoulli($\frac{1}{2}$) record, for the pairs $j > k$ where they are not zero.

Pair (j, k)	$w_{j-1} w_k$	$w_{k-1} w_j$	Weight factor
$(1, 0)$	$w_0 w_0 = \frac{1}{4}$	$w_{-1} w_1 = 0$	$\frac{1}{4}$
$(2, 0)$	$w_1 w_0 = \frac{1}{4}$	$w_{-1} w_2 = 0$	$\frac{1}{4}$
$(2, 1)$	$w_1 w_1 = \frac{1}{4}$	$w_0 w_2 = 0$	$\frac{1}{4}$

F.6.3. Derivation

Set $w_i = 0$ for i outside $0, \ldots, m$, and write φ for φ_σ. Substituting $j = k + 1$ in $q(y) = f(y - 1)$ writes both densities as sums over a centre:

$$p(y) = \sum_k w_k \, \varphi(y - k), \qquad q(y) = \sum_j w_{j-1} \varphi(y - j). \tag{F.48}$$

1. **What to show.** The ratio increases exactly when $q(y')/p(y') \geq q(y)/p(y)$ for every $y < y'$. Multiplying by the positive $p(y)p(y')$, this is $\Delta = q(y')p(y) - q(y)p(y') \geq 0$.
2. **Expand.** Multiplying out the sums,

$$\Delta = \sum_{j,k} a_{jk} b_{jk}, \qquad a_{jk} = w_{j-1} w_k, \qquad b_{jk} = \varphi(y' - j)\varphi(y - k) - \varphi(y - j)\varphi(y' - k). \tag{F.49}$$

3. **Pair each term with its mirror.** Swapping j and k swaps the two products in b_{jk}, so $b_{kj} = -b_{jk}$ and $b_{jj} = 0$. Split the sum into the terms with $j > k$ and those with $j < k$, and rename the indices in the second part. Then

$$\Delta = \sum_{j>k} (a_{jk} - a_{kj}) b_{jk} = \sum_{j>k} \left(w_{j-1} w_k - w_{k-1} w_j\right) b_{jk}. \tag{F.50}$$

4. **The weight factor is non-negative.** Take $j > k$. If $w_{k-1} = 0$ or $w_j = 0$, the subtracted product is 0 and the factor is at least 0. Otherwise $k-1$ and j both carry weight, and so does every index between them, because there are no internal zeros. Log-concavity, $w_i^2 \geq w_{i-1} w_{i+1}$, says that the ratio w_{i-1}/w_i never decreases as i grows. So $w_{j-1}/w_j \geq w_{k-1}/w_k$, which is $w_{j-1} w_k \geq w_{k-1} w_j$. For the binomial, $w_{i-1}/w_i = i/(m-i+1)$, which increases with i.
5. **The kernel factor is positive.** Take $j > k$ and $y < y'$. Compare the logarithms of the two products in b_{jk}. Expanding the squares in the normal densities, the terms in y^2, y'^2, j^2 and k^2 cancel, and

$$\ln \frac{\varphi(y'-j)\varphi(y-k)}{\varphi(y-j)\varphi(y'-k)} = \frac{(y-j)^2 + (y'-k)^2 - (y'-j)^2 - (y-k)^2}{2\sigma^2} = \frac{(y'-y)(j-k)}{\sigma^2} > 0. \tag{F.51}$$

   So $b_{jk} > 0$. In words, a larger observation is relatively more likely under the larger centre.
6. **Conclude.** Every term of step 3 is a non-negative weight factor times a positive kernel factor, so $\Delta \geq 0$. The pair $(1, 0)$ has weight factor $w_0^2 > 0$, so $\Delta > 0$ and the ratio is strictly increasing. This proves Equation F.47.
7. **The best attack is a threshold.** By the Neyman–Pearson lemma (Section 4.4), the most powerful test rejects where the likelihood ratio q/p is above a cut-off. When the ratio increases with y, that region is $\{y > \tau\}$ for some threshold τ.
8. **The threshold.** The binomial weights are symmetric, $w_k = w_{m-k}$, and so is the noise, so $f(m/2 + s) = f(m/2 - s)$ for every s. The ratio equals 1 where $f(y-1) = f(y)$. That happens when $y - 1$ and y sit symmetrically around $m/2$, at $y = m/2 + \frac{1}{2}$. Because the ratio is strictly increasing, it crosses 1 only there. The test with the best advantage rejects exactly where $q > p$, that is, where the ratio is above 1 (Section 4.8), which is $\{y > 50.5\}$ for $m = 100$.

F.6.4. Checking it

For the Bernoulli($\frac{1}{2}$) record with $\sigma = 0.2$, the script finds two peaks in the density. On a grid of 4,001 points the log-ratio still increases at every step. It also evaluates the double sum of step 3 directly and matches Δ to rounding error, both for this case and for $m = 100$. For $m = 100$ and $\sigma = 1$, the ratio crosses 1 at 50.5000, and the advantage of that threshold is 0.0779, the exact value in Table 9.6. The largest second difference of $\ln f$ on a grid is negative (-3.8×10^{-6}) at $\sigma = 1$ and positive ($+5.5 \times 10^{-5}$) at $\sigma = 0.5$. So the density is log-concave in the chapter's case but not for smaller noise. The ratio increases in both cases, as the right panel of Figure F.9 shows.

F.6.5. What it does not cover

The proof needs the kernel inequality of step 5 for the noise. Step 5 proves it for normal noise, and it holds for every log-concave noise density, such as the Laplace density (Karlin calls such shift kernels totally positive of order 2). For other noise the argument does not apply. It also needs log-concave weights without internal zeros. A count whose other records have unequal probabilities is a sum of independent Bernoulli variables, and such a count still has log-concave weights, so the result covers it too.

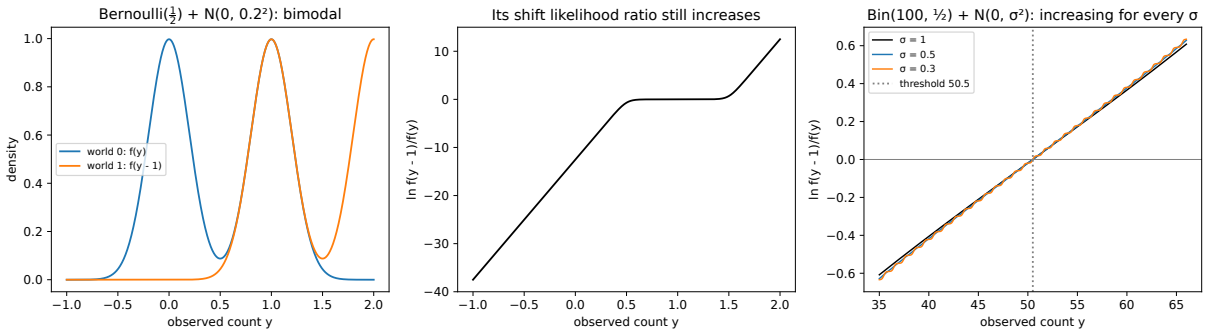

Figure F.9.: Left: the densities of a Bernoulli($\frac{1}{2}$) bit plus normal noise with standard deviation 0.2, in world 0 and shifted by 1 in world 1; each has two peaks. Middle: the logarithm of their likelihood ratio still increases with the observation. Right: the log-likelihood ratio of the chapter's noisy count of 100 records for three noise levels, increasing for each and crossing 0 at 50.5.

F.7. Code

The script `code/appendix-derivations/apx_tails.py` computes every number on this page and draws its figures. For each derivation it checks the inequalities numerically, compares each bound with the exact value, and recomputes the numbers the chapters quote. Run it with

```
uv run python code/appendix-derivations/apx_tails.py
```

Table F.7 lists the main numbers it prints.

Table F.7.: Numbers printed by the script for this appendix.

Section	Quantity	Value
Bernstein	Exact tail, mean of 1,000 Bernoulli(0.01) at $t = 0.01$	3.29×10^{-3}
Bernstein	Bernstein, optimized Chernoff, Hoeffding bounds there	2.26×10^{-2}, 2.00×10^{-2}, 0.819
Bernstein	Width at $\beta = 0.05$: exact root, chapter formula, Hoeffding	0.00875, 0.00968, 0.0387
Cramér	Exact exponent at $n = 100, 1{,}000, 10{,}000$; limit $\mathrm{kl}(0.2 \Vert 0.1)$	0.06225, 0.04728, 0.04481; 0.04440
Chernoff–Stein	Spam example: exponent at $n = 200$; limit KL	0.3730; 0.4564
Clopper–Pearson	$u(0)$, $u(1)$, $u(10)$ at $n = 1{,}000$, level 0.025	0.003682, 0.005559, 0.018313
Clopper–Pearson	Smallest coverage at $n = 100$: Clopper–Pearson, Wald	0.9504, 0.0488

Section	Quantity	Value
Rényi to KL	Die: $D_{0.99}$, KL, $D_{1.01}$	0.2907, 0.2939, 0.2971
Rényi entropy	PIN: $H_{0.999}$, H, $H_{1.001}$ (bits)	12.4310, 12.4278, 12.4246
Perspective	Violations of joint convexity, subadditivity, quasi-convexity	0, 0, 0
Perspective	$F(Q, P)$ and its bound, subsampled Gaussian	1.0115, 1.1718
Noisy count	Crossing point and advantage, $m = 100$, $\sigma = 1$	50.5000, 0.0779

Each bound sits on the right side of its exact value, and the limits are approached at the slow rates the proofs predict. The Wald coverage of 0.0488 occurs at the extreme rates of the grid, 0.0005 and 0.9995. At $p = 0.0005$, for example, the count is 0 in 95% of runs, and then the Wald interval is the single point $[0, 0]$, which misses p. The counts of violations are the numerical form of the convexity proofs.

G. Optimization and estimation

This appendix proves six results that the chapters on optimization, generalization and attacks use without deriving them in full. The first four are about gradient methods on convex functions. Convexity can be recognized in three ways, and on a strongly convex function gradient descent (GD) closes the gap to the minimum by a constant factor per step. On a convex smooth function, a small enough gradient step never pushes two points apart. And on functions whose slope is bounded (Lipschitz functions), no gradient method can beat the rate of stochastic gradient descent (SGD), one over the square root of the number of steps. The other results treat a trained model as a random object, random because its training set is. Here the appendix finds the limit of the error of the 1-nearest-neighbour rule, and shows that the parameters fitted by logistic regression are approximately Gaussian, with a formula for how much one record moves them. It ends by showing when the best attack on the membership of a target record looks at the parameters only through that record's loss. Table G.1 lists where each result is stated or used.

G.1. Convexity three ways, and the linear rate of gradient descent

G.1.1. What the chapter uses

Optimization defines a convex function by its chords, saying that the straight segment between two points of the graph never dips below it. It then works with its tangents, Equation 6.1, which say that the graph lies above each of its tangent planes. It proves that chords give tangents

and says "the other direction, from tangents to chords, is in the references". In Section 6.3 it also states, citing Nesterov's *Lectures on Convex Optimization*, §2.1, that convexity and strong convexity can be read off the Hessian $\nabla^2 f$, the matrix of second derivatives, and that a strongly monotone gradient makes a function strongly convex. Strong monotonicity, Equation 6.7, says that $\langle \nabla f(\theta) - \nabla f(\theta'), \theta - \theta' \rangle \geq \lambda \|\theta - \theta'\|^2$: moving from θ' to θ raises the slope along the direction of travel by at least λ per unit of distance. Its logistic-regression example uses the Hessian test to conclude that the loss is convex. Finally, it proves the linear rate Equation 6.9, a geometric shrinking of the distance to the minimizer, only for a quadratic, while its interpretation says that GD converges linearly on every strongly convex smooth function.

Write f for a differentiable function of the parameters $\theta \in \mathbb{R}^d$, and $\lambda \geq 0$ for a level of curvature. The four claims proved here are these. First, tangents give chords. Suppose f lies above all its tangents, $f(\theta') \geq f(\theta) + \langle \nabla f(\theta), \theta' - \theta \rangle$ for all points θ and θ'. Then, for every mixing weight $\omega \in [0, 1]$,

$$f(\omega\theta' + (1-\omega)\theta) \leq \omega f(\theta') + (1-\omega) f(\theta). \tag{G.1}$$

Second, a Hessian with every eigenvalue at least λ makes f lie above each tangent by a bowl of curvature λ. In symbols, with I the identity matrix, if $\nabla^2 f(\theta) \succeq \lambda I$ everywhere, then

$$f(\theta') \geq f(\theta) + \langle \nabla f(\theta), \theta' - \theta \rangle + \frac{\lambda}{2} \|\theta' - \theta\|^2. \tag{G.2}$$

This inequality is what **λ-strongly convex** means, and with $\lambda = 0$ it is convexity. The Hessian test also works backwards for $\lambda = 0$: a convex twice-differentiable f has $\nabla^2 f \succeq 0$. Third, a strongly monotone gradient gives Equation G.2 without any second derivatives.

The fourth claim is about GD on the training objective. Take an empirical risk $\mathcal{L}(\theta; D)$, written $\mathcal{L}(\theta)$ here because the dataset D stays fixed. Let it be λ-strongly convex, with minimum value $\mathcal{L}^*$, and let it also be β-smooth, so that no curvature exceeds the number β, and write $\kappa = \beta/\lambda$ for its condition number. Then GD with the learning rate $\eta = 1/\beta$ shrinks the gap to the minimum by the factor $1 - 1/\kappa$ at every step, where θ_t is the point reached after t steps:

$$\mathcal{L}(\theta_t) - \mathcal{L}^* \leq \left(1 - \frac{1}{\kappa}\right)^t (\mathcal{L}(\theta_0) - \mathcal{L}^*). \tag{G.3}$$

And when $\mathcal{L}$ is twice differentiable with $\lambda I \preceq \nabla^2 \mathcal{L} \preceq \beta I$, the chapter's distance bound Equation 6.9 holds exactly as stated for the quadratic.

G.1.2. The idea

To get a chord from tangents, look at the mixed point $z = \omega\theta' + (1-\omega)\theta$ and draw the tangent there. The graph lies above this tangent at both ends, θ and θ', so it still lies above it after you average the two endpoint values with the weights $1-\omega$ and ω. The tangent is a straight line, so its weighted average over the two ends is its value at the weighted average of the ends, which is z itself. So the average of the function values is at least the tangent's value at z, which is $f(z)$. Take $f(\theta) = \theta^2$, $\theta = 0$, $\theta' = 2$ and $\omega = \frac{1}{2}$, so $z = 1$. The tangent at 1 is $1 + 2(\theta - 1)$. At the two ends it gives -1 and 3, below the function values 0 and 4. The two tangent values average to $1 = f(z)$, and the function values average to 2, which is at least 1.

The Hessian test works one line at a time. Restricted to the line from θ to θ', the function is a function of one variable whose second derivative is at least λ times the squared length of the step. Its slope therefore grows at least linearly along the line, and integrating twice gives the bowl.

The linear rate combines two inequalities. The chapter shows that a GD step with the learning rate $\eta = 1/\beta$ (the learning rate is also called the step size) lowers $\mathcal{L}$ by at least $\|\nabla\mathcal{L}\|^2/(2\beta)$. Strong convexity adds that the gradient cannot be small while the gap is large: the gap is at most $\|\nabla\mathcal{L}\|^2/(2\lambda)$. So each step removes at least the fraction $\lambda/\beta = 1/\kappa$ of the gap that remains.

G.1.3. Derivation

1. **Tangents give chords.** Let $z = \omega\theta' + (1-\omega)\theta$. The tangent inequality at z, applied towards θ and towards θ', gives $f(\theta) \geq f(z) + \langle \nabla f(z), \theta - z\rangle$ and $f(\theta') \geq f(z) + \langle \nabla f(z), \theta' - z\rangle$. Multiply the first by $1-\omega$ and the second by ω, and add. The inner products combine into $\langle \nabla f(z), (1-\omega)\theta + \omega\theta' - z\rangle$, which is zero because the vector on the right is $z - z$. What is left is $(1-\omega)f(\theta) + \omega f(\theta') \geq f(z)$, the chord inequality. Figure G.1 (left) draws the two gaps and their average.
2. **A curvature bound gives the bowl.** Fix θ and θ', and let $u = \theta' - \theta$ be the step between them. Walking a fraction $s \in [0,1]$ of that step gives the one-variable function $g(s) = f(\theta + su)$, the values of f along the segment. By the chain rule, $g'(s) = \langle \nabla f(\theta + su), u\rangle$ and $g''(s) = u^\top \nabla^2 f(\theta + su)\, u$. A symmetric matrix A satisfies $A \succeq \lambda I$ exactly when $u^\top A u \geq \lambda \|u\|^2$ for every u, so the curvature bound says $g''(s) \geq \lambda\|u\|^2$. Now integrate twice. By the fundamental theorem of calculus, the slope at s is the slope at 0 plus the integral of g'' from 0 to s, so $g'(s) \geq g'(0) + \lambda s\|u\|^2$. Integrating again over $s \in [0,1]$ gives $g(1) \geq g(0) + g'(0) + \frac{\lambda}{2}\|u\|^2$, which is Equation G.2 written in terms of f.
3. **And back: convexity gives a Hessian with no negative eigenvalue.** Step 5 of Section 6.3, with $\lambda = 0$, shows that a convex f has a monotone gradient, $\langle \nabla f(\theta + su) - \nabla f(\theta), su\rangle \geq 0$. In terms of g this says $s\,(g'(s) - g'(0)) \geq 0$. Divide by s^2 and let $s \to 0$: the ratio $(g'(s) - g'(0))/s$ tends to $g''(0) = u^\top \nabla^2 f(\theta) u$, so that is at least 0 for every direction u.
4. **Strong monotonicity gives the bowl.** Keep the same g. Strong monotonicity Equation 6.7, applied to the points $\theta + su$ and θ, says $\langle \nabla f(\theta + su) - \nabla f(\theta), su\rangle \geq \lambda s^2 \|u\|^2$. Dividing by $s > 0$ gives $g'(s) - g'(0) \geq \lambda s\|u\|^2$, which is the inequality of step 2 obtained without second derivatives. Integrating it over $s \in [0,1]$ again gives Equation G.2.
5. **A small gradient means a small gap.** Apply Equation G.2 at a point θ towards every other point θ'. The right side is a parabola in θ', and completing the square shows that its lowest value is $\mathcal{L}(\theta) - \|\nabla\mathcal{L}(\theta)\|^2/(2\lambda)$, reached at $\theta' = \theta - \nabla\mathcal{L}(\theta)/\lambda$. Every value of $\mathcal{L}$ is above the right side, and so above that lowest value. In particular $\mathcal{L}^* \geq \mathcal{L}(\theta) - \|\nabla\mathcal{L}(\theta)\|^2/(2\lambda)$, which rearranges to the **Polyak–Łojasiewicz inequality**:

$$\mathcal{L}(\theta) - \mathcal{L}^* \leq \frac{\|\nabla\mathcal{L}(\theta)\|^2}{2\lambda}. \tag{G.4}$$

6. **Each step removes a fixed fraction of the gap.** The chapter derives from the descent lemma Equation 6.6 that one GD step with the learning rate $\eta = 1/\beta$ gives $\mathcal{L}(\theta_{t+1}) \leq \mathcal{L}(\theta_t) - \|\nabla\mathcal{L}(\theta_t)\|^2/(2\beta)$. Subtract $\mathcal{L}^*$ from both sides. By Equation G.4, $\|\nabla\mathcal{L}(\theta_t)\|^2 \geq 2\lambda(\mathcal{L}(\theta_t) - \mathcal{L}^*)$, so the subtracted term is at least $\frac{\lambda}{\beta}(\mathcal{L}(\theta_t) - \mathcal{L}^*)$. Hence $\mathcal{L}(\theta_{t+1}) - \mathcal{L}^* \leq (1 - 1/\kappa)(\mathcal{L}(\theta_t) - \mathcal{L}^*)$, and repeating this t times gives Equation G.3.

7. **The distance bound, when second derivatives exist.** Write θ^* for the minimizer. It has zero gradient, so the GD step can be written as $\theta_{t+1} - \theta^* = (\theta_t - \theta^*) - \frac{1}{\beta}(\nabla\mathcal{L}(\theta_t) - \nabla\mathcal{L}(\theta^*))$. Step 4 of Section 6.3 writes the gradient difference as $\bar{H}_t(\theta_t - \theta^*)$, where $\bar{H}_t = \int_0^1 \nabla^2\mathcal{L}(\theta^* + s(\theta_t - \theta^*))\,ds$ is the average Hessian along the segment. For a unit vector u, $u^\top \bar{H}_t u$ is an average of numbers $u^\top \nabla^2\mathcal{L}\, u$ that all lie in $[\lambda, \beta]$, so it lies there too. The smallest and largest values of $u^\top A u$ over unit vectors are the extreme eigenvalues of a symmetric A, so every eigenvalue of $\bar{H}_t$ is in $[\lambda, \beta]$. Substituting $\bar{H}_t(\theta_t - \theta^*)$ for the gradient difference in the GD step gives $\theta_{t+1} - \theta^* = (I - \bar{H}_t/\beta)(\theta_t - \theta^*)$, a matrix with eigenvalues between 0 and $1 - 1/\kappa$ applied to the error. This is the quadratic's step 1 with the fixed H replaced by $\bar{H}_t$, and its steps 2 and 3 then go through unchanged and give Equation 6.9.

Step 7 also gives a faster rate for the gap. The gradient vanishes at θ^*, so the descent lemma at θ^* gives $\mathcal{L}(\theta_t) - \mathcal{L}^* \le \frac{\beta}{2}\|\theta_t - \theta^*\|^2$, and with Equation 6.9 the gap falls like $(1 - 1/\kappa)^{2t}$. That exponent is twice the one in Equation G.3. The slower rate is the price of an argument that uses only first derivatives.

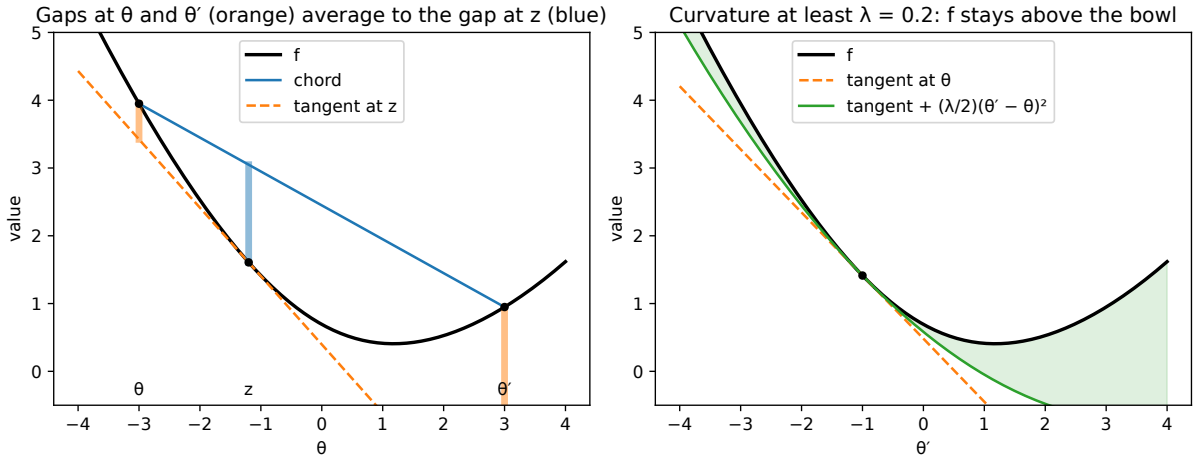

Figure G.1.: Left: the chord of $f(\theta) = \ln(1 + e^{-\theta}) + 0.1\theta^2$ between $\theta = -3$ and $\theta' = 3$, the tangent at the mixed point z, and the two gaps between f and the tangent at the ends (orange), whose weighted average is the gap between the chord and $f(z)$ (blue). Right: the same function with curvature at least $\lambda = 0.2$, which stays above its tangent plus the bowl $\frac{\lambda}{2}(\theta' - \theta)^2$.

G.1.4. Checking it

The script uses the logistic data of the optimization chapter: $n = 1{,}000$ records with x uniform on the unit sphere in $\mathbb{R}^5$ and labels from a logistic model. It adds a ridge penalty $\frac{\lambda}{2}\|\theta\|^2$ with $\lambda = 0.01$. Each x has length 1, so the logistic curvature is at most $\frac{1}{4}$, and the ridge adds λ. So $\beta = 0.26$ and $\kappa = 26$. Over 2,000 random pairs of points in the ball of radius 5, the smallest ratio of the tangent gap $\mathcal{L}(\theta') - \mathcal{L}(\theta) - \langle\nabla\mathcal{L}(\theta), \theta' - \theta\rangle$ to $\frac{1}{2}\|\theta' - \theta\|^2$ is 0.0372, above $\lambda = 0.01$ as Equation G.2 requires.

GD from $\theta_0 = 0$ satisfies both bounds with room to spare. Over the first 40 steps, the gap shrinks by a factor of at most 0.7131 per step and the distance by at most 0.8445, both below

$1 - 1/\kappa = 0.9615$. After 25 steps the gap is 1.22×10^{-5}, against 5.30×10^{-2} from Equation G.3. After 50 steps it is 2.59×10^{-9}, against 1.99×10^{-2}.

The bounds are loose here because they know only the curvature $\lambda = 0.01$ of the penalty, while the data add curvature of their own. At the minimizer, the smallest eigenvalue of $\nabla^2 \mathcal{L}$ is 0.0404. The rate of step 7 with that curvature in place of λ is $(1 - 0.0404/0.26)^2 = 0.713$ per step, and the measured rate between steps 20 and 40 is 0.712. So the form of the rate is exact, and only the curvature it is given is pessimistic. Figure G.2 shows the run.

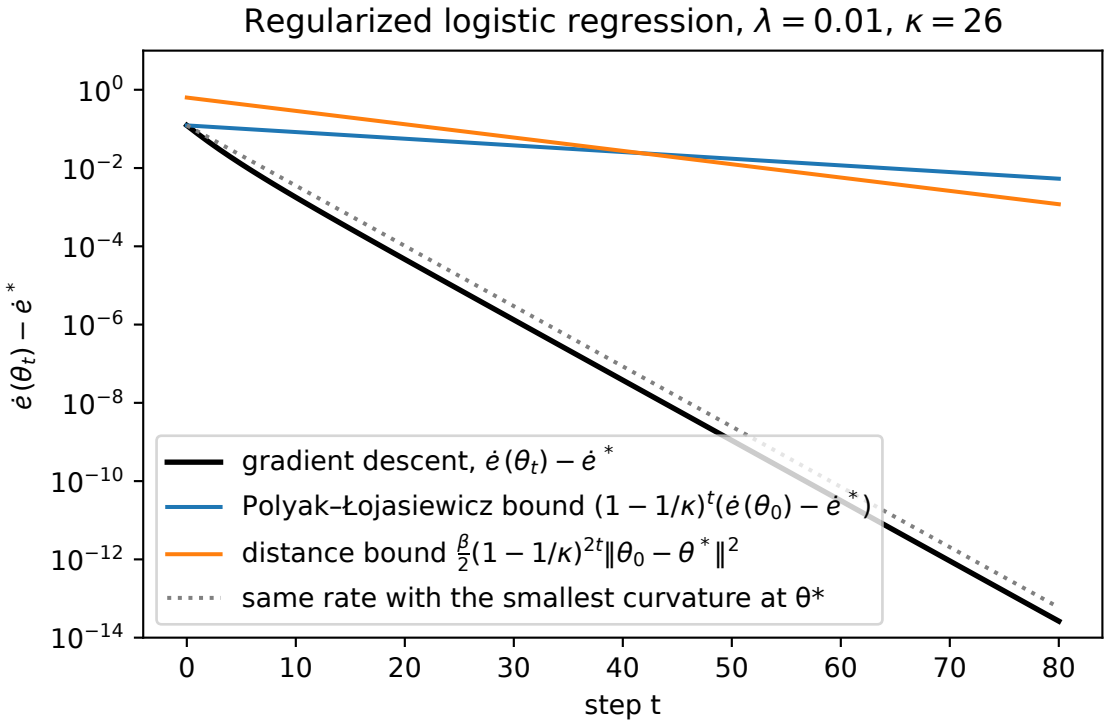

Figure G.2.: The gap $\mathcal{L}(\theta_t) - \mathcal{L}^*$ of GD on ridge-regularized logistic regression ($\lambda = 0.01$, $\kappa = 26$), with the Polyak–Łojasiewicz bound Equation G.3, the bound from the distance Equation 6.9, and the same rate computed with the smallest curvature at the minimizer, which tracks the run.

G.1.5. What it does not cover

The distance bound Equation 6.9 was proved here only for twice-differentiable $\mathcal{L}$. It holds without second derivatives as well. That proof applies the co-coercivity of the next section to $\mathcal{L} - \frac{\lambda}{2}\|\theta\|^2$, which is convex and $(\beta - \lambda)$-smooth (Nesterov 2018, Theorem 2.1.12), and it is longer than the short argument of step 7. The gap bound Equation G.3 needs only the descent lemma and Equation G.4, so it holds for any function that satisfies the Polyak–Łojasiewicz inequality, even one that is not convex (Karimi, Nutini & Schmidt 2016).

G.2. The gradient of a convex smooth function is co-coercive

G.2.1. What the chapter uses

Fact 4 of Algorithmic stability and generalization states that the gradient of a convex β-smooth function f is **co-coercive**. In words, two gradients that differ by a lot must come from points that are far apart along the direction of that difference. For all u and v,

$$\langle \nabla f(u) - \nabla f(v),\, u - v \rangle \geq \frac{1}{\beta} \|\nabla f(u) - \nabla f(v)\|^2. \tag{G.5}$$

The chapter cites Nesterov's Theorem 2.1.5 and says "the proof needs more than a few lines". It then derives from Equation G.5 that a gradient step $\psi(\theta) = \theta - \eta \nabla f(\theta)$ with $0 \leq \eta \leq 2/\beta$ is non-expansive, $\|\psi(u) - \psi(v)\| \leq \|u - v\|$. That fact drives the stability bound Equation 7.19 for SGD, and Section 35.5 uses the same contraction in amplification by iteration.

G.2.2. The idea

Subtract from f its tangent at v. The result, φ, is still convex and β-smooth, and its gradient is zero at v, so v is its lowest point. Now stand at u and take a gradient step on φ. By the descent lemma, the step lowers φ by at least $\|\nabla\varphi(u)\|^2/(2\beta)$, and no step can go below the lowest value $\varphi(v)$. So $\varphi(u)$ must sit at least $\|\nabla\varphi(u)\|^2/(2\beta)$ above $\varphi(v)$. In words, a convex smooth function cannot have a steep slope close to its minimum. This gives a tangent inequality with an extra term. Writing it once from u and once from v, and adding the two, gives Equation G.5.

A one-dimensional case makes the inequality concrete. Take the logistic loss

$$f(\theta) = \ln(1 + e^{-\theta}), \tag{G.6}$$

whose slope is $f'(\theta) = -\sigma(-\theta)$, where $\sigma(s) = 1/(1 + e^{-s})$ is the logistic function, and whose curvature is at most $\beta = \frac{1}{4}$. At the two points $u = 0$ and $v = 2$ the slopes are -0.5000 and -0.1192. The left side of Equation G.5 is $(-0.5000 + 0.1192)(0 - 2) = 0.7616$, and the right side is $0.3808^2/0.25 = 0.5800$, smaller as it should be. For the quadratic $f(\theta) = \frac{\beta}{2}\theta^2$ the slope difference is $\beta(u - v)$, so both sides equal $\beta(u - v)^2$, and the inequality is tight.

G.2.3. Derivation

1. **Shift the minimum to v.** Define $\varphi(\theta) = f(\theta) - \langle \nabla f(v), \theta \rangle$. Subtracting a linear function changes neither the curvature nor the differences between gradients, so φ is convex and β-smooth. Its gradient is $\nabla\varphi(\theta) = \nabla f(\theta) - \nabla f(v)$, which is zero at $\theta = v$. The tangent inequality Equation 6.1 for φ at v then reads $\varphi(\theta) \geq \varphi(v)$ for every θ, so v minimizes φ.
2. **A gradient step from u cannot go below the minimum.** Apply the descent lemma Equation 6.6 to φ at u, with the step $\theta' = u - \nabla\varphi(u)/\beta$. The computation is the chapter's GD step with $\beta = \beta$, and it gives $\varphi(\theta') \leq \varphi(u) - \|\nabla\varphi(u)\|^2/(2\beta)$. Since $\varphi(v) \leq \varphi(\theta')$ by step 1, we get $\varphi(v) \leq \varphi(u) - \|\nabla\varphi(u)\|^2/(2\beta)$.

3. **Return to f.** Write $\Delta = \nabla f(u) - \nabla f(v)$, which is $\nabla\varphi(u)$. The difference $\varphi(u) - \varphi(v)$ is $f(u) - f(v) - \langle \nabla f(v), u - v\rangle$, so step 2 becomes a tangent inequality with an extra term:

$$f(u) \geq f(v) + \langle \nabla f(v), u - v\rangle + \frac{1}{2\beta}\|\Delta\|^2. \tag{G.7}$$

4. **Swap and add.** The same inequality with u and v exchanged is $f(v) \geq f(u) + \langle \nabla f(u), v - u\rangle + \frac{1}{2\beta}\|\Delta\|^2$, because exchanging the points only flips the sign of Δ. Adding the two, the function values cancel and the inner products combine into $-\langle \Delta, u - v\rangle$, which leaves $0 \geq -\langle \Delta, u - v\rangle + \frac{1}{\beta}\|\Delta\|^2$. That is Equation G.5.
5. **The step is non-expansive.** This is the chapter's own argument, repeated so that the page stands alone. Expand $\psi(u) - \psi(v) = (u - v) - \eta\Delta$ as a square and replace $\langle \Delta, u - v\rangle$ by the smaller $\|\Delta\|^2/\beta$:

$$\|\psi(u) - \psi(v)\|^2 = \|u - v\|^2 - 2\eta\langle \Delta, u - v\rangle + \eta^2\|\Delta\|^2 \leq \|u - v\|^2 - \eta\Big(\frac{2}{\beta} - \eta\Big)\|\Delta\|^2. \tag{G.8}$$

   For $0 \leq \eta \leq 2/\beta$ the subtracted term is not negative, so the distance does not grow.

G.2.4. Checking it

The script draws 500 pairs (u, v) from a normal distribution with standard deviation 4 and evaluates both sides of Equation G.5 for the logistic loss. The smallest ratio of left to right side is 1.0006, so the inequality holds and is nearly tight. The tight pairs lie near 0, where the curvature of the logistic loss is close to $\frac{1}{4}$ and the loss looks like the quadratic of the example. For the five-dimensional logistic risk of the previous section, the smallest ratio over 2,000 pairs is 5.3704. That risk curves much less than $\frac{1}{4}$ in most directions, so the bound has slack there.

The non-expansive step behaves as step 5 says. Over the 500 pairs, the largest ratio $|\psi(u) - \psi(v)|/|u - v|$ is 0.9993 at $\eta = 4$ and 0.9988 at $\eta = 8 = 2/\beta$. At $\eta = 10$ it is 1.4985, so the step pushes some pairs apart. Figure G.3 shows both checks.

G.2.5. What it does not cover

Both convexity and smoothness are needed. Without convexity, step 1 fails, because a zero gradient no longer marks a minimum. A gradient step can then expand distances by up to the factor $1 + \eta\beta$, as on the concave function $-\frac{\beta}{2}\theta^2$, whose step multiplies every distance by exactly $1 + \eta\beta$. Without smoothness there is no descent lemma, and the gradient of a function with a kink, such as $|\theta|$, jumps by 2 between points arbitrarily close together, so no constant β can work.

G.3. No gradient method beats $RL/\sqrt{T}$ on every convex Lipschitz function

G.3.1. What the chapter uses

The section on SGD for convex Lipschitz objectives in Optimization proves Equation 6.11, an error of at most $RL/\sqrt{T}$ after T steps. Here R is the distance from the start to the minimizer, and L is the Lipschitz constant, the largest size of a gradient. Its interpretation then says that

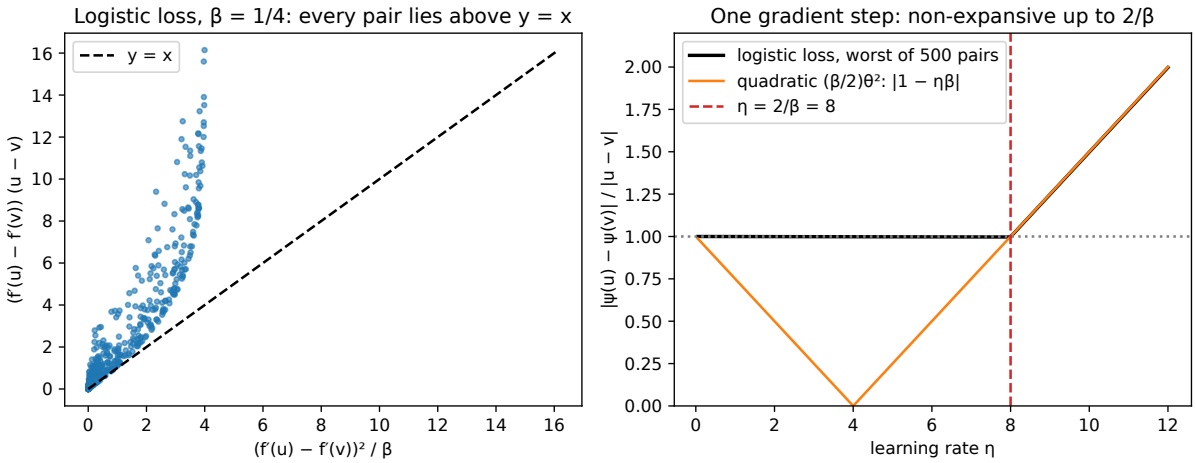

Figure G.3.: Left: for 500 random pairs, $(f'(u)-f'(v))(u-v)$ against $(f'(u)-f'(v))^2/\beta$ for the logistic loss, $\beta=\frac{1}{4}$. Every point lies above the line $y=x$. Right: the largest ratio of distances after and before one gradient step, over the same pairs, against the learning rate η, with the quadratic's factor $|1-\eta\beta|$. Both cross 1 at $\eta=2/\beta=8$.

the rate cannot be improved: "there are convex L-Lipschitz functions on which every method that only queries gradients has error at least of order $RL/\sqrt{T}$ after T queries (Bubeck 2015, §3.5)."

This section proves that claim for the methods the book uses. A method is **span-restricted** if it starts at $\theta_1=0$ and every point it queries or outputs is a combination of the gradients it has received so far. Gradient descent and SGD, with a constant or a changing learning rate, with projection onto a ball centred at 0 (which only rescales a vector), and with averaged iterates, are all span-restricted. The claim is that in dimension $d\ge T+1$ there is a convex function that is L-Lipschitz on the ball $\{\|\theta\|\le R\}$, with its minimizer at distance R from the start, on which every span-restricted method, after T gradient queries, outputs a point θ with

$$f(\theta)-f^*\ge\frac{RL}{2(1+\sqrt{T+1})}. \tag{G.9}$$

The right side is close to half of $RL/\sqrt{T}$ for large T, so the SGD guarantee is optimal up to a factor of about 2.

G.3.2. The idea

The hard function hides its minimum in many coordinates and reveals them one gradient at a time. It uses one more coordinate than the method has queries, $k=T+1$. Its first term is a positive constant γ times the largest of the first k coordinates, and its second is a small bowl with a positive weight α. Both constants are chosen below:

$$f(\theta)=\gamma\max_{i\le k}\theta_i+\frac{\alpha}{2}\|\theta\|^2. \tag{G.10}$$

Its lowest point spreads equal negative values over all k coordinates, which brings the largest coordinate down. But the gradient at a point whose later coordinates are all zero involves only one

new coordinate, the first place where the largest value is reached. So after T gradients the method has touched at most T coordinates. The last coordinate is still zero, so the largest coordinate is at least zero, and f is at least zero. The minimum is negative, and its distance below zero is the bound.

Take $T = 2$, so $k = 3$, with $R = L = 1$. The constants are then $\gamma = 0.6340$ and $\alpha = 0.3660$, and the minimum is $f^* = -0.1830$. The first query is at $\theta_1 = 0$, where all three coordinates tie at 0, so the gradient points along the first coordinate. The method's next point has the form $(a, 0, 0)$. Whatever a is, the largest coordinate is first reached at the first or the second position, so the second gradient involves only the first two coordinates. Any output is then of the form $(a', b', 0)$, its third coordinate makes the largest coordinate at least 0, and $f \geq 0$. The error is at least 0.1830, which is $1/(2(1+\sqrt{3}))$, the right side of Equation G.9.

G.3.3. Derivation

1. **The minimum.** The largest of k numbers is at least their average, so $f(\theta) \geq \sum_{i \leq k} (\frac{\gamma}{k}\theta_i + \frac{\alpha}{2}\theta_i^2) + \frac{\alpha}{2}\sum_{i>k}\theta_i^2$. Each term of the first sum is a parabola in θ_i whose lowest value is $-\gamma^2/(2\alpha k^2)$, at $\theta_i = -\gamma/(\alpha k)$. The terms of the second sum are at least 0. Adding up, $f(\theta) \geq -\gamma^2/(2\alpha k)$. The point with $\theta_i = -\gamma/(\alpha k)$ for $i \leq k$ and 0 elsewhere reaches this value, because its first k coordinates are equal and so their largest equals their average. So
$$f^* = -\frac{\gamma^2}{2\alpha k}, \qquad \|\theta^*\| = \frac{\gamma}{\alpha\sqrt{k}}. \tag{G.11}$$
2. **The constants.** The max term changes by at most γ times the distance moved, since no coordinate changes by more than the distance. On the ball of radius R the quadratic term changes by at most αR times the distance, since $\frac{\alpha}{2}(\|\theta\|^2 - \|\theta'\|^2) = \frac{\alpha}{2}\langle\theta + \theta', \theta - \theta'\rangle$ and $\|\theta + \theta'\| \leq 2R$. So f is $(\gamma + \alpha R)$-Lipschitz on the ball. Asking for $\gamma + \alpha R = L$ and $\|\theta^*\| = R$, and solving the two equations, gives
$$\gamma = \frac{L\sqrt{k}}{1+\sqrt{k}}, \qquad \alpha = \frac{L}{R(1+\sqrt{k})}, \qquad -f^* = \frac{RL}{2(1+\sqrt{k})}. \tag{G.12}$$
3. **The gradients the method sees.** At a point θ, let i be the first index at which $\theta_1, \dots, \theta_k$ reach their largest value, and return $g = \gamma e_i + \alpha\theta$, where e_i is the i-th unit vector. This is a legitimate gradient for a function with a kink, a subgradient as in the chapter: its tangent stays below the graph. The reason is that $\max_j \theta'_j \geq \theta'_i = \max_j \theta_j + \langle e_i, \theta' - \theta\rangle$, while the quadratic term lies above its own tangent. Adding the two gives $f(\theta') \geq f(\theta) + \langle g, \theta' - \theta\rangle$.
4. **One new coordinate per query.** Write V_s for the vectors whose coordinates after the s-th are zero. The claim is that the s-th query point lies in V_{s-1} and its gradient in V_s. The first query is at $0 \in V_0$. Suppose the s-th query point θ_s is in V_{s-1}, with $s \leq k$. Its coordinates $s, \dots, k$ are zero, so its largest coordinate among the first k is at least 0. If that largest value is 0, coordinate s reaches it, so the first index that does is at most s. If it is positive, it is reached among the first $s-1$ coordinates. Either way $e_i \in V_s$, and $\alpha\theta_s \in V_{s-1}$, so $g_s \in V_s$. A span-restricted method then chooses θ_{s+1} in V_s.
5. **The error after T queries.** Any output lies in the span of $g_1, \dots, g_T$, which is inside V_T. Its coordinate $k = T + 1$ is zero, so its largest coordinate is at least 0 and $f(\theta) \geq \frac{\alpha}{2}\|\theta\|^2 \geq 0$. The error is therefore at least $-f^*$, which by step 2 with $k = T + 1$ is Equation G.9.

G.3.4. Checking it

The script runs the projected subgradient method of the chapter, with the learning rate $\eta = R/(L\sqrt{T})$ and the averaged iterate, against these gradients, with $R = L = 1$. Table G.2 shows that its error always lies between the two bounds.

Table G.2.: Error of the averaged iterate on the hard function, $R = L = 1$, against the lower and upper bounds.

T	Lower bound Equation G.9	Subgradient method	SGD guarantee $RL/\sqrt{T}$
10	0.1158	0.1285	0.3162
100	0.0452	0.0519	0.1000
1,000	0.0153	0.0178	0.0316
10,000	0.0050	0.0058	0.0100

No iterate ever has a negative value of f, as step 5 predicts. The method sits just above the lower bound, about 17% above it at $T = 10{,}000$ (a ratio of 1.17), so the lower bound is close to exact for this method. The upper bound is about twice the lower one, as the ratio $2(1 + \sqrt{T+1})/\sqrt{T}$ approaches 2. Figure G.4 shows the three on a log scale.

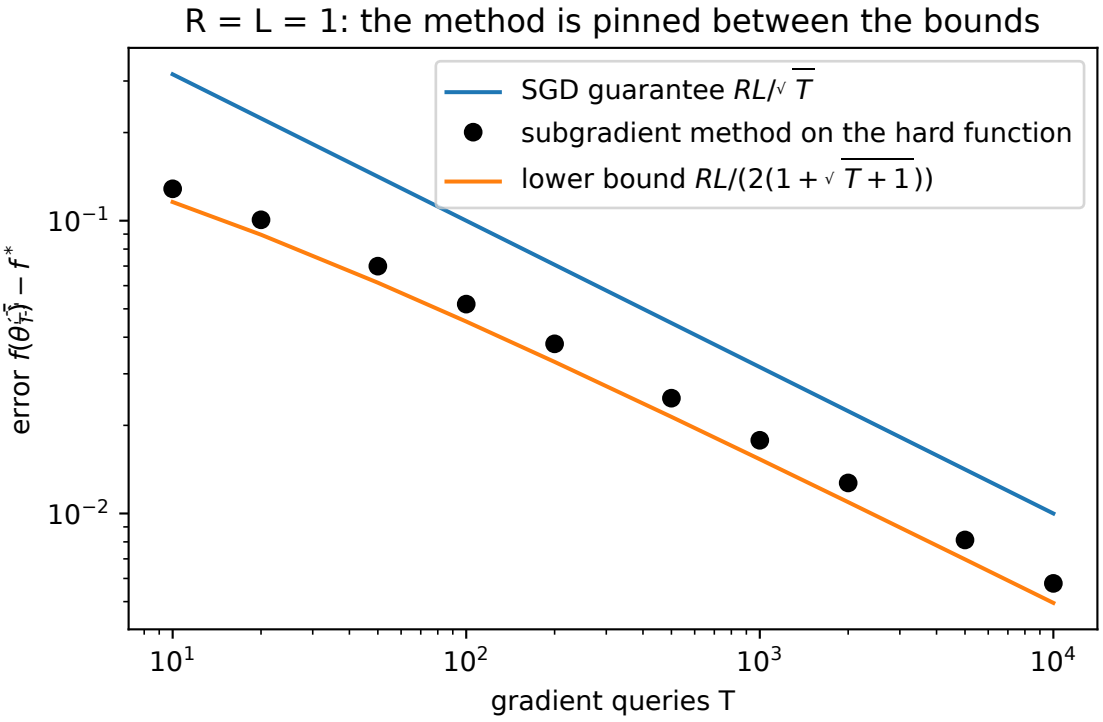

Figure G.4.: The lower bound $RL/(2(1 + \sqrt{T+1}))$, the SGD guarantee $RL/\sqrt{T}$, and the error of the projected subgradient method on the hard function, against the number of gradient queries T, with $R = L = 1$.

G.3.5. What it does not cover

The proof needs the method to stay in the span of its gradients. Nemirovski & Yudin (1983) remove that condition, and prove the same order of bound for every method that uses only gradients, by hiding the coordinates in a random rotation that the method cannot know in advance; their argument is longer and stays cited. The dimension must also be at least $T + 1$, because in low dimension, methods that cut away part of the space at each query, such as the ellipsoid method, have an error that shrinks like $e^{-cT/d}$ for a constant c (Bubeck 2015, ch. 2). Finally, the bound is for functions that are not smooth. On a smooth function GD with exact gradients does better than $1/\sqrt{T}$, and the $1/\sqrt{T}$ of SGD then comes from its gradient noise.

G.4. The 1-nearest-neighbour error tends to $\mathbb{E}[2p(1-p)]$

G.4.1. What the chapter uses

The nearest neighbour (NN) rule with one neighbour, 1-NN, predicts the label of the closest training point. Algorithmic stability and generalization states, citing Cover & Hart (1967), that its test error tends to $\mathbb{E}[2p(x)(1-p(x))]$ as the number n of training points grows. Here $p(x) = \Pr[y = 1 \mid x]$ is the probability that the label at x is $+1$. Its argument is a sketch, whose step 3 says that for large n "the nearest neighbour of a test point x lies at (essentially) x". In its running example the limit is 0.338 and the Bayes error, the error of the best possible classifier, is 0.250.

The precise statement proved here is this. Let the training pairs (x_i, y_i) and the test pair (x, y) be independent draws from the same distribution. Assume that x lies in a closed and bounded set K, and that p is continuous on K. Ties between equally near neighbours may be broken by any rule that looks only at the points, not at their labels. Then the test error R_n of 1-NN, averaged over the training set and the test pair, satisfies

$$\lim_{n\to\infty} R_n = \mathbb{E}\big[2p(x)(1-p(x))\big]. \tag{G.13}$$

G.4.2. The idea

The argument has two parts. First, the nearest neighbour gets close. For a fixed test point, the chance that none of the n training points lands within a distance r of it is $(1-P)^n$, where P is the chance that one point lands there. As long as $P > 0$, this goes to zero. Second, the labels behave like two coins. Given where all the points are, the neighbour's label is $+1$ with probability $p(x')$, where x' is the neighbour, and the test label is $+1$ with probability $p(x)$, independently. They disagree with probability

$$e(x, x') = p(x)(1-p(x')) + (1-p(x))p(x'). \tag{G.14}$$

As x' approaches x, $e(x, x')$ approaches $2p(x)(1-p(x))$.

Table G.3 shows the two coins at a test point with $p(x) = 0.8$. A neighbour where $p = 0.7$ disagrees with probability 0.38. A neighbour at the same p disagrees with probability 0.32, which is $2 \times 0.8 \times 0.2$. Even a perfect neighbour disagrees often, because both labels are noisy.

Table G.3.: The chance that the 1-NN prediction is wrong at a test point with $p(x) = 0.8$, for two neighbours.

Neighbour's $p(x')$	Test $+1$, neighbour -1	Test -1, neighbour $+1$	Disagree
0.7	$0.8 \times 0.3 = 0.24$	$0.2 \times 0.7 = 0.14$	0.38
0.8	$0.8 \times 0.2 = 0.16$	$0.2 \times 0.8 = 0.16$	0.32

G.4.3. Derivation

1. **The error given the points.** Fix all the feature vectors, of the training set and the test point. The nearest neighbour x'_n is then fixed, since it depends only on the points. Given the points, the labels are independent, each $+1$ with probability p at its own point. The neighbour was chosen without looking at labels, so its label is still $+1$ with probability $p(x'_n)$. The prediction is wrong when the two labels differ, which has probability $e(x, x'_n)$. Averaging over the points gives $R_n = \mathbb{E}[e(x, x'_n)]$.
2. **The nearest neighbour gets close.** Fix the test point x and a radius $r > 0$, and write $P_r(x)$ for the probability that one training point lands within distance r of x. The training points are independent, so the probability that none of them does is

$$\Pr\left[\|x'_n - x\| > r \,\middle|\, x\right] = (1 - P_r(x))^n, \tag{G.15}$$

   which tends to 0 whenever $P_r(x) > 0$.
3. **Almost every test point has $P_r(x) > 0$.** Suppose some ball around x has probability zero. Then a smaller ball inside it, with a centre whose coordinates are fractions and a radius that is a fraction, also has probability zero and still contains x. Such a ball exists because fractions come arbitrarily close to any number: take a centre within $r/3$ of x and a radius between $r/3$ and $2r/3$, where r is the radius of the original ball. There are only countably many such balls, and each of them that has probability zero contributes nothing, so by the union bound their union has probability zero. So the test points with a zero-probability ball around them have probability zero together. For all other test points, step 2 applies for every r. The averaged probability $\Pr[\|x'_n - x\| > r] = \mathbb{E}[(1 - P_r(x))^n]$ then tends to 0. This uses the **bounded convergence theorem**: if quantities between 0 and 1 tend to 0 at almost every point, so does their average.
4. **The error converges.** Expanding e gives $e(x, x') - e(x, x) = (p(x') - p(x))(1 - 2p(x))$, so $|e(x, x') - e(x, x)| \le |p(x') - p(x)|$. A continuous function on a closed and bounded set is uniformly continuous. So for every tolerance $\xi > 0$ there is an $r > 0$ with $|p(x') - p(x)| \le \xi$ whenever $\|x' - x\| \le r$. Split the average according to whether the neighbour is within r. Inside, the difference is at most ξ, and outside it is at most 1, so

$$\left|R_n - \mathbb{E}[2p(1-p)]\right| \le \mathbb{E}\left|e(x, x'_n) - e(x, x)\right| \le \xi + \Pr\left[\|x'_n - x\| > r\right]. \tag{G.16}$$

   By step 3 the last term tends to 0. The limit of the left side is therefore at most ξ, for every $\xi > 0$, which proves Equation G.13.

G.4.4. Checking it

In the chapter's running example, x is uniform on the unit sphere in $\mathbb{R}^{10}$ and $p(x) = \sigma(5x_1)$. The script computes the Bayes error $\mathbb{E}[\min(p, 1-p)] = 0.250$ and the limit $\mathbb{E}[2p(1-p)] = 0.338$, by numerical integration over the first coordinate. The sphere looks the same from every point, so every test point sees the same P_r, so the median distance to the nearest neighbour can be computed exactly, by solving $(1 - P_r)^n = \frac{1}{2}$ for r. Table G.4 shows that it shrinks very slowly.

Table G.4.: Exact median distance from a test point to its nearest neighbour, for points uniform on the unit sphere in $\mathbb{R}^{10}$.

Training points n	100	4,000	10^6	10^9
Median distance to the nearest neighbour	0.758	0.489	0.261	0.121

The sphere in $\mathbb{R}^{10}$ is a nine-dimensional surface, so P_r grows like r^9 and the distance shrinks only like $n^{-1/9}$. That is why the error approaches its limit slowly. In the script's table, with 4,000 test points, the measured 1-NN error is 0.398 at $n = 100$ and 0.356 at $n = 4{,}000$. The average of $e(x, x'_n)$ over the same test points, which step 1 says has the same mean, is 0.392 and 0.358. Both are still above 0.338, because at $n = 4{,}000$ the typical neighbour is still about 0.49 away, where p differs noticeably. Figure G.5 shows both parts of the argument.

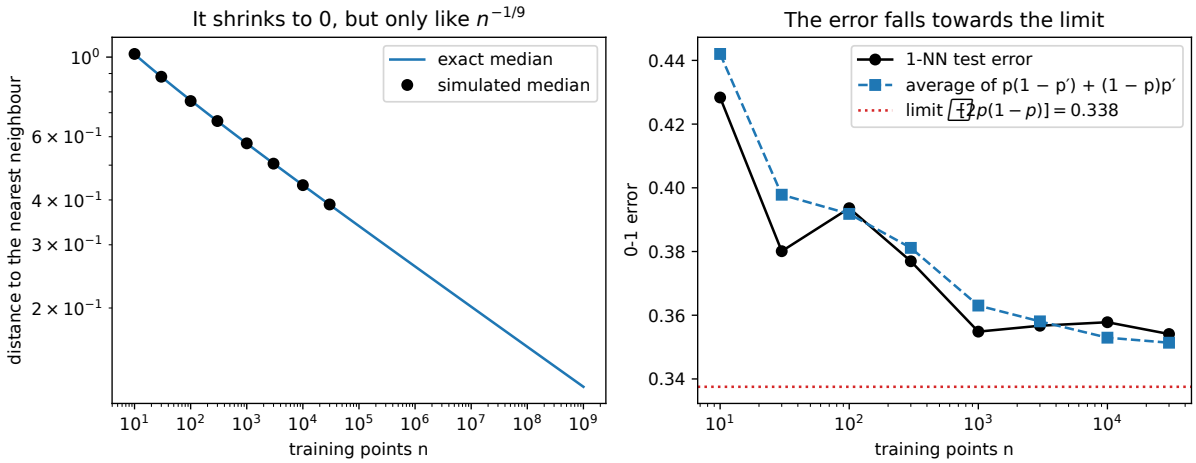

Figure G.5.: Left: the median distance from a test point to its nearest neighbour against n, exact (line) and simulated (dots), for points uniform on the unit sphere in $\mathbb{R}^{10}$. Right: the measured 1-NN test error and the average of $p(1-p') + (1-p)p'$ over the same 20,000 test points, with the limit $\mathbb{E}[2p(1-p)] = 0.338$.

G.4.5. What it does not cover

The limit holds without continuity of p, by a longer argument that approximates p by continuous functions, which is left to Devroye, Györfi & Lugosi (1996, ch. 5). The proof says nothing about the

speed of convergence, and the example shows why none can be given without more assumptions: the speed depends on the dimension of the data. Finally, k-NN with k growing and k/n shrinking converges to the Bayes error itself, because averaging many neighbours' labels estimates $p(x)$ rather than drawing one more coin (Stone 1977).

G.5. Fitted parameters are approximately Gaussian, and one record moves them by its gradient

G.5.1. What the chapter uses

Section 12.5 states that parameters fitted by minimizing an average loss, which statisticians call **M-estimators**, are approximately Gaussian, centred on the population fit with covariance Σ_1/n. Here $\Sigma_1 = H^{-1}GH^{-1}$ is the **sandwich covariance**, H is the average curvature of the loss at the population fit, and G is the covariance of one record's gradient there. The chapter gives a four-step sketch and cites "the standard asymptotic normality of M-estimators (van der Vaart 1998, ch. 5)". The statement feeds the attack accuracy Equation 12.12 and the constant Equation 12.13. Section 10.5 uses the same fact to explain why the margin ϕ_z is close to Gaussian over retrainings. Section 10.7 explains in words which records have a large self-influence $\mu_{\text{in},z} - \mu_{\text{out},z}$, the numerator of the separation in Equation 10.9. And Section 11.5 asserts that as n grows the model approaches the population's probabilities.

This section proves the result for logistic regression, the model all four chapters use. A record is $z = (x, y)$, with a feature vector x, which may include a constant 1 for an intercept, and a label $y = \pm 1$. (The property-inference chapter writes the whole record as x; here the features get their own name.) The loss is $\ell(\theta; z) = \ln(1 + e^{-y\langle\theta, x\rangle})$. The fit $\hat{\theta}$ minimizes the training objective on the dataset $D = (z_1, \dots, z_n)$, here the average loss plus a ridge term, and the population fit θ^* minimizes its average over the data distribution $\mathcal{D}$:

$$\mathcal{L}(\theta; D) = \frac{1}{n}\sum_{i=1}^{n} \ell(\theta; z_i) + \frac{\lambda}{2}\|\theta\|^2, \qquad \mathcal{L}_{\mathcal{D}}(\theta) = \mathbb{E}_{z\sim\mathcal{D}}\, \ell(\theta; z) + \frac{\lambda}{2}\|\theta\|^2. \tag{G.17}$$

The ridge weight $\lambda \geq 0$ may be zero. (The property-inference chapter writes θ for the fit and $\theta(t)$ for the population fit. Here θ is any parameter vector, $\hat{\theta}$ the fit and θ^* the population fit.) The curvature and the gradient covariance are

$$H = \nabla^2 \mathcal{L}_{\mathcal{D}}(\theta^*), \qquad G = \mathbb{E}[g\, g^\top], \quad g = \nabla \ell(\theta^*; z) + \lambda\theta^*. \tag{G.18}$$

The assumptions are that the records are independent draws from one distribution, that $\mathbb{E}\|x\|^6$ is finite (true for bounded or Gaussian features, and needed so that the averages in step 2 have finite variance), and that H has no zero eigenvalue. Write $h > 0$ for its smallest eigenvalue. The claim has two parts. First, $\hat{\theta}$ is within a distance of order $1/\sqrt{n}$ of θ^*. Second, $\sqrt{n}(\hat{\theta} - \theta^*)$ is approximately Gaussian. It **converges in distribution** to a Gaussian, which means that for large n the probability that it lands in any box or half-space approaches the probability for the Gaussian:

$$\sqrt{n}\,(\hat{\theta} - \theta^*) \to \mathcal{N}(0,\ H^{-1}GH^{-1}). \tag{G.19}$$

The influence of one record is a statement about one fixed dataset, so it uses the membership-inference chapter's setting, with a ridge weight $\lambda > 0$ and the margin $\phi_z = y\langle\theta, x\rangle$ of a record

$z = (x, y)$. Compare the fit $\hat{\theta}_D$ on a dataset D that contains z with the fit $\hat{\theta}_{-z}$ of the same objective with z's term removed. Training on z raises its margin by

$$\phi_z(\hat{\theta}_D) - \phi_z(\hat{\theta}_{-z}) = \frac{1}{n}\,\sigma(-\phi_z)\,x^\top H^{-1}x + O(1/n^2), \tag{G.20}$$

where ϕ_z on the right is the margin under $\hat{\theta}_{-z}$, and $\sigma(s) = 1/(1+e^{-s})$ is the logistic function. Here H is the Hessian of the full training objective, with z's term included, at $\hat{\theta}_{-z}$, and "removed" means that the other terms keep their weight $1/n$.

G.5.2. The idea

The argument takes four moves. The first is that the fit is close to the population fit. With high probability the training objective curves upward by at least $h/2$ near θ^*. Its gradient at θ^* is an average of n independent terms with mean zero, so it has size about $1/\sqrt{n}$. A function that curves up by at least $h/2$ cannot have its minimum farther than about $2/h$ times the gradient away. The second move is that, near θ^*, the gradient is almost linear. The condition "gradient zero at $\hat{\theta}$" then becomes, exactly, $0 = \nabla\mathcal{L}(\theta^*; D) + \bar{H}(\hat{\theta} - \theta^*)$, where $\bar{H}$ is the average Hessian between the two points. Solving it gives $\hat{\theta} - \theta^* = -\bar{H}^{-1}\nabla\mathcal{L}(\theta^*; D)$. The third move is that the average gradient is approximately Gaussian, by the central limit theorem, with covariance G/n. The fourth is that $\bar{H}$ approaches H, and multiplying a Gaussian vector by the matrix $-H^{-1}$ multiplies its covariance by H^{-1} on both sides.

The simplest case shows why the covariance is a sandwich. For the loss $\frac{1}{2}(\theta - a)^2$ of a number a, the fit is the sample mean. The curvature is $H = 1$ and the gradient $\theta^* - a$ has variance $G = \mathrm{Var}(a)$, so the sandwich gives the familiar $\mathrm{Var}(a)/n$. Doubling the loss to $(\theta - a)^2$ doubles the curvature and quadruples the gradient variance. The two copies of H^{-1} undo the quadrupling, so the fit's variance does not change, as it should not, since the fit is still the mean.

G.5.3. Derivation

1. **The curvature of the logistic loss changes slowly.** The Hessian of one record's loss is $s(\langle\theta, x\rangle)\,xx^\top$, with $s(m) = \sigma(m)(1-\sigma(m))$. Its derivative is $s'(m) = \sigma(1-\sigma)(1-2\sigma)$, whose largest size is $c = 1/(6\sqrt{3}) \approx 0.0962$. To see this, write $\sigma = \frac{1}{2} + v$, so that $|s'| = 2|v|(\frac{1}{4} - v^2)$, which is largest at $v = 1/(2\sqrt{3})$. The matrix $xx^\top$ stretches no vector by more than $\|x\|^2$, and $|\langle\theta - \theta', x\rangle| \le \|\theta - \theta'\|\,\|x\|$, so the Hessian moves by at most $c\|x\|^3\|\theta - \theta'\|$. Averaging over the records, with $\hat{M}_3 = \frac{1}{n}\sum_i \|x_i\|^3$,

$$\left\|\nabla^2\mathcal{L}(\theta; D) - \nabla^2\mathcal{L}(\theta'; D)\right\| \le c\,\hat{M}_3\,\|\theta - \theta'\|. \tag{G.21}$$

2. **Three averages settle down.** Each of $\nabla^2\mathcal{L}(\theta^*; D)$, $\hat{M}_3$ and $\nabla\mathcal{L}(\theta^*; D)$ is an average of n independent terms. Their means are H, the third moment $M_3 = \mathbb{E}\|x\|^3$, and 0. The last mean is 0 because θ^* minimizes $\mathcal{L}_\mathcal{D}$, so $\mathbb{E}g = \nabla\mathcal{L}_\mathcal{D}(\theta^*) = 0$. Their variances are finite, because the sixth moment is. By Chebyshev's inequality, an average of n terms with variance v strays from its mean by more than a with probability at most $v/(na^2)$. (For a matrix, apply it to the sum of the squared entries, which is at least the square of the largest factor by which the matrix stretches a vector.) So each average is near its mean with probability

tending to 1. Choose the radius $r = h/(8cM_3)$, whose role step 3 shows, and call E_n the event that all three are near their means in the following sense:

$$\big\|\nabla^2\mathcal{L}(\theta^*;D) - H\big\| \le \frac{h}{4}, \qquad \hat{M}_3 \le 2M_3, \qquad \big\|\nabla\mathcal{L}(\theta^*;D)\big\| < \frac{hr}{4}. \tag{G.22}$$

Then E_n holds with probability tending to 1. For the gradient there is even an exact formula for the mean square. The cross terms of independent mean-zero vectors average to zero, so

$$\mathbb{E}\big\|\nabla\mathcal{L}(\theta^*;D)\big\|^2 = \frac{\operatorname{tr} G}{n}. \tag{G.23}$$

3. **The objective curves up near θ^*.** On E_n, take any θ within distance r of θ^*. By step 1 its Hessian differs from $\nabla^2\mathcal{L}(\theta^*;D)$ by at most $c\cdot 2M_3\cdot r = h/4$, and that one differs from H by at most $h/4$. Since $H \succeq hI$, every eigenvalue of $\nabla^2\mathcal{L}(\theta;D)$ is at least $h - h/4 - h/4 = h/2$. So, by step 2 of Section G.1 applied to segments inside the ball, $\mathcal{L}(\cdot;D)$ is $(h/2)$-strongly convex on the ball of radius r around θ^*.
4. **The fit is inside the ball, and close.** On the sphere $\|\theta-\theta^*\| = r$, strong convexity and Cauchy–Schwarz give $\mathcal{L}(\theta;D) \ge \mathcal{L}(\theta^*;D) - \|\nabla\mathcal{L}(\theta^*;D)\|r + \frac{h}{4}r^2$. This is larger than $\mathcal{L}(\theta^*;D)$, by the third condition of E_n. A convex function that is higher on a whole sphere than at its centre cannot be lower anywhere outside. If some outside point θ had $\mathcal{L}(\theta;D) \le \mathcal{L}(\theta^*;D)$, the segment from θ^* to θ would cross the sphere, and by the chord inequality the value at the crossing would be at most $\mathcal{L}(\theta^*;D)$. So the minimizer $\hat\theta$ is inside the ball. There, consequence (a) of Section 6.3, with strong convexity $h/2$ and $\nabla\mathcal{L}(\hat\theta;D) = 0$, gives

$$\|\hat\theta - \theta^*\| \le \frac{2}{h}\,\|\nabla\mathcal{L}(\theta^*;D)\|, \tag{G.24}$$

whose square has mean at most $4\operatorname{tr} G/(h^2 n)$ by step 2. So the fit is within a distance of order $1/\sqrt{n}$ of the population fit, and in particular it converges to it.
5. **An exact linear equation for the error.** The fit has zero gradient. By the fundamental theorem of calculus along the segment from θ^* to $\hat\theta$, as in step 4 of Section 6.3, $0 = \nabla\mathcal{L}(\hat\theta;D) = \nabla\mathcal{L}(\theta^*;D) + \bar{H}_n(\hat\theta - \theta^*)$. Here $\bar{H}_n$ is the average of $\nabla^2\mathcal{L}(\cdot;D)$ along the segment, whose eigenvalues are at least $h/2$ by step 3, so it can be inverted:

$$\hat\theta - \theta^* = -\bar{H}_n^{-1}\,\nabla\mathcal{L}(\theta^*;D). \tag{G.25}$$

This is the chapter's step 2 with "$\approx$" replaced by "$=$" and H replaced by $\bar{H}_n$.
6. **The average curvature approaches H.** By step 1, $\bar{H}_n$ differs from $\nabla^2\mathcal{L}(\theta^*;D)$ by at most $c\hat{M}_3\|\hat\theta - \theta^*\|/2$, which tends to 0 by step 4. By step 2, $\nabla^2\mathcal{L}(\theta^*;D)$ tends to H. The inverses follow, because $\bar{H}_n^{-1} - H^{-1} = \bar{H}_n^{-1}(H - \bar{H}_n)H^{-1}$ has size at most $\frac{2}{h}\cdot\frac{1}{h}\|H - \bar{H}_n\|$.
7. **The average gradient is approximately Gaussian.** The scaled gradient $\sqrt{n}\,\nabla\mathcal{L}(\theta^*;D) = \frac{1}{\sqrt{n}}\sum_i g_i$ is a scaled sum of independent vectors with mean 0 and covariance G. Take any fixed direction a. The numbers $\langle a, g_i\rangle$ are independent with mean 0 and variance $a^\top G a$, so the central limit theorem in one dimension (Section E.3) makes their scaled sum approximately $\mathcal{N}(0, a^\top G a)$. That is the distribution of $\langle a, Y\rangle$ for $Y \sim \mathcal{N}(0, G)$. The **Cramér–Wold device** says that the distributions of all the one-dimensional views $\langle a, \cdot\rangle$ determine the distribution of a vector, also in the limit (van der Vaart 1998, §2.2). So $\sqrt{n}\,\nabla\mathcal{L}(\theta^*;D)$ approaches $\mathcal{N}(0, G)$.
8. **Combine.** Multiply Equation G.25 by $\sqrt{n}$ and split it in two:

$$\sqrt{n}(\hat\theta - \theta^*) = -H^{-1}\sqrt{n}\,\nabla\mathcal{L}(\theta^*;D) + (H^{-1} - \bar{H}_n^{-1})\sqrt{n}\,\nabla\mathcal{L}(\theta^*;D). \tag{G.26}$$

By step 7 the first term approaches $-H^{-1}Y$. A linear map A turns a Gaussian with covariance G into one with covariance $AGA^\top$, which here is $H^{-1}GH^{-1}$ because H is symmetric. In the second term, the matrix tends to 0 by step 6, while the vector has mean square $\operatorname{tr} G$ for every n. So their product tends to 0 in probability, by Chebyshev's inequality. Adding a term that tends to 0 in probability does not change the limiting distribution (Slutsky's lemma, van der Vaart 1998, Lemma 2.8). This proves Equation G.19. The event E_n fails with probability tending to 0, so it changes no limit.

9. **When the model is right, $G = H$.** Suppose $\lambda = 0$ and the labels really follow the model, $\Pr[y = 1 \mid x] = \sigma(\langle \theta^*, x\rangle) = p$. One record's gradient is $-\sigma(-y\langle\theta^*, x\rangle)\, y\, x$, so $gg^\top$ is $(1-p)^2 xx^\top$ when $y = 1$, which has probability p, and $p^2 xx^\top$ when $y = -1$. On average, given x, that is $p(1-p)^2 + (1-p)p^2 = p(1-p)$ times $xx^\top$. That is exactly the Hessian's weight s. So $G = H$ and the covariance is H^{-1}, the inverse of the Fisher information. The same case answers Section 11.5. The expected log-loss at each x is smallest when the predicted probability equals the true one, so the population fit of a correct model is the true parameter. By step 4 the fitted model then converges to the population's probabilities.
10. **The influence of one record.** Now fix the dataset D and the record $z = (x, y)$ in it, with $\lambda > 0$. The objective without z's term is $\mathcal{L}_{-z}$, and with it $\mathcal{L}(\cdot; D) = \mathcal{L}_{-z} + \frac{1}{n}\ell(\cdot; z)$. At $\hat\theta_{-z}$ the gradient of $\mathcal{L}_{-z}$ is zero, so the gradient of $\mathcal{L}(\cdot; D)$ there is just $\frac{1}{n}\nabla\ell(\hat\theta_{-z}; z)$. Step 5, applied to $\mathcal{L}(\cdot; D)$ around $\hat\theta_{-z}$ instead of around θ^*, gives exactly $\hat\theta_D - \hat\theta_{-z} = -\frac{1}{n}\bar H^{-1}\nabla\ell(\hat\theta_{-z}; z)$, with $\bar H$ the average Hessian of $\mathcal{L}(\cdot; D)$ along the segment. This move is small: $\mathcal{L}(\cdot; D)$ is λ-strongly convex and the logistic gradient has length at most $\|x\|$, so consequence (a) gives $\|\hat\theta_D - \hat\theta_{-z}\| \le \|x\|/(\lambda n)$. Replacing $\bar H$ by the Hessian H of $\mathcal{L}(\cdot; D)$ at $\hat\theta_{-z}$ therefore changes the matrix by $O(1/n)$, by step 1, and the move by $O(1/n^2)$. The logistic gradient is $\nabla\ell = -\sigma(-\phi_z)\, y\, x$, so the move is $\frac{1}{n}\sigma(-\phi_z)\, y\, H^{-1}x$. The margin $\phi_z = y\langle\theta, x\rangle$ changes by y times the inner product of the move with x, which is $\frac{1}{n}\sigma(-\phi_z)\, y^2\, x^\top H^{-1}x$. Since $y^2 = 1$, that is Equation G.20.

Step 10 turns the heuristic of Section 10.7 into a formula. The factor $\sigma(-\phi_z)$ is close to 1 when the model trained without z gets its label wrong, and close to 0 when it already predicts it confidently. The factor $x^\top H^{-1}x$ counts the length of x twice, once for how hard z pulls the weights and once for how much a move of the weights changes z's own margin, and divides by the curvature in that direction. In the chapter, the models without z train on the same number of records, with another record in z's place. That record pulls the fit by its own gradient. Averaged over which record it is, the pull is the average gradient of the loss, which is close to zero near the population fit, where only the small ridge term $\lambda\theta$ balances it. So, to first order, the self-influence $\mu_{\text{in},z} - \mu_{\text{out},z}$ is the average of Equation G.20 over training sets.

G.5.4. Checking it

The script checks the Gaussian picture on the logistic-regression toy of Section 12.5. The features are $x \sim \mathcal{N}(0, I_2)$ with an intercept. Records from the majority get the label $+1$ with probability $\sigma(2x_1 + x_2)$, records from a hidden subgroup with probability $\sigma(2x_1 - x_2)$, and the subgroup makes up a share $t = \frac{1}{2}$ of the population. Numerically, the largest of $|s'|$ is 0.09623, which is $1/(6\sqrt{3})$. Computed by quadrature, the population fit is $(1.704, 0, 0)$ for $(\theta_1, \theta_2, \text{intercept})$, and the sandwich has diagonal $(12.59, 6.94, 6.04)$, the chapter's values. The chapter trains its models with a ridge weight 10^{-3}. Including it in $\mathcal{L}_\mathcal{D}$, as the theorem allows, gives the population fit

$(1.683, 0, 0)$ and the diagonal $(11.83, 6.76, 5.89)$. This is the right comparison for models trained that way.

Table G.5 compares n times the variance over 2,000 refits, with that ridge weight, against this sandwich. It also shows the share of refits whose θ_2 lands within 1.96 predicted standard deviations of its centre, which is 0.950 for an exact Gaussian.

Table G.5.: Scaled variances of logistic regressions refitted on 2,000 training sets at subgroup share $t = \frac{1}{2}$, against the sandwich covariance, which includes the ridge weight 10^{-3}.

n	$n\,\mathrm{Var}(\theta_1)$	$n\,\mathrm{Var}(\theta_2)$	$n\,\mathrm{Var}(\text{intercept})$	θ_2 within ± 1.96 sd
50	22.06	9.62	7.94	0.902
200	13.61	7.48	6.16	0.935
1,000	11.72	6.95	5.92	0.950
sandwich	11.83	6.76	5.89	0.950

At $n = 1{,}000$ every variance is within 3% of the sandwich, about the sampling error of a variance estimated from 2,000 refits. At $n = 50$ the variances are larger and the tails heavier, because the linearization of step 5 is not yet accurate. This also explains a remark in Section 12.5. There the chapter compares its refits with the sandwich without the ridge weight, and finds a gap of about 5% in θ_1. The ridge weight alone accounts for most of it, since it lowers the predicted value from 12.59 to 11.83. Figure G.6 shows the histograms becoming Gaussian, and Figure G.7 (left) shows the scaled variances settling on the sandwich.

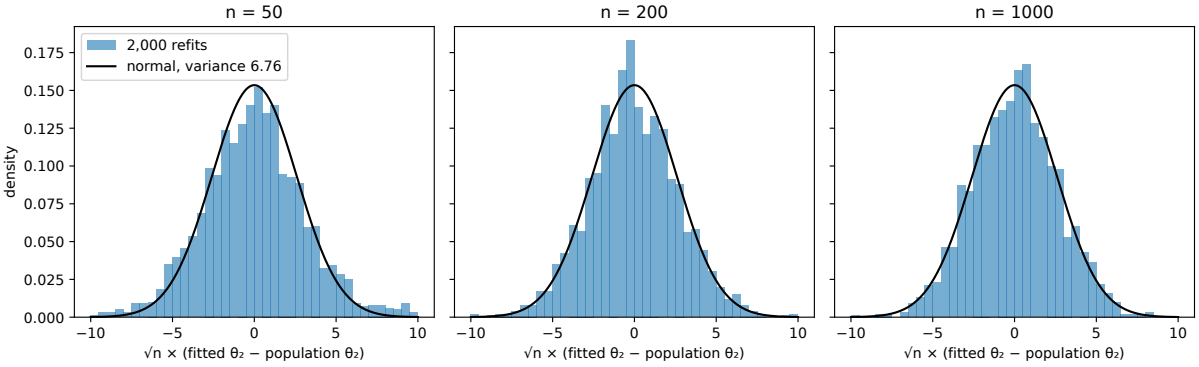

Figure G.6.: Histograms of $\sqrt{n}(\hat{\theta}_2 - \theta_2^*)$ over 2,000 logistic regressions refitted at subgroup share $t = \frac{1}{2}$, for $n = 50$, 200 and 1,000, with the normal density whose variance is the sandwich value.

Step 9 checks out as well, with $\lambda = 0$ as it requires. With the majority's rule alone, $t = 0$, the model is correct. Its population fit is $(2.000, 1.000, 0.000)$, the true weights, and G and H agree to rounding error, within 10^{-12}. At $t = \frac{1}{2}$ the model is wrong, because no single logistic rule describes the mixture. Then the diagonals differ: G has $(0.076, 0.191, 0.166)$ and H has $(0.078, 0.166, 0.166)$.

The influence formula is checked on the running example of the membership-inference chapter. That example has $d = 100$ features, 950 typical points and 50 outliers with five times longer x

and a random label, and $\lambda = 10^{-3}$. One model is trained on $n = 500$ points. For 200 of them the script removes the point's term, refits, and compares the measured change in its margin with Equation G.20. For the 188 typical points, the mean change is 0.2287 against a predicted 0.2291, and the median ratio of measured to predicted is 1.003. For the 12 outliers, the mean change is 3.92 against a predicted 8.21, with a median ratio of 0.671. An outlier moves its own margin by several units, far outside the range where the linear expansion is accurate. The $O(1/n^2)$ term of step 10 has a constant that grows with $\|x\|$ and with $1/\lambda$, and both are large for outliers. So the formula ranks the records correctly but overstates the largest influences. Figure G.7 (right) shows both groups.

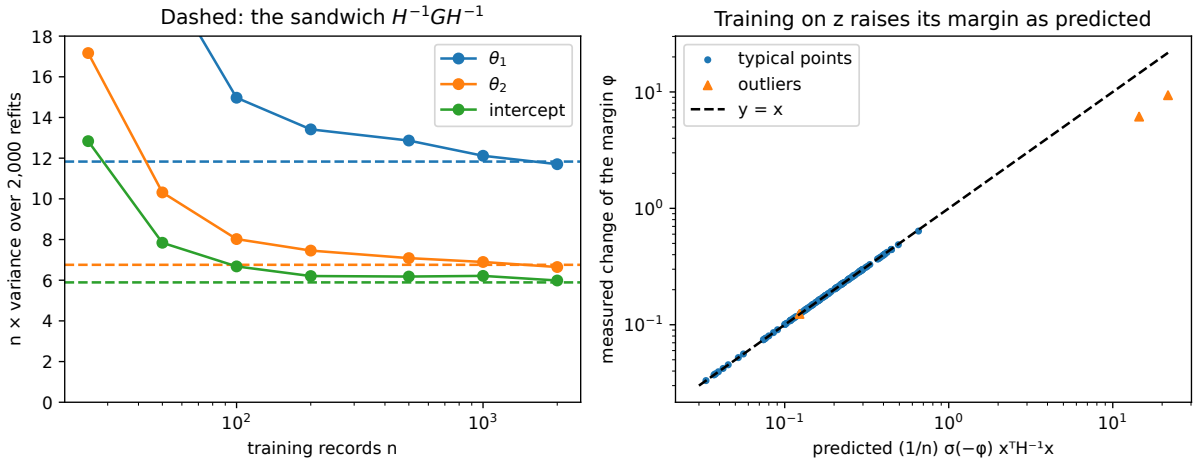

Figure G.7.: Left: n times the variance of each fitted parameter over 2,000 refits, against n, with the sandwich values (dashed). Right: for points of the membership-inference running example, the measured change of the margin ϕ_z when the point's term is added, against the first-order prediction Equation G.20. Typical points lie on the diagonal; outliers fall below it.

G.5.5. What it does not cover

The result is a limit, so it says nothing about how large n must be; a finite-sample version (a Berry–Esseen bound) needs further moment assumptions. The proof also needs H to be invertible and a minimizer to exist. Both can fail with $\lambda = 0$: when a line separates the classes perfectly, the loss keeps falling as the weights grow, so no minimizer exists at all. When the number of features grows with n, so that d/n does not go to zero, the sandwich is wrong: the fitted weights are too large in size, pushed away from zero, and their variance is larger than predicted (Sur & Candès 2019). This matters for the membership example, where $d/n = 0.2$. The general theory of M-estimators, for other losses and without convexity, is in van der Vaart (1998, ch. 5). For deep networks, which have many minima, the Gaussian shape of ϕ_z that Section 10.5 relies on is an empirical finding of Carlini et al., not a consequence of this theorem.

G.6. The best membership attack looks at the parameters through the loss

G.6.1. What the chapter uses

Section 9.3 studies a **centroid detector**: the model is the mean θ of n records, and an attacker who holds a record z plays a game against it. In the member world z is one of the n records, and in the non-member world all n records are fresh draws. The chapter gives the log likelihood ratio between the two worlds, saying only that "expanding the squares in the two Gaussian densities gives" it. It then cites Sablayrolles et al. (2019): if training draws the parameters with a probability that decreases exponentially in the training loss, the Bayes-optimal membership attack depends on the parameters, to a good approximation, only through the target's loss, calibrated for each target, and white-box access then adds little. The chapter's chain Equation 9.7 compares access levels, and this result explains why, in its example, access to the weights (white-box) gives no better attack than access to the loss of each query, compared with what that loss would typically be (calibrated black-box).

The setting of Sablayrolles et al. is this. There are n candidate records $z_1, \dots, z_n$. Each is a member of the training set independently with probability π_1, and $m_i \in \{0,1\}$ marks whether z_i is one. Training draws the parameters θ from a **Gibbs posterior** at a temperature $\nu > 0$, a density that falls exponentially in the total training loss:

$$p(\theta \mid m) = \frac{1}{Z(m)} \exp\Big(-\frac{1}{\nu} \sum_{i=1}^{n} m_i \, \ell(\theta; z_i) \Big), \tag{G.27}$$

where $Z(m)$ makes the density integrate to 1. Write m_{-1} for the memberships of the other candidates, and σ for the logistic function. The attacker knows the candidates and sees θ. The posterior probability that the target z_1 is a member is then exactly

$$\Pr[m_1 = 1 \mid \theta] = \mathbb{E}\Big[\sigma\Big(-\frac{\ell(\theta; z_1) - \tau(z_1, m_{-1})}{\nu} + \ln \frac{\pi_1}{1-\pi_1} \Big) \,\Big|\, \theta \Big], \tag{G.28}$$

with the calibration

$$\tau(z_1, m_{-1}) = -\nu \ln \mathbb{E}_{\theta' \sim p(\cdot \mid m_1 = 0,\ m_{-1})} \big[e^{-\ell(\theta'; z_1)/\nu} \big]. \tag{G.29}$$

Inside the logistic function, θ appears only through the loss $\ell(\theta; z_1)$. It also appears in the outer average over the unknown m_{-1}, and that is where the result becomes an approximation. If τ hardly depends on the other memberships, it can be replaced by one number $\tau(z_1)$ per target, and the best attack thresholds $\ell(\theta; z_1) - \tau(z_1)$. That last step is Sablayrolles et al.'s approximation, not a theorem.

For the centroid detector no approximation is needed. Write $q(\theta \mid z)$ for the density of θ in the member world and $p(\theta \mid z)$ in the non-member world. The model is $\theta = \frac{1}{n}\sum_i x_i$ for n records $x_i \sim \mathcal{N}(0, I_d)$, and its loss is $\ell(\theta; z) = \frac{1}{2}\|\theta - z\|^2$. The log likelihood ratio between the member and non-member worlds is exactly

$$\ln \frac{q(\theta \mid z)}{p(\theta \mid z)} = -\frac{n}{n-1}\big(\ell(\theta; z) - \tau(z)\big) + \frac{d}{2} \ln \frac{n}{n-1}, \qquad \tau(z) = \frac{(n-1)\|z\|^2}{2n}. \tag{G.30}$$

G.6.2. The idea

Fix the memberships of all the other candidates for a moment. Then the only question is whether the term of z_1 is in the exponent or not. Adding it multiplies the density of θ by $e^{-\ell(\theta;z_1)/\nu}$ and changes the normalizing constant. The change of normalizing constant is a number that does not depend on θ, and τ is $-\nu$ times its logarithm. So, with the others fixed, the log of the posterior odds is a straight-line function of the loss. The attacker does not know the others, so it averages over them.

Two targets with the same loss show why the calibration matters. Take $\nu = 1$ and $\pi_1 = \frac{1}{2}$, so that the prior term $\ln(\pi_1/(1-\pi_1))$ is zero. A hard target has $\tau = 2$, because models trained without it give it a typical loss near 2. If the released model gives it loss 0.5, the posterior is $\sigma(2-0.5) = \sigma(1.5) = 0.8176$, likely a member. An easy target has $\tau = 0.3$, because every model fits it well. The same loss 0.5 gives $\sigma(0.3-0.5) = \sigma(-0.2) = 0.4502$, slightly less likely than not. A low loss is evidence of membership only relative to what the target's loss would be without it.

G.6.3. Derivation

1. **Bayes' rule with the others fixed.** Write $A = \pi_1\, p(\theta \mid m_1 = 1, m_{-1})$ and $B = (1-\pi_1)\, p(\theta \mid m_1 = 0, m_{-1})$ for the two joint weights. Bayes' rule says $\Pr[m_1 = 1 \mid \theta, m_{-1}] = A/(A+B)$. A ratio of this form equals $\sigma(\ln(A/B))$, because $1/(1+B/A) = 1/(1+e^{-\ln(A/B)})$. So
$$\Pr[m_1 = 1 \mid \theta, m_{-1}] = \sigma\Big(\ln \frac{p(\theta \mid m_1 = 1, m_{-1})}{p(\theta \mid m_1 = 0, m_{-1})} + \ln \frac{\pi_1}{1-\pi_1}\Big). \tag{G.31}$$
2. **The density ratio.** The two exponents differ by the target's term only, so the density ratio is $e^{-\ell(\theta;z_1)/\nu}\, Z_0/Z_1$, where Z_1 and Z_0 are the normalizing constants with and without the target. Write Z_1 as the integral of $e^{-\ell(\theta';z_1)/\nu}$ times the unnormalized density without the target. Dividing by Z_0 turns that integral into an average over θ' drawn from the posterior without the target:
$$\frac{Z_1}{Z_0} = \mathbb{E}_{\theta' \sim p(\cdot \mid m_1 = 0,\ m_{-1})}\big[e^{-\ell(\theta';z_1)/\nu}\big] = e^{-\tau(z_1, m_{-1})/\nu}. \tag{G.32}$$
So the log density ratio is $-(\ell(\theta; z_1) - \tau(z_1, m_{-1}))/\nu$, a function of θ only through the loss.
3. **Average over the unknown others.** By the law of total probability, $\Pr[m_1 = 1 \mid \theta]$ is the average of $\Pr[m_1 = 1 \mid \theta, m_{-1}]$ over m_{-1}, weighted by $\Pr[m_{-1} \mid \theta]$. Together with steps 1 and 2 that is Equation G.28. The weights depend on θ, which is why replacing $\tau(z_1, m_{-1})$ by a single $\tau(z_1)$ is an approximation.
4. **The centroid: two Gaussians.** If z is a member, $\theta = (z+S)/n$, where S, the sum of the other $n-1$ records, is $\mathcal{N}(0, (n-1)I_d)$. So θ is Gaussian with mean z/n and variance $(n-1)/n^2$ per coordinate. If it is not, all n records are fresh draws, so θ is Gaussian with mean 0 and variance $1/n$ per coordinate. The log of each density is minus the squared distance to the mean over twice the variance, plus $-\frac{d}{2}\ln$ of the variance. Their difference is
$$-\frac{n^2}{2(n-1)}\Big\|\theta - \frac{z}{n}\Big\|^2 + \frac{n}{2}\|\theta\|^2 + \frac{d}{2}\ln\frac{n}{n-1}. \tag{G.33}$$

5. **Expand the squares.** The first square is $\|\theta\|^2 - \frac{2}{n}\langle z, \theta\rangle + \frac{1}{n^2}\|z\|^2$. Collecting terms, $\|\theta\|^2$ has coefficient $\frac{n}{2} - \frac{n^2}{2(n-1)} = -\frac{n}{2(n-1)}$, and $\langle z, \theta\rangle$ has coefficient $\frac{n}{n-1}$. So the log ratio is $\frac{n}{2(n-1)}(2\langle z, \theta\rangle - \|\theta\|^2) - \frac{\|z\|^2}{2(n-1)} + \frac{d}{2}\ln\frac{n}{n-1}$, the chapter's formula with its constant made explicit.
6. **Write it with the loss.** Since $\ell(\theta; z) = \frac{1}{2}\|z\|^2 - \frac{1}{2}(2\langle z, \theta\rangle - \|\theta\|^2)$, the bracket of step 5 equals $\|z\|^2 - 2\ell(\theta; z)$. Substituting, the $\|z\|^2$ terms are $\frac{n}{2(n-1)}\|z\|^2 - \frac{1}{2(n-1)}\|z\|^2 = \frac{1}{2}\|z\|^2$, which is $\frac{n}{n-1}\tau(z)$. The result is Equation G.30. It has the Gibbs form exactly, with temperature $(n-1)/n$, and no approximation was needed. The reason is that the other records enter only through their sum S, whose distribution does not depend on which records they are.

The chapter's remark that the white-box and calibrated black-box attacks "agree to four decimals" follows from step 5. The calibrated score $\|z\|^2 - \|z - \theta\|^2$ is the bracket $2\langle z, \theta\rangle - \|\theta\|^2$, so the log ratio is a fixed multiple of it minus the term $\|z\|^2/(2(n-1))$. That term changes from target to target, so the two scores do not rank the games (pairs of model and target) in exactly the same order. But it changes very little: its standard deviation is 0.0504, against 0.757 for the log ratio itself, at $n = 100$ and $d = 50$.

G.6.4. Checking it

The script checks Equation G.28 exactly on a small Gibbs posterior. It uses 10 candidates $z_i \sim \mathcal{N}(0, 1)$, the loss $\frac{1}{2}(\theta - z)^2$, $\nu = 1$, $\pi_1 = \frac{1}{2}$, and θ on a grid of 801 points in $[-4, 4]$. Enumerating all 2^9 memberships of the other candidates, the exact posterior and the right side of Equation G.28 differ by less than 10^{-12}, which is rounding error. Replacing $\tau(z_1, m_{-1})$ by the single value $\bar{\tau}(z_1) = -\nu \ln \mathbb{E}_{m_{-1}}[e^{-\tau(z_1, m_{-1})/\nu}]$, an average over memberships drawn from their prior, changes the posterior by up to 0.054 over the grid points that carry 99.9% of the probability of θ, so in this small example the approximation is reasonable but visible.

For the centroid, Equation G.30 matches the log ratio computed from the two densities to within 10^{-10}, rounding error. Over 100,000 games per world, the best advantage is 0.2804 for the exact likelihood ratio, 0.2800 for the calibrated score and 0.0422 for the raw loss. (The chapter's own run gives 0.2789 for the first two.) Figure G.8 shows why calibration matters. Against the raw loss, the exact log ratio is a cloud, because a target's loss mixes its membership with how typical it is. Against $\ell - \tau(z)$ it is a line of slope $-n/(n-1)$.

G.6.5. What it does not cover

Real training is not a Gibbs posterior. SGD with a constant learning rate behaves like one only roughly, and an exactly trained model, like the centroid, is deterministic given its data. The centroid escapes the problem because, from the attacker's view, the unknown other records make θ random, and the result has the Gibbs form anyway. In general the per-target calibration $\tau(z)$ must be estimated, which is what shadow models do in the per-example attacks of Membership inference.

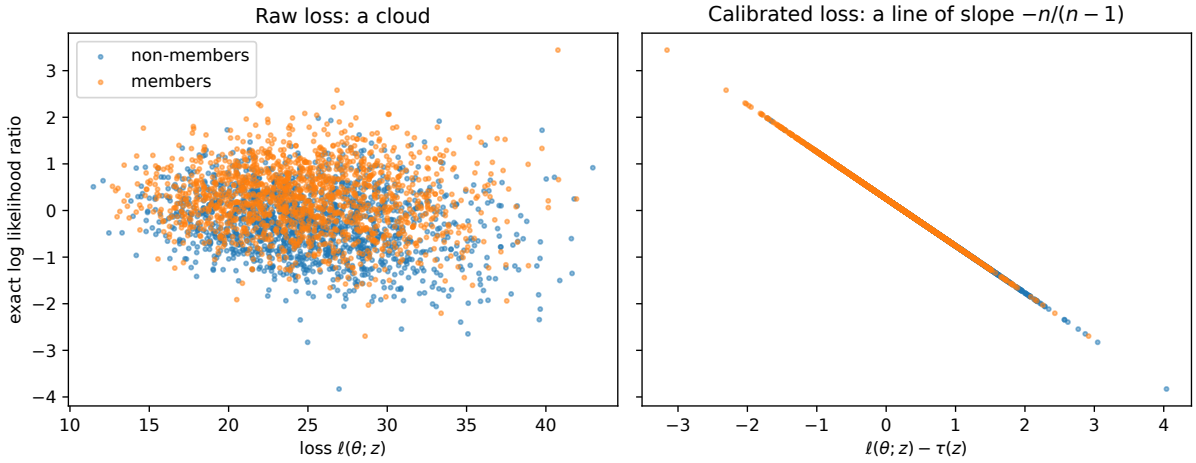

Figure G.8.: For 1,500 member and 1,500 non-member games of the centroid detector ($n = 100$, $d = 50$), the exact log likelihood ratio against the raw loss $\ell(\theta; z)$ (left) and against the calibrated loss $\ell(\theta; z) - \tau(z)$ (right).

G.7. Code

The script apx_optimization.py computes every number on this page and draws every figure. It checks the inequalities on random pairs and on gradient-descent runs. It runs the subgradient method against the resisting gradients and computes the exact nearest-neighbour distances on the sphere. It also refits logistic regressions thousands of times, compares leave-one-out refits with the influence formula, and enumerates a small Gibbs posterior. From the repository root:

```
uv run python code/appendix-derivations/apx_optimization.py
```

Table G.6 collects the main numbers it prints.

Table G.6.: The main numbers printed by the appendix's script.

Check	Result
Strong convexity of the ridge logistic risk, $\lambda = 0.01$	smallest ratio 0.0372 over 2,000 pairs
GD, largest gap ratio per step against $1 - 1/\kappa = 0.9615$	0.7131
GD gap after 50 steps, against Equation G.3	2.59×10^{-9} against 1.99×10^{-2}
Co-coercivity, smallest ratio of the two sides	1.0006 (logistic loss), 5.3704 (logistic risk)
Worst distance ratio after one step, $\eta = 8$ and $\eta = 10$	0.9988 and 1.4985
Hard function, $T = 10{,}000$: lower bound, method, SGD bound	0.0050, 0.0058, 0.0100
1-NN limit and Bayes error	0.338 and 0.250

Check	Result
1-NN error and plug-in average at $n = 4{,}000$	0.356 and 0.358
Sandwich diagonal at $t = \frac{1}{2}$, ridge 10^{-3}	$(11.83, 6.76, 5.89)$
n Var over 2,000 refits at $n = 1{,}000$	$(11.72, 6.95, 5.92)$
Influence, median measured/predicted: typical points, outliers	1.003, 0.671
Gibbs identity, largest error	below 10^{-12}
Centroid advantage: likelihood ratio, calibrated score, raw loss	0.2804, 0.2800, 0.0422

Every bound holds where it should, and the checks also show how loose each one is. The linear rate of GD is exact in form but pessimistic in its curvature, while co-coercivity is tight where the loss is most curved, and the lower bound is within 17% of what the subgradient method achieves. The Gaussian picture of a fitted model is accurate to sampling error at $n = 1{,}000$, while its first-order influence formula fails exactly for the records that matter most to membership attacks, the outliers.

H. Random matrices and factorizations

Two chapters of the book lean on facts about matrices that they quote rather than prove. Reconstruction attacks decodes noisy answers by least squares, so its error depends on two properties of the random query matrix. The average of the inverse of its Gram matrix sets the error under random noise, and its smallest singular value sets the error under worst-case noise. The chapter on training with differential privacy (DP) by follow the regularized leader (FTRL), DP-FTRL and matrix factorization, releases the running sums of a training run by splitting the prefix-sum matrix into a product of two matrices. That chapter quotes several facts about this matrix and its factorizations, from its singular values to the form of the best factorization, and this appendix proves them. Each section starts by restating, in the chapter's notation, exactly what it proves. They sit together because each one is a statement about how a matrix stretches or shrinks vectors, and each proof comes down to an eigenvalue, a singular value or a projection.

The two chapters both call their matrix A, but it is a different matrix in each. In the first two sections, the query matrix A has one row for each of m queries and one column for each of n people. In the last three, A is the prefix-sum matrix, with one row and one column for each of T training steps. Table H.1 lists the results and where each chapter states or uses them.

Table H.1.: The derivations in this appendix and the chapter sections that use them.

Result	Where the chapter states or uses it

H.1. The average inverse of a random Gram matrix

H.1.1. What the chapter uses

Least squares turns noisy answers into an estimate, and under random noise its error is set by the inverse of the **Gram matrix** $A^\top A$, the matrix of inner products between the columns of the

query matrix. In Section 17.5, step 4 of the random-noise derivation needs the average of that inverse. The chapter uses a result for Gaussian rows. Let Z be an $m \times n$ matrix whose m rows are independent, each a normal vector with mean 0 and covariance matrix Σ. Then $Z^\top Z$ is called a **Wishart matrix**, and, as long as $m \geq n + 2$,

$$\mathbb{E}\big[(Z^\top Z)^{-1}\big] = \frac{\Sigma^{-1}}{m - n - 1}. \tag{H.1}$$

Here m is the number of rows, n the number of columns and Σ^{-1} the inverse of the covariance. The chapter cites Muirhead (1982, ch. 3) for it. It applies it to rows that are random 0/1 queries q, by matching a normal row with the same second-moment matrix, $\Sigma = \mathbb{E}[qq^\top]$, and it says that for 0/1 rows this is only an approximation. Section 17.7 reuses it in its step 4, which gives Equation 17.13. The chapter checks the final recovery rates by simulation but not the formula itself.

H.1.2. The idea

Start with one column, $n = 1$. Then $Z^\top Z$ is a single number, the sum of m squared standard normal values, and its average is m. The naive guess for the average of its inverse is $1/m$. But an average of inverses is always larger than the inverse of the average, because small values blow up under $1/x$ much more than large values shrink. For example, a number that is 1 or 3 with equal chance has average 2, while the average of its inverses is $\frac{1}{2}(1 + \frac{1}{3}) = \frac{2}{3}$, not $\frac{1}{2}$. For the sum of m squared normals the exact answer is $1/(m - 2)$, so the naive guess is off by two rows. The formula says this is $1/(m - n - 1)$ with $n = 1$.

With more columns, and $\Sigma = I$ for now, there are two separate questions. Which matrix is the average? Symmetry answers that: flipping the sign of a column, or swapping two columns, does not change the distribution of Z, so the average inverse cannot prefer any column or any sign, and it must be a multiple of the identity. And what is the multiple? One diagonal entry of the inverse of a Gram matrix has a meaning of its own. It is one over the squared length of the part of the first column that the other columns cannot explain, the residual of regressing column 1 on the others. With Gaussian columns, that residual is a standard normal vector squeezed into a space of $m - n + 1$ dimensions, so its squared length is a sum of $m - n + 1$ squared normals. The one-column calculation then gives $1/(m - n + 1 - 2) = 1/(m - n - 1)$.

H.1.3. Derivation

Take $\Sigma = I$ first, so that the entries of Z are independent standard normal numbers. Write $W = Z^\top Z$ and $z_1, \dots, z_n$ for the columns of Z.

1. **The inverse exists.** With $m \geq n$ Gaussian rows, the columns are linearly independent with probability 1. Add the columns one at a time: given the earlier ones, their span is a fixed subspace of lower dimension, and a column with a continuous distribution lands in it with probability 0. So W is invertible. (The stronger condition $m \geq n + 2$ is needed only in step 6, to make the average finite.)

2. **Off-diagonal entries average to 0.** Flip the sign of column i of Z. The flipped matrix has the same distribution, because a standard normal entry and its negative have the same distribution. Flipping column i flips the sign of every inner product between column i and another column, so it flips row i and column i of W, except the diagonal entry. The inverse changes in the same way, since the flip is multiplication by a diagonal matrix Λ of signs on both sides, and $(\Lambda W \Lambda)^{-1} = \Lambda W^{-1} \Lambda$. So every entry of W^{-1} in row i, off the diagonal, has the same average as its negative, and that average, which is finite by steps 4 to 6 and the Cauchy–Schwarz inequality, is 0.
3. **Diagonal entries share one average.** Swapping columns i and k also leaves the distribution unchanged, and it swaps the diagonal entries i and k of W^{-1}. So all diagonal entries have the same average c, and $\mathbb{E}[W^{-1}] = cI$.
4. **A diagonal entry is one over a residual.** Let P be the orthogonal projection onto the span of $z_2, \dots, z_n$, so that $(I - P)z_1$ is the part of z_1 that the other columns cannot explain. Let w be the first column of W^{-1}, so $Ww = e_1$, where $e_1 = (1, 0, \dots, 0)$. Set $u = Zw$, a vector of length m. Then $Z^\top u = Z^\top Z w = Ww = e_1$, and this equation says two things: u is orthogonal to $z_2, \dots, z_n$, and $z_1^\top u = 1$. Now $u = w_1 z_1 + (\text{a combination of } z_2, \dots, z_n)$. Applying $I - P$ removes the combination and leaves u unchanged, since u is orthogonal to the other columns, so $u = w_1 (I - P) z_1$. Substituting this into $z_1^\top u = 1$ gives $w_1 \|(I - P) z_1\|^2 = 1$, because $z_1^\top (I - P) z_1 = \|(I - P) z_1\|^2$ for a projection. So

$$[W^{-1}]_{11} = \frac{1}{\|(I - P) z_1\|^2}. \tag{H.2}$$

5. **The residual is a sum of $m - n + 1$ squared normals.** Fix the other columns. Then $I - P$ is a fixed projection onto a subspace of dimension $k = m - n + 1$, the m dimensions minus the $n - 1$ spanned by $z_2, \dots, z_n$. The column z_1 is independent of the others, and a standard normal vector keeps its distribution under any rotation, because its density depends only on the length of the vector. So rotate the coordinates until the subspace is spanned by the first k axes. In the new coordinates z_1 is still standard normal, and $\|(I - P) z_1\|^2$ is the sum of the squares of its first k coordinates, a **chi-squared** variable χ^2_k with k degrees of freedom. This holds for every value of the other columns, so it holds without conditioning too.
6. **The average of $1/\chi^2_k$.** The trick is to write $1/x$ as an integral of exponentials, $1/x = \int_0^\infty e^{-tx}\, dt$ for $x > 0$, because exponentials of a sum of independent squares are easy to average. For one standard normal number g and a number $t \geq 0$,

$$\mathbb{E}\big[e^{-tg^2}\big] = (1 + 2t)^{-1/2}, \tag{H.3}$$

because e^{-tg^2} times the normal density is a normal density with variance $1/(1 + 2t)$, missing only its normalizing factor. A χ^2_k variable X is a sum of k independent such squares, so the averages multiply and $\mathbb{E}[e^{-tX}] = (1 + 2t)^{-k/2}$. Exchanging the average and the integral, which is allowed because everything is positive,

$$\mathbb{E}\Big[\frac{1}{X}\Big] = \int_0^\infty (1 + 2t)^{-k/2}\, dt = \frac{1}{k - 2} \quad \text{for } k \geq 3. \tag{H.4}$$

The integral converges only when $k/2 > 1$. Putting in $k = m - n + 1$ gives $c = 1/(m - n - 1)$, and the condition $k \geq 3$ becomes $m \geq n + 2$.
7. **General covariance.** Write $\Sigma^{1/2}$ for the symmetric square root of Σ, the matrix whose square is Σ. A normal row with covariance Σ can be written as a standard normal row

times $\Sigma^{1/2}$, so $Z = Z_0\Sigma^{1/2}$ with Z_0 standard. Then $Z^\top Z = \Sigma^{1/2} Z_0^\top Z_0 \Sigma^{1/2}$, its inverse is $\Sigma^{-1/2}(Z_0^\top Z_0)^{-1}\Sigma^{-1/2}$, and averaging, with the fixed matrices taken outside the average, and using steps 3 and 6 gives Equation H.1.

H.1.4. Checking it

The script draws Gaussian matrices with $n = 50$ columns and averages m times the diagonal of $(Z^\top Z)^{-1}$ over 4,000 draws. The formula predicts $m/(m-n-1)$. It also draws 0/1 matrices, as in the chapter, whose second-moment matrix is $\Sigma = \frac{1}{4}(I + \mathbf{1}\mathbf{1}^\top)$. The diagonal of Σ^{-1} is $4n/(n+1)$, as computed in Section 17.5, step 3. Dividing by it puts both kinds of rows on the same scale, so that both are predicted to give $m/(m-n-1)$. Table H.2 shows the result.

Table H.2.: m times the average diagonal entry of the inverse Gram matrix, $n = 50$ columns, 4,000 draws per entry.

Rows m	60	100	200	400
Predicted, $m/(m-n-1)$	6.667	2.041	1.342	1.146
Gaussian rows, simulated	6.661	2.041	1.342	1.146
0/1 rows, simulated and rescaled	6.456	2.000	1.329	1.140

The Gaussian rows match the formula within the simulation noise. The 0/1 rows fall a little below it, by $6.667 - 6.456 = 0.211$ at $m = 60$, about 3%, and by less as m grows. So for subset queries the chapter's approximation is slightly pessimistic: it predicts a slightly larger error than the attack suffers. Figure H.1 shows the same comparison over a range of m. The gap between the curve $m/(m-n-1)$ and the naive line at 1 is the correction that step 4 of the chapter makes, and it is large only when m is close to n.

Steps 4 and 5 can be checked one at a time. For one Gaussian matrix with $m = 60$ rows, the script regresses the first column on the others and finds a squared residual of 4.931982. One over the first diagonal entry of the inverse is the same 4.931982, as Equation H.2 says. Figure H.2 repeats this for 20,000 matrices and compares the histogram with the χ^2 density with $m - n + 1 = 11$ degrees of freedom. Step 6 for $k = 11$ predicts $1/9 = 0.1111$, and a million simulated χ^2_{11} values give 0.1112. Finally, the symmetry of steps 2 and 3 shows up in simulation as an average inverse whose off-diagonal entries are tiny. With $n = 10$, $m = 30$ and 20,000 draws, their average size is 0.0013 of the diagonal for Gaussian rows. For 0/1 rows the ratio is 0.1000, because 0/1 entries have a nonzero mean and flipping a column's sign is no longer a symmetry. That is still the shape the approximation predicts, since Σ^{-1} is proportional to $I - \frac{1}{n+1}\mathbf{1}\mathbf{1}^\top$, whose off-diagonal entries are $\frac{1}{n} = 0.1$ times its diagonal ones.

H.1.5. What it does not cover

The proof needs Gaussian rows in two places. Step 2 needs each column to keep its distribution when its sign flips, and step 5 needs rotation invariance. Rows of 0/1 entries have neither property, which is why the chapter calls the formula an approximation and checks the attack by simulation. There is also a technical gap for 0/1 rows. A 0/1 matrix is singular with a small but positive probability, for example when two columns happen to be equal, so the average of its inverse is

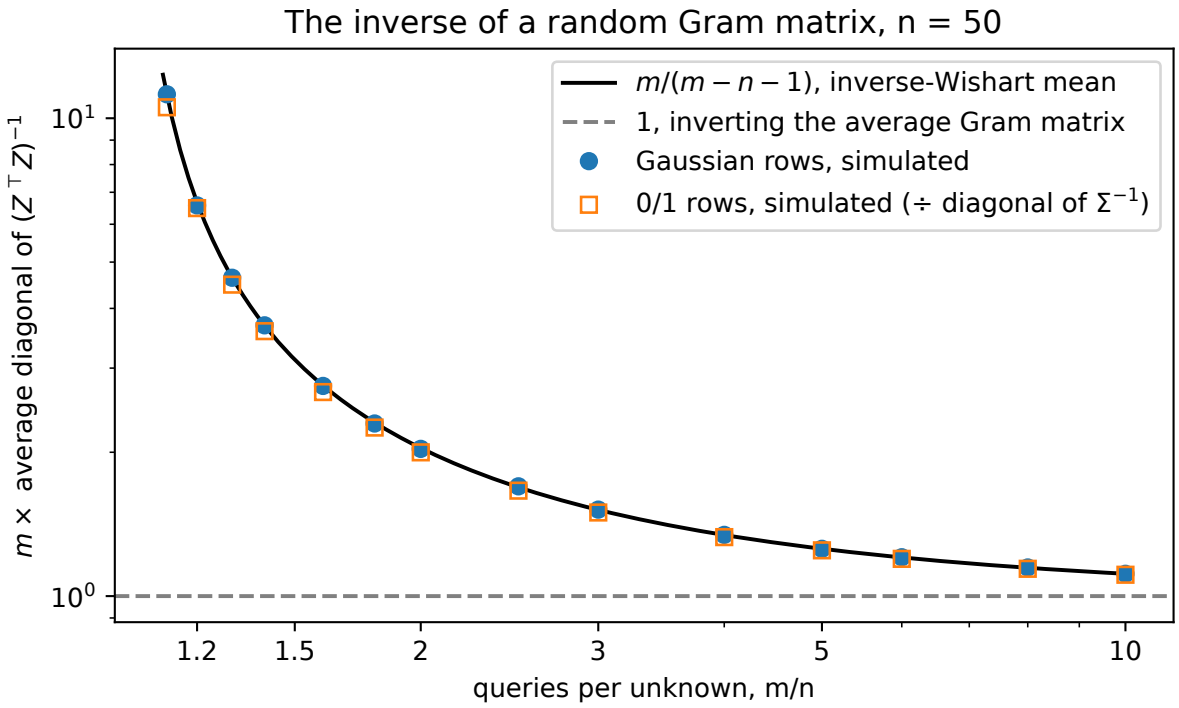

Figure H.1.: The average diagonal entry of $(Z^\top Z)^{-1}$, multiplied by m, against the number of rows per column m/n for $n = 50$. Circles are Gaussian rows and squares are 0/1 rows rescaled by the diagonal of Σ^{-1}. The black curve is $m/(m-n-1)$ and the dashed line is the naive value 1, from inverting the average Gram matrix.

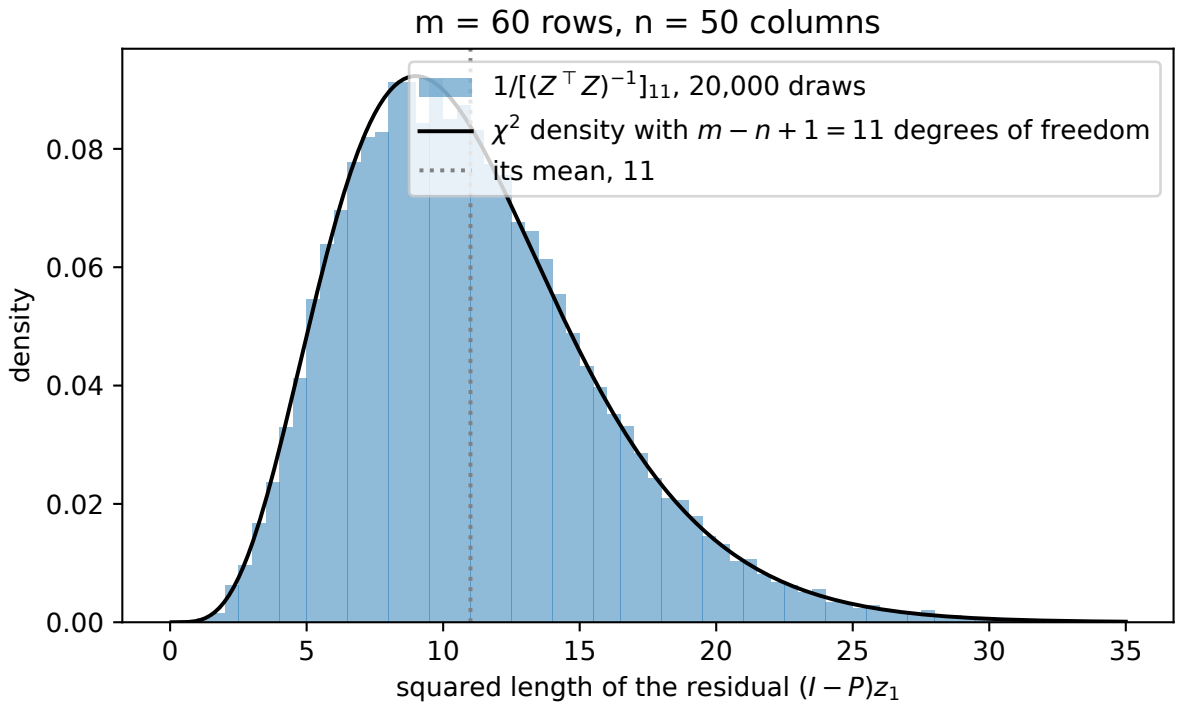

Figure H.2.: Histogram of $1/[(Z^\top Z)^{-1}]_{11}$ over 20,000 Gaussian matrices with $m = 60$ rows and $n = 50$ columns, against the χ^2 density with $m-n+1 = 11$ degrees of freedom. The two agree, as steps 4 and 5 predict.

not even defined. The rescaled values in Table H.2 are averages over draws that happened to be invertible, which at these sizes is every draw.

The condition $m \geq n + 2$ is needed. At $m = n + 1$ the residual is a χ_2^2 variable, whose inverse has an infinite average, because χ_2^2 puts too much probability near 0. Even for $m \geq n+2$, the diagonal entries of the inverse have a heavy right tail when m is close to n, which makes simulations there noisy.

H.2. A random subset matrix shrinks no direction much

H.2.1. What the chapter uses

The worst-case bound of Section 17.5, Equation 17.9, says that least squares gets at most $4mE^2/s_{\min}(A)^2$ bits wrong when every answer has error at most E. Here $s_{\min}(A)$, the **smallest singular value**, is the smallest length $\|Ax\|$ over unit vectors x. The bound is useful only if $s_{\min}(A)$ is of order $\sqrt{m}$. Step 5 there says that for a random matrix $s_{\min}$ "concentrates near $\sqrt{m} - \sqrt{n}$ times the scale of the rows" and cites Vershynin, *High-Dimensional Probability*, ch. 4. It then argues by a heuristic that $s_{\min}(A) \approx \frac{1}{2}(\sqrt{m} - \sqrt{n})$ for random subsets, checks this at one size, and concludes that error $E = o(\sqrt{n})$ gives $o(n)$ wrong bits with $m = 4n$ queries.

This section proves a version with a worse constant and an extra logarithm, but a complete proof. Let A be an $m \times n$ matrix whose rows are independent uniformly random subsets $q_1, \ldots, q_m$, so each entry is an independent fair 0 or 1. For a failure probability β,

$$s_{\min}(A) \geq \frac{\sqrt{m}}{14} \quad \text{with probability at least } 1 - \beta, \quad \text{once} \quad m \geq 128\Big(n \ln(80n + 1) + \ln \frac{1}{\beta}\Big). \tag{H.5}$$

Substituted into Equation 17.9, this gives at most $4mE^2 \cdot 196/m = 784E^2$ wrong bits. So with $m = O(n \log n)$ queries, error $E = o(\sqrt{n})$ leaves $o(n)$ wrong bits.

H.2.2. The idea

The proof reuses a lemma from the chapter's linear-programming section, Section 17.4, in three moves. The lemma says that one random query catches any fixed direction: for any fixed vector x, the squared answer $\langle q, x\rangle^2$ exceeds $\|x\|^2/16$ with probability at least $\frac{3}{16}$. Over m independent queries, Hoeffding's inequality then makes it nearly certain that a good share of the queries catch x, and each caught query adds a fixed amount to $\|Ax\|^2$. That handles one direction. To handle all directions at once, round every unit vector to a nearby point of a fine grid, use the union bound over the finitely many grid points, and pay for the rounding with a crude bound on how much A can stretch the small difference. Table H.3 lists the chain of constants.

Table H.3.: How the lemma for one query becomes a bound on the smallest singular value.

Move	What it gives	Holds
Lemma, one query	$\langle q, x\rangle^2 > \|x\|^2/16$	with probability $\geq \frac{3}{16}$, for each fixed x

Move	What it gives	Holds
Hoeffding, m queries	more than $m/8$ such queries, so $\|Ax\|^2 > m\|x\|^2/128$	except with probability $e^{-m/128}$, for each fixed x
Union bound over the grid	the same for every grid point	except with probability $(80n+1)^n e^{-m/128}$
Rounding	$\|Ax\| \geq \sqrt{m}/14$ for every unit x	whenever the previous row holds

The all-ones direction deserves a word, because subset queries have a nonzero mean. Every entry of A is $\frac{1}{2}$ on average, so A stretches the all-ones vector a lot: each answer $\langle q, \mathbf{1}\rangle$ is about $n/2$. That direction gives the largest singular value, not the smallest, and the lemma already allows for it, since a nonzero mean only pushes $\langle q, x\rangle$ away from 0.

H.2.3. Derivation

1. **One query catches a fixed direction.** This is the chapter's lemma, whose proof holds for every vector x (the chapter adds an assumption about large coordinates only afterwards). Fix a nonzero x with n coordinates, and write a random subset as $q_i = (1 + s_i)/2$ with independent fair signs s_i, so that a person is in the subset when the sign is $+1$. The answer $Y = \langle q, x\rangle$ is then the constant $\frac{1}{2}\sum_i x_i$ plus the sum $\frac{1}{2}\sum_i s_i x_i$ of terms with random signs. Write τ for the standard deviation of that sum, so $\tau^2 = \frac{1}{4}\|x\|^2$. Counting which terms survive in the expansion of the fourth power shows that a random-sign sum has fourth moment at most 3 times its squared variance, as for a normal variable, and the chapter's step 3 shows that adding the constant keeps $\mathbb{E}Y^4 \leq 3(\mathbb{E}Y^2)^2$. The Paley–Zygmund inequality (Equation 17.2) says that a non-negative variable W exceeds $\xi\,\mathbb{E}W$ with probability at least $(1-\xi)^2(\mathbb{E}W)^2/\mathbb{E}[W^2]$, for any level ξ between 0 and 1. Applied to $W = Y^2$, the ratio of moments is at least $\frac{1}{3}$. Finally, $\mathbb{E}Y^2$ is τ^2 plus the squared constant, so it is at least τ^2, and

$$\Pr\left[|Y| > \sqrt{\xi}\,\tau\right] \geq \frac{(1-\xi)^2}{3}. \tag{H.6}$$

   With $\xi = \frac{1}{4}$ the bound reads

$$\Pr\left[\langle q, x\rangle^2 > \frac{\|x\|^2}{16}\right] \geq \frac{3}{16}. \tag{H.7}$$

2. **Many queries catch it, by Hoeffding's inequality.** Call query j *good* for x when $\langle q_j, x\rangle^2 > \|x\|^2/16$, and let N be the number of good queries. The queries are independent, so N is a sum of m independent 0/1 terms, each 1 with probability $p \geq \frac{3}{16}$. Hoeffding's inequality (Concentration inequalities) says that the average of m independent terms in $[0,1]$ falls more than t below its mean with probability at most e^{-2mt^2}. The event $N \leq m/8$ means the average falls at least $p - \frac{1}{8} \geq \frac{1}{16}$ below its mean, so with $t = \frac{1}{16}$ it has probability at most $e^{-2m/256} = e^{-m/128}$.
3. **Many good queries make $\|Ax\|$ large.** $\|Ax\|^2 = \sum_j \langle q_j, x\rangle^2$ is a sum of non-negative terms, and each good query contributes more than $\|x\|^2/16$. If $N > m/8$, then $\|Ax\|^2 > \frac{m}{8} \cdot \frac{\|x\|^2}{16} = \frac{m\|x\|^2}{128}$.

4. **A finite grid.** Every unit vector has its coordinates in $[-1, 1]$. Take the grid of points in $[-1, 1]^n$ whose coordinates are multiples of $h = 1/(40n)$. Each coordinate takes $2/h + 1 = 80n+1$ values, so there are $(80n+1)^n$ grid points. Rounding each coordinate of a unit vector x to the nearest multiple of h gives a grid point y with $|x_i - y_i| \le h/2$, so $\|x-y\| \le \frac{h}{2}\sqrt{n} = \frac{1}{80\sqrt{n}}$, and hence $\|y\| \ge 1 - \frac{1}{80\sqrt{n}}$.
5. **Union bound over the grid.** By steps 2 and 3, each nonzero grid point fails $\|Ay\|^2 > m\|y\|^2/128$ with probability at most $e^{-m/128}$, and the point 0 does not matter, because no unit vector is rounded to it. The union bound says that the chance that at least one of several events happens is at most the sum of their chances. So every grid point satisfies it except with probability at most $(80n+1)^n e^{-m/128}$. Taking logarithms, this is at most β exactly when $m \ge 128(n\ln(80n+1) + \ln(1/\beta))$, the condition of Equation H.5.
6. **A crude bound on stretching.** Every entry of A is 0 or 1, so $\|Av\|^2 = \sum_j \langle q_j, v\rangle^2 \le \sum_j \|q_j\|^2\|v\|^2 \le mn\|v\|^2$, by the Cauchy–Schwarz inequality and because each query has at most n ones, so $\|q_j\|^2 \le n$. So A stretches any vector by at most $\sqrt{mn}$.
7. **From the grid to every unit vector.** Outside the bad event of step 5, take any unit vector x and its grid point y. By the triangle inequality and steps 3 to 6,

$$\|Ax\| \ge \|Ay\| - \|A(x-y)\| \ge \sqrt{\frac{m}{128}}\Big(1 - \frac{1}{80\sqrt{n}}\Big) - \sqrt{mn}\cdot\frac{1}{80\sqrt{n}}. \tag{H.8}$$

   The right side equals $\sqrt{m}$ times $\frac{1}{\sqrt{128}} - \frac{1}{80}(1 + \frac{1}{\sqrt{128n}})$, which grows with n, so it is smallest at $n = 1$, where it is $\sqrt{m}\,(\frac{79}{80\sqrt{128}} - \frac{1}{80}) = 0.0748\sqrt{m}$, which is more than $\sqrt{m}/14 = 0.0714\sqrt{m}$. The smallest $\|Ax\|$ over unit vectors is $s_{\min}(A)$, which gives Equation H.5.
8. **The consequence for least squares.** Substituting $s_{\min}(A)^2 \ge m/196$ into Equation 17.9 bounds the number of wrong bits by $4mE^2/(m/196) = 784E^2$. If $E = o(\sqrt{n})$, then $E^2 = o(n)$, so the wrong bits are $o(n)$.

H.2.4. Checking it

The proof is far from tight. Figure H.3 plots the simulated $s_{\min}(A)/\sqrt{m}$ against m/n for $n = 50$, 100 and 200. It falls below the proved floor of $1/14$ only at $m = 1.25n$, and from about $m = 4n$ on it sits on the cited asymptotic $\frac{1}{2}(1 - \sqrt{n/m})$. At the chapter's size, $n = 500$ and $m = 2000$, the script finds $s_{\min}(A) = 11.44$, which is $0.2558\sqrt{m}$. The asymptotic predicts $\frac{1}{2}(1 - \sqrt{1/4}) = 0.25$ times $\sqrt{m}$, and the proof guarantees $\sqrt{m}/14$. The price of the proof is the number of queries it asks for. For $n = 100$ people and failure probability $\beta = 0.01$, Equation H.5 asks for 115,627 queries, about 1,156 per person. The simulation shows the floor holding from $m = 1.5n$ on.

Figure H.4 shows where the slack comes from. For one matrix with $n = 100$ and $m = 400$, it plots $\|Ax\|^2/m$ for 4,000 random unit directions. Random directions land between about 0.2 and 3. For a unit vector the average of $\langle q, x\rangle^2$ is $\frac{1}{4}(1 + (\sum_i x_i)^2)$, the variance of one entry plus a share of the mean that grows with how far x points along the all-ones direction. The weakest direction is lower, and the all-ones direction is about a hundred times higher, because of the nonzero mean of the entries. The proof's levels, $\frac{1}{128}$ for a grid point and $\frac{1}{196}$ for every direction, are well below all of them. The lemma itself has slack too. For the weakest direction of this matrix, 0.3075 of the queries are good, and no random direction of the 4,000 has fewer than 0.5550 good queries. The lemma guarantees only $\frac{3}{16} = 0.1875$ on average.

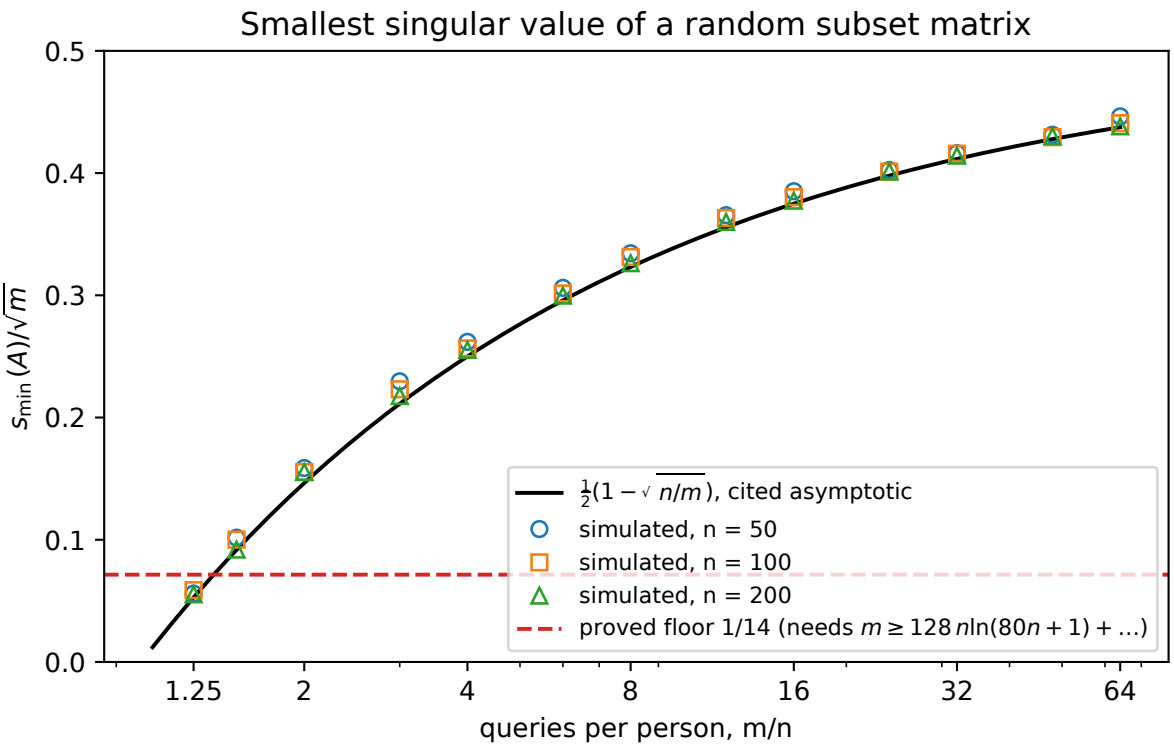

Figure H.3.: The smallest singular value of a random $m \times n$ subset matrix, divided by $\sqrt{m}$, against m/n, for three values of n (three draws each). The black curve is the cited asymptotic $\frac{1}{2}(1-\sqrt{n/m})$, and the dashed line is the floor $1/14$ proved here, which the proof guarantees only once m is of order $128\, n \ln(80n)$.

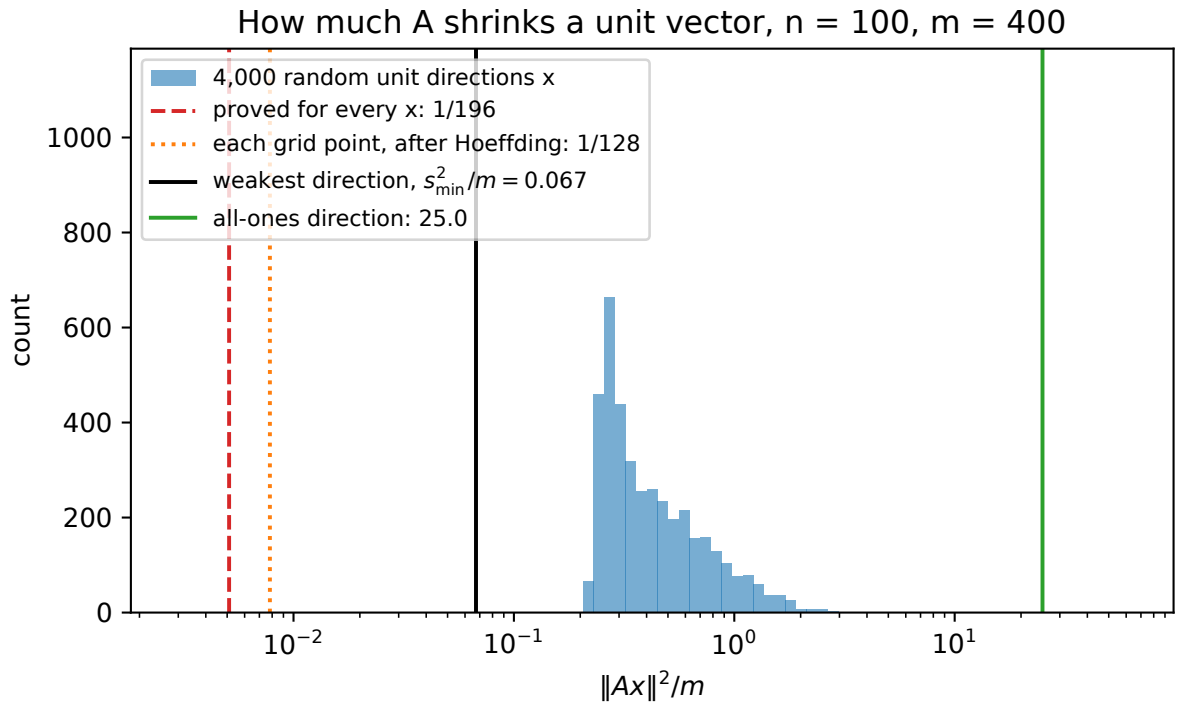

Figure H.4.: Histogram of $\|Ax\|^2/m$ over 4,000 random unit vectors x, for one random subset matrix with $n = 100$ and $m = 400$ (log scale). The vertical lines mark the weakest direction $s_{\min}^2/m$, the all-ones direction, and the two levels of the proof: $\frac{1}{128}$ for each grid point after Hoeffding's inequality, and $\frac{1}{196}$ for every direction.

H.2.5. What it does not cover

The proof gives $m = O(n \log n)$, not $m = 4n$. The logarithm comes from the union bound over a grid fine enough to absorb the crude stretching bound of step 6. For matrices whose entries have mean 0, called centred, a sharper argument bounds the stretching by about $\sqrt{m} + \sqrt{n}$, so it can use a much coarser grid of directions (a net), and it needs only $m = O(n)$ (Vershynin, ch. 4). For subset matrices it would also have to treat the all-ones direction separately, and this appendix does not carry that out. The sharp constant, $s_{\min} \approx \frac{1}{2}(\sqrt{m} - \sqrt{n})$ for large m and n at a fixed ratio, is the Bai–Yin law for matrices with independent centred entries (Bai and Yin 1993; Vershynin, ch. 4). Subset matrices are not centred, but they differ from $\frac{1}{2}$ times a random-sign matrix by the rank-one matrix $\frac{1}{2}\mathbf{1}\mathbf{1}^\top$, and on vectors orthogonal to $\mathbf{1}$ the two act the same. Turning that observation into a proof of the sharp constant takes a perturbation argument for the one remaining direction, which stays cited. So the chapter's statement with $m = 4n$ rests on the cited asymptotics and on its simulation, while the $O(n \log n)$ version is proved here.

H.3. The prefix-sum matrix

H.3.1. What the chapter uses

In DP-FTRL and matrix factorization, A is the $T \times T$ **prefix-sum matrix**: lower-triangular, with every entry on and below the diagonal equal to 1, so that row t of Ax is the running sum $x_1 + \cdots + x_t$. A factorization $A = LR$ releases $L(Rx + z)$, where z is Gaussian noise. Its **sensitivity** $\Delta_2 R$ is the largest length of a column of R, and its error per unit of privacy at step t is $e_t = \Delta_2 R \, \|\ell_t\|$, with ℓ_t the t-th row of L. The chapter uses four facts about this matrix.

The first two are in Section 41.4, steps 5 and 6. Every factorization has a root-mean-square error (RMSE) of at least $\|A\|_*/T$ (Equation 41.8), where the RMSE is $(\frac{1}{T}\sum_t e_t^2)^{1/2}$, the typical error over the T released sums, where the **trace norm** $\|A\|_*$ is the sum of the singular values. The proof uses the duality

$$\operatorname{tr}(U^\top A) \le \|A\|_* \quad \text{for every } U \text{ whose largest singular value is at most 1,} \tag{H.9}$$

which the chapter states without proof. It also states the singular values, with $\omega_k = (2k - 1)\pi/(2T + 1)$,

$$\sigma_k(A) = \frac{1}{2\sin\frac{(2k-1)\pi}{4T+2}} = \frac{1}{2\sin(\omega_k/2)}, \qquad k = 1, \dots, T, \tag{H.10}$$

and says that the eigenvalues of $(A^{-1})^\top A^{-1}$ are $4\sin^2(\omega_k/2)$, checking this numerically.

The other two are in Section 41.6. The square-root factorization uses the lower-triangular matrix with entries $r_k = \binom{2k}{k}4^{-k}$ on its k-th diagonal, and step 6 bounds its sensitivity and largest error, $\sum_{k<T} r_k^2$, with Equation 41.11. That step quotes the Wallis-type inequality

$$\frac{1}{\pi(k + \frac{1}{2})} \le r_k^2 \le \frac{1}{\pi(k + \frac{1}{4})} \tag{H.11}$$

from Fichtenberger, Henzinger and Upadhyay (2023) and checks it numerically for $k < 100{,}000$. Finally, the chapter compares the square root with the lower bound at $T = 100$ and $T = 10{,}000$

and finds it within 9% and 6%. This section proves the duality, the singular values and the Wallis bounds, and it explains the comparison by proving that the ratio tends to 1:

$$\frac{\ln(2T+1)}{\pi} \le \frac{\|A\|_*}{T} \le \text{RMSE of any factorization}, \qquad \text{RMSE of the square root} \le 1 + \frac{0.8 + \ln\frac{4T-3}{5}}{\pi}. \tag{H.12}$$

H.3.2. The idea

The singular values of A are hard to see directly, but its inverse is simple. Taking running sums is undone by taking differences, so A^{-1} has 1 on the diagonal and -1 just below it. Then $(A^{-1})^\top A^{-1}$ is the matrix of a second difference, $-v_{j-1} + 2v_j - v_{j+1}$, the same matrix that describes a vibrating string. Its eigenvectors are sine waves, and the two ends of the matrix decide which frequencies fit. For $T = 2$ the whole computation fits in a few lines:

$$A^{-1} = \begin{pmatrix} 1 & 0 \\ -1 & 1 \end{pmatrix}, \qquad (A^{-1})^\top A^{-1} = \begin{pmatrix} 2 & -1 \\ -1 & 1 \end{pmatrix}. \tag{H.13}$$

The eigenvalues of the second matrix are $(3 \pm \sqrt{5})/2$, that is 2.618 and 0.382. The formula proved below gives the same two numbers, as $4\sin^2(3\pi/10)$ and $4\sin^2(\pi/10)$. The singular values of A are one over their square roots, the golden ratio 1.618 and its inverse 0.618.

The duality is a statement about lining up. The singular value decomposition writes A as a sum of simple pieces, one for each singular value σ_k, and each piece maps one input direction v_k to one output direction u_k. A matrix U that stretches no vector can line up with each piece at best perfectly, so it collects at most σ_k from each, and $\|A\|_*$ in total. The Wallis bounds come from squeezing. Two sequences built from r_k^2, one decreasing and one increasing, close in on the same limit $1/\pi$, so each stays on its side. Finally, the near-optimality of the square root follows by putting the bounds side by side. The lower bound on every factorization and the upper bound on the square root both grow like $(\ln T)/\pi$, so their ratio tends to 1.

H.3.3. Derivation

The singular values.

1. **The inverse.** Write N for the matrix with ones just below the diagonal and zeros elsewhere, so that $Nx = (0, x_1, \dots, x_{T-1})$ shifts a vector down by one. Taking the differences $x_t - x_{t-1}$ of running sums gives back the x_t, so $A^{-1} = I - N$.
2. **The product.** $(A^{-1})^\top A^{-1} = (I - N^\top)(I - N) = I - N - N^\top + N^\top N$. The matrix $N^\top N$ is diagonal with entries $1, \dots, 1, 0$, because N maps the last basis vector to 0 and every other basis vector to the next one. So the product $M = (A^{-1})^\top A^{-1}$ is tridiagonal, with -1 next to the diagonal and 2 on the diagonal, except for a 1 in the bottom-right corner.
3. **Interior rows.** Try $v_j = \sin(j\omega)$ for $j = 1, \dots, T$. Row j of Mv, for $1 < j < T$, is $-v_{j-1} + 2v_j - v_{j+1}$. The identity $\sin((j-1)\omega) + \sin((j+1)\omega) = 2\cos\omega\sin(j\omega)$ turns this into $(2 - 2\cos\omega)v_j = 4\sin^2(\omega/2)\, v_j$. So $\nu = 4\sin^2(\omega/2)$ is the eigenvalue, if the first and last rows agree.
4. **The first row.** Row 1 is $2v_1 - v_2$, which is the interior formula with $v_0 = 0$. The sine satisfies $\sin(0) = 0$, so row 1 holds for every ω.

5. **The last row.** Row T is $-v_{T-1}+v_T$, which is the interior formula with $v_{T+1}=v_T$. So the sine must take the same value at T and $T+1$, which means it must be symmetric about $T+\frac{1}{2}$, a peak or a trough there. That requires $(T+\frac{1}{2})\omega$ to be an odd multiple of $\frac{\pi}{2}$, that is, $\omega_k=(2k-1)\pi/(2T+1)$. The values $k=1,\dots,T$ give T different angles in $(0,\pi)$, where $\sin^2(\omega/2)$ increases, hence T different eigenvalues, which is all of them.
6. **Back to A.** The eigenvalues of $M=(AA^\top)^{-1}$ are the squares of the singular values of A^{-1}, which are one over the singular values of A. So $\sigma_k(A)=1/\sqrt{4\sin^2(\omega_k/2)}=1/(2\sin(\omega_k/2))$, which is Equation H.10, largest at $k=1$.

The duality. Write the singular value decomposition $A=\sum_k \sigma_k u_k v_k^\top$, with orthonormal u_k and orthonormal v_k. Since $\operatorname{tr}(U^\top u_k v_k^\top)=v_k^\top U^\top u_k=\langle Uv_k,u_k\rangle$, linearity of the trace gives

$$\operatorname{tr}(U^\top A)=\sum_k \sigma_k\langle Uv_k,u_k\rangle \le \sum_k \sigma_k\|Uv_k\|\,\|u_k\| \le \sum_k \sigma_k = \|A\|_*. \tag{H.14}$$

The middle step is the Cauchy–Schwarz inequality, and the last uses $\|Uv_k\|\le 1$, because U stretches no vector and v_k has length 1. Equality holds for $U=\sum_k u_k v_k^\top$, which maps each v_k exactly onto u_k. This is Equation H.9.

The Wallis bounds.

1. **Two integrals.** Let $I_n=\int_0^{\pi/2}\sin^n x\,dx$. Integrating by parts gives $I_n=\frac{n-1}{n}I_{n-2}$, and $I_0=\frac{\pi}{2}$, $I_1=1$. Unrolling the recursion, $I_{2k}=\frac{\pi}{2}\cdot\frac{1}{2}\cdot\frac{3}{4}\cdots\frac{2k-1}{2k}=\frac{\pi}{2}r_k$, because the square root's coefficients satisfy $r_k=r_{k-1}\frac{2k-1}{2k}$ (Equation 41.10). In the same way $I_{2k+1}=\frac{2}{3}\cdot\frac{4}{5}\cdots\frac{2k}{2k+1}=\frac{1}{(2k+1)r_k}$.
2. **The lower bound.** On $[0,\frac{\pi}{2}]$, $0\le\sin x\le 1$, so higher powers are smaller and I_n decreases in n. From $I_{2k+1}\le I_{2k}$ you get $\frac{1}{(2k+1)r_k}\le\frac{\pi}{2}r_k$, that is, $r_k^2\ge\frac{2}{\pi(2k+1)}=\frac{1}{\pi(k+\frac{1}{2})}$.
3. **A first upper bound, and the limit.** From $I_{2k}\le I_{2k-1}=\frac{1}{2kr_k}$, the same way, $r_k^2\le\frac{1}{\pi k}$ for $k\ge 1$. Together with step 2, $k\,r_k^2$ is squeezed between $\frac{k}{\pi(k+1/2)}$ and $\frac{1}{\pi}$, so it tends to $\frac{1}{\pi}$. This is Wallis's product in disguise.
4. **Two monotone sequences.** Let $a_k=(k+\frac{1}{2})r_k^2$ and $b_k=(k+\frac{1}{4})r_k^2$. Both tend to $\frac{1}{\pi}$ by step 3. Using $r_{k+1}/r_k=(2k+1)/(2k+2)$,

$$\frac{a_{k+1}}{a_k}=\frac{(2k+3)(2k+1)}{(2k+2)^2}=\frac{4k^2+8k+3}{4k^2+8k+4}<1, \qquad \frac{b_{k+1}}{b_k}=\frac{(4k+5)(2k+1)^2}{(4k+1)(2k+2)^2}=\frac{16k^3+36k^2+24k+5}{16k^3+36k^2+24k+4}> \tag{H.15}$$

   So a_k decreases and b_k increases.
5. **Conclude.** A decreasing sequence stays above its limit, so $a_k\ge\frac{1}{\pi}$, which is the lower bound of Equation H.11 again. An increasing sequence stays below its limit, so $b_k\le\frac{1}{\pi}$, which is the upper bound. Both hold for every $k\ge 0$.

How close the square root is to optimal.

1. **A floor under every factorization.** For $0<x\le\frac{\pi}{2}$, $\sin x\le x$, so each singular value in Equation H.10 is at least $\frac{1}{\omega_k}=\frac{2T+1}{(2k-1)\pi}$. The function $\frac{1}{2x-1}$ decreases, so each term $\frac{1}{2k-1}$ is at least its integral from k to $k+1$. Adding these up, and then dividing the sum of the singular values by T,

$$\sum_{k=1}^{T}\frac{1}{2k-1}\ge\frac{1}{2}\ln(2T+1), \qquad \frac{\|A\|_*}{T}\ge\frac{2T+1}{2\pi T}\ln(2T+1)\ge\frac{\ln(2T+1)}{\pi}. \tag{H.16}$$

2. **A ceiling over the square root.** For the square root, $L = R$. Row t holds $r_{t-1}, \dots, r_0$, so each row of L is no longer than the last one, whose squared length is $\sum_{k<T} r_k^2 = (\Delta_2 R)^2$ (step 5 of Section 41.6). So every $e_t \le (\Delta_2 R)^2$, and the RMSE, an average of the e_t^2 under a square root, is at most the largest e_t, which is $\sum_{k<T} r_k^2$, which Equation 41.11 bounds by $1 + (0.8 + \ln \frac{4T-3}{5})/\pi$. With the Wallis bounds proved above, that step of the chapter is now complete.
3. **The ratio tends to 1.** By Equation 41.8, the optimal RMSE lies between $\|A\|_*/T$ and the square root's RMSE, so all three lie in the band of Equation H.12. Both ends of the band are $(\ln T)/\pi$ plus a constant, so the square root's RMSE divided by the lower bound tends to 1 as T grows, like $1 + O(1/\ln T)$.

H.3.4. Checking it

The script compares Equation H.10 with a numerical singular value decomposition at $T = 256$, and the largest relative gap is 2.7×10^{-15}. Each $\sin(j\omega_k)$ vector satisfies $Mv = \nu v$ to within 1.4×10^{-14}. Figure H.5 draws the first three eigenvectors for $T = 16$. Each starts from 0 just before position 1 and is flat across the mirror at $T + \frac{1}{2}$, which is how steps 4 and 5 select the angles.

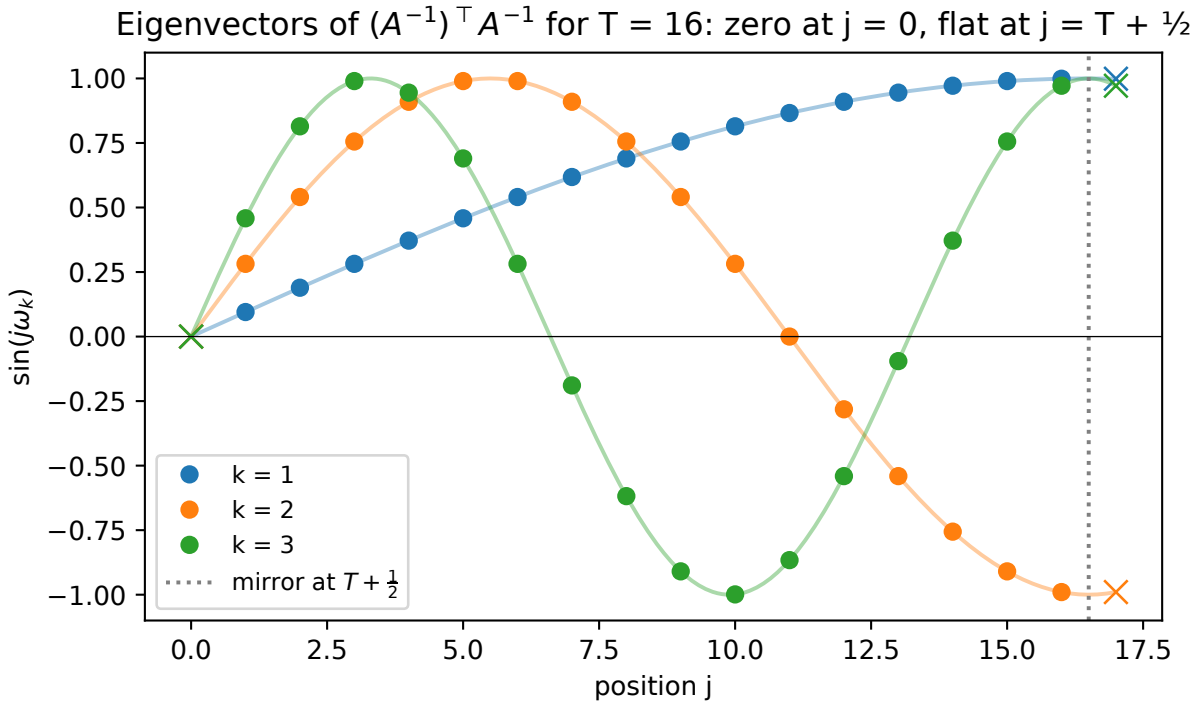

Figure H.5.: The first three eigenvectors $v_j = \sin(j\omega_k)$ of $(A^{-1})^\top A^{-1}$ for $T = 16$, as dots, with the sine curves they sample. Crosses mark the extra points $j = 0$, where every curve is 0, and $j = T + 1$, where every curve repeats its value at $j = T$, because it is symmetric about the dotted line at $T + \frac{1}{2}$.

For the duality at $T = 16$, the trace norm is 26.0552. The largest $\mathrm{tr}(U^\top A)$ over 2,000 random

matrices U, each scaled so that its largest singular value is 1, is 4.9448, well below it, and the aligned choice $U = \sum_k u_k v_k^\top$ attains 26.0552, the trace norm itself.

For the Wallis bounds, the script checks the two ratio inequalities of step 4 in exact integer arithmetic for every $k < 10^6$, and Equation H.11 itself in floating point for every $k < 10^4$. A floating-point check cannot go much further, because b_k approaches $\frac{1}{\pi}$ like $1/(32\pi k^2)$, which soon drowns in rounding error. At $k = 9999$, a_k is still above $\frac{1}{\pi}$ by 8.0×10^{-6} and b_k below it by 9.9×10^{-11}. Figure H.6 shows the two sequences closing in on $\frac{1}{\pi}$ from either side.

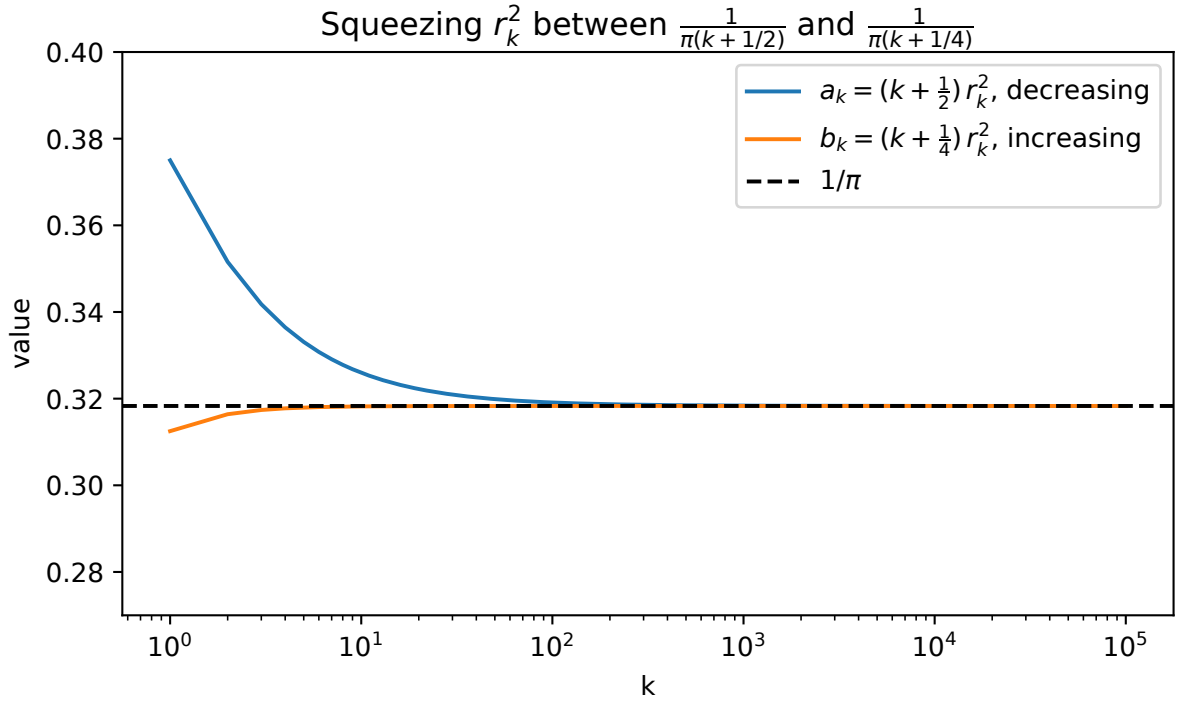

Figure H.6.: The sequences $a_k = (k + \frac{1}{2})r_k^2$ and $b_k = (k + \frac{1}{4})r_k^2$ against k (log scale). The first decreases and the second increases, and both tend to $1/\pi$ (dashed), which squeezes r_k^2 between $\frac{1}{\pi(k+1/2)}$ and $\frac{1}{\pi(k+1/4)}$.

Table H.4 gives the band of Equation H.12 and the two curves inside it. The chapter's "within 9% and 6%" are the ratios 1.089 and 1.056. The ratio keeps falling slowly, to 1.040 at $T = 10^6$, as the $1 + O(1/\ln T)$ of step 3 predicts. The proved band is wide. At $T = 100$ the ceiling divided by the floor is 1.568, so the band only guarantees a ratio below that, while the actual ratio is 1.089, because both $\sin x \le x$ and the bound of each row by the last one give away a constant. Figure H.7 shows the band and both curves from $T = 10$ to 10^6. Every factorization has its RMSE above the blue curve, and the optimal one has its RMSE between the blue and the orange curve.

Table H.4.: The lower bound on every factorization and the square root's RMSE, per unit of privacy, with the proved floor and ceiling of Equation H.12.

T	Floor $\frac{\ln(2T+1)}{\pi}$	Lower bound $\frac{\|A\|_*}{T}$	Square root RMSE	Ratio	Ceiling	$\frac{\ln T}{\pi}$
100	1.688	2.178	2.371	1.089	2.647	1.466
10,000	3.152	3.634	3.836	1.056	4.115	2.932
1,000,000	4.618	5.100	5.302	1.040	5.581	4.398

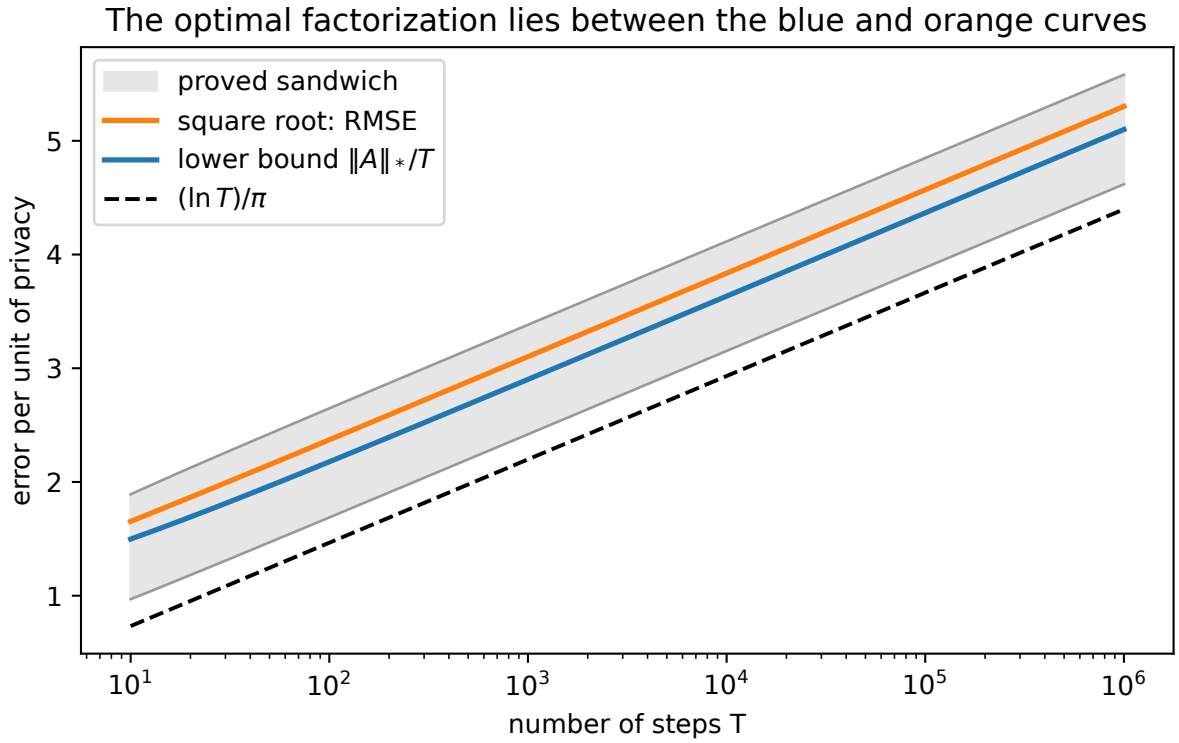

Figure H.7.: The trace-norm lower bound $\|A\|_*/T$ (blue) and the square root's RMSE (orange) against the number of steps T, per unit of privacy, with $(\ln T)/\pi$ dashed. The grey band is the proved sandwich of Equation H.12. The optimal RMSE lies between the blue and orange curves, which approach each other in ratio.

H.3.5. What it does not cover

The chapter also quotes the finer approximation $\sum_{k<T} r_k^2 \approx (\ln T + \gamma + 4\ln 2)/\pi$, with γ Euler's constant. It follows from a longer expansion of r_k^2 in powers of $1/k$, and it stays unproved here, as in the chapter. The ratio of step 3 tends to 1 only slowly, so the comparison says that the square root is nearly optimal for the RMSE, not that it is optimal at any finite T. The next section finds the optimum.

H.4. The optimal factorization for the root-mean-square error

H.4.1. What the chapter uses

In Section 41.6, under "The optimal factorization", the chapter looks for the factorization $A = LR$ with the smallest RMSE. Scaling the encoder R up and the decoder L down by the same factor changes nothing. So the chapter fixes $\Delta_2 R \le 1$, which means that every column of R has length at most 1. It then minimizes the **Frobenius norm** $\|L\|_F$, the square root of the sum of the squared entries of L, and the RMSE per unit of privacy is $\|L\|_F/\sqrt{T}$. The encoder enters only through the matrix $X = R^\top R$ of inner products of its columns, whose diagonal holds the squared column lengths. The chapter states that the problem is

$$\text{minimize } \operatorname{tr}(A^\top A X^{-1}) \quad \text{over positive definite } X \text{ with } X_{ii} \le 1 \text{ for every } i, \tag{H.17}$$

that it is convex, and that its solution is

$$X = V^{-1/2}\big(V^{1/2}A^\top A V^{1/2}\big)^{1/2}V^{-1/2}, \qquad v = \operatorname{diag}\Big(\big(V^{1/2}A^\top A V^{1/2}\big)^{1/2}\Big), \tag{H.18}$$

with V the diagonal matrix of the vector v, so that v is a fixed point of the map on the right. It cites Denisov et al. (2022, Theorem 3.2) for this, sketches the Lagrangian step and iterates the map. A matrix is **positive definite** when it is symmetric and $x^\top X x > 0$ for every nonzero x, and $Y^{1/2}$ is the positive definite square root of such a Y.

H.4.2. The idea

There are four steps. First, once the encoder R is chosen, the best decoder is forced. It is the one that undoes R with no wasted motion, and its size depends on R only through $X = R^\top R$. That turns a problem about two matrices into one about X. Second, the objective is convex in X: along any straight line through the positive definite matrices it bends upward, in the same way that $1/x$ does for positive x. Third, at the optimum the gradient of the objective must be balanced by a price κ_i on each column-length constraint, and solving that balance gives Equation H.18. Fourth, convexity makes any balanced point the global minimum.

The smallest case shows the answer. At $T = 2$, $A^\top A$ has rows $(2, 1)$ and $(1, 1)$. A feasible X with both columns of length 1 has rows $(1, \rho)$ and $(\rho, 1)$, and the objective is $(3 - 2\rho)/(1 - \rho^2)$. Setting its derivative to zero gives $\rho^2 - 3\rho + 1 = 0$, so $\rho = (3 - \sqrt{5})/2 = 0.382$ and the minimum is 2.618, the golden ratio squared. Table H.5 compares it with the other factorizations at $T = 2$.

Table H.5.: The four quantities for $T = 2$, per unit of privacy. The RMSE is $\Delta_2 R\|L\|_F/\sqrt{T}$.

Factorization	$(\Delta_2 R)^2$	$\|L\|_F^2$	RMSE
Independent noise, $R = I$	1	3	1.2247
Square root, $r = (1, \frac{1}{2})$	1.25	2.25	1.1859
Optimum, $\rho = 0.382$	1	2.618	1.1441
Lower bound $\|A\|_*/T = \sqrt{5}/2$			1.1180

H.4.3. Derivation

Write $B = A^\top A$. It is positive definite because A is invertible.

1. **The best decoder for a given encoder.** The encoder R has some number of rows and T columns. The equation $LR = A$ can only hold if R has rank T, because A has rank T, and then $X = R^\top R$ is positive definite. Let $R^+ = X^{-1}R^\top$, so that $R^+R = I$, and let $\Pi = RR^+$, the orthogonal projection onto the column space of R. Any decoder with $LR = A$ satisfies $L\Pi = LRR^+ = AR^+$. Split $L = L\Pi + L(I - \Pi)$. Each row of $L\Pi$ lies in the column space of R and each row of $L(I - \Pi)$ is orthogonal to it, so the squared lengths add, and $\|L\|_F^2 = \|AR^+\|_F^2 + \|L(I - \Pi)\|_F^2 \geq \|AR^+\|_F^2$, with equality for $L = AR^+$. And

$$\|AR^+\|_F^2 = \operatorname{tr}\left(AR^+(R^+)^\top A^\top\right) = \operatorname{tr}\left(AX^{-1}A^\top\right) = \operatorname{tr}(BX^{-1}), \tag{H.19}$$

   because $R^+(R^+)^\top = X^{-1}R^\top RX^{-1} = X^{-1}$, and the trace does not change when a product is rotated. So the problem over (L, R) is Equation H.17 over X.
2. **The objective is convex.** Take positive definite X, a symmetric direction H, and $X(t) = X + tH$. Differentiating $X(t)X(t)^{-1} = I$ gives $\frac{d}{dt}X^{-1} = -X^{-1}HX^{-1}$, and differentiating again gives $2X^{-1}HX^{-1}HX^{-1}$. So the second derivative of $f(t) = \operatorname{tr}(BX(t)^{-1})$ at $t = 0$ is

$$f''(0) = 2\operatorname{tr}\left(X^{-1}BX^{-1} \cdot HX^{-1}H\right). \tag{H.20}$$

   Both $X^{-1}BX^{-1}$ and $HX^{-1}H$ are positive semidefinite, and the trace of a product of two positive semidefinite matrices is at least 0, because $\operatorname{tr}(GH) = \operatorname{tr}(G^{1/2}HG^{1/2})$ is a sum of non-negative diagonal entries. So f bends upward along every line. The positive definite matrices form a convex set, and the constraints $X_{ii} \leq 1$ are linear, so the problem is convex.
3. **The balance condition.** Give each constraint a price $\kappa_i \geq 0$ and let K be the diagonal matrix of the prices. The gradient of $\operatorname{tr}(BX^{-1})$ with respect to X is $-X^{-1}BX^{-1}$, by step 2, and that of $\sum_i \kappa_i X_{ii}$ is K. At an optimum such prices exist, because the constraints are linear, and the two gradients balance:

$$X^{-1}BX^{-1} = K, \qquad \text{that is,} \qquad XKX = B. \tag{H.21}$$

   Since B is positive definite, so is $K = X^{-1}BX^{-1}$, so every price is positive. The optimality conditions also require each price times the slack of its constraint, $\kappa_i(1 - X_{ii})$, to be 0, which is called complementary slackness. So a positive price forces $X_{ii} = 1$, for every i. All columns of the optimal encoder have length exactly 1.
4. **Solving the balance.** Multiply Equation H.21 by $K^{1/2}$ on both sides: $(K^{1/2}XK^{1/2})^2 = K^{1/2}BK^{1/2}$. The matrix $K^{1/2}XK^{1/2}$ is positive definite, and a positive definite matrix has only one positive definite square root, so $K^{1/2}XK^{1/2} = (K^{1/2}BK^{1/2})^{1/2}$, which is the first half of Equation H.18 with $V = K$. Its diagonal entries read $\kappa_i X_{ii} = \left[(K^{1/2}BK^{1/2})^{1/2}\right]_{ii}$, and with $X_{ii} = 1$ this is the fixed point $v = \operatorname{diag}\left((V^{1/2}BV^{1/2})^{1/2}\right)$, the second half.
5. **A balanced point is the minimum.** A convex function lies above its tangent, so for any feasible Y,

$$\operatorname{tr}(BY^{-1}) \geq \operatorname{tr}(BX^{-1}) - \operatorname{tr}\left(X^{-1}BX^{-1}(Y - X)\right) = \operatorname{tr}(BX^{-1}) - \sum_i \kappa_i(Y_{ii} - 1) \geq \operatorname{tr}(BX^{-1}), \tag{H.22}$$

   using Equation H.21, $X_{ii} = 1$, $Y_{ii} \leq 1$ and $\kappa_i > 0$. So a fixed point of Equation H.18 gives the optimum.

6. **The optimum exists, and its value is the sum of the prices.** The feasible matrices have entries in $[-1, 1]$, since $|X_{ij}| \le \sqrt{X_{ii}X_{jj}}$, and the objective grows without bound near a singular X, so the minimum is attained at a positive definite matrix, where step 3 applies. Its value follows from Equation H.21, which gives $BX^{-1} = XK$:

$$\|L\|_F^2 = \operatorname{tr}(BX^{-1}) = \operatorname{tr}(XK) = \sum_i v_i, \qquad \text{RMSE} = \sqrt{\frac{1}{T}\sum_i v_i}. \tag{H.23}$$

7. **A lower-triangular encoder.** Any R with $R^\top R = X$ gives the same RMSE, and streaming needs a lower-triangular one. Let J be the matrix that reverses the order of coordinates. The Cholesky factorization writes the positive definite matrix JXJ as $GG^\top$ with G lower-triangular. Then $R = JG^\top J$ is lower-triangular, because reversing both rows and columns turns the upper-triangular $G^\top$ into a lower-triangular matrix, and $R^\top R = JGJJG^\top J = J(JXJ)J = X$. The decoder $L = AR^{-1}$ is lower-triangular too.

That the iteration $v \leftarrow \operatorname{diag}\left((V^{1/2}BV^{1/2})^{1/2}\right)$ converges to the fixed point is shown by Denisov et al. (2022), and it stays cited. The script observes it.

H.4.4. Checking it

The script runs the iteration from $v = \mathbf{1}$ with the chapter's stopping rule, a relative change below 10^{-10}. It reproduces the chapter's counts, 155 iterations at $T = 100$ and 193 at $T = 256$, and the RMSE 2.2355 and 2.5244, against 2.3707 and 2.6688 for the square root. At $T = 64$ it checks every step. The balance condition Equation H.21 holds to 5.5×10^{-13}, the diagonal of X equals 1 to 8.4×10^{-11}, the encoder has no nonzero entry above the diagonal, and $LR = A$ to 6.7×10^{-16}. The RMSE computed from L, 2.0999, equals $\sqrt{\sum_i v_i/T}$ as step 6 says. Moving X in 200 random feasible directions never lowers the objective: the smallest increase is 3.4857.

Figure H.8 shows the iteration and what it buys. On the left, the quantity $\max_i |X_{ii} - 1|$ for the current v falls geometrically, and the number of iterations grows slowly with T. On the right, the square root spends its privacy unevenly. Its first column is the longest and fixes the sensitivity, and its later columns are shorter, so the noise that hides them is larger than they need. The optimum makes every column exactly as long as the first, as step 3 requires.

H.5. Streaming: triangular factors and adaptive participations

H.5.1. What the chapter uses

Two facts in DP-FTRL and matrix factorization concern streams. There the mechanism must release its estimate $\hat{S}_t$ of the running sum at step t, and the gradients are chosen after seeing earlier outputs. Recall the setting. Each step's gradient sum is a vector of d numbers, one per model weight, so x and the noise z are matrices with one row per step. One record adds a vector of length at most the clipping norm C to each step it takes part in, and the noise has standard deviation sC, where s is the noise scale. Under "Streaming needs lower-triangular factors" in Section 41.4, the chapter says that for any factorization there is a lower-triangular one with the same distribution of the release $\hat{S} = L(Rx + z)$, citing Denisov et al. (2022, Proposition 2.2).

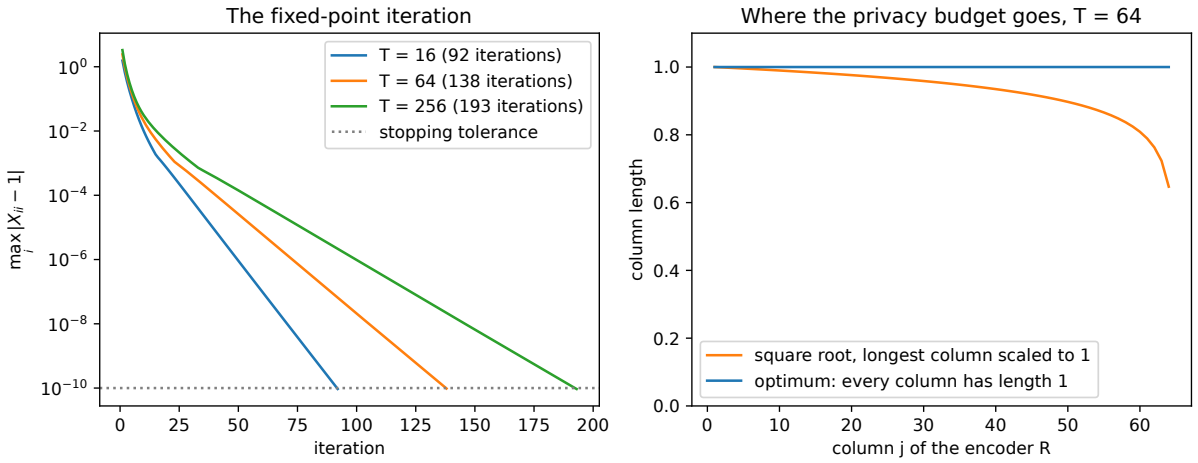

Figure H.8.: Left: the gap $\max_i |X_{ii} - 1|$ of the fixed-point iteration against the iteration number, for $T = 16$, 64 and 256 (log scale), down to the stopping tolerance 10^{-10}. Right: the column lengths of the encoder R for $T = 64$, for the square root scaled so its longest column has length 1, and for the optimum, where every column has length 1.

Precisely, if $A = LR$ with L of size $T \times m$ and R of size $m \times T$, there are lower-triangular $T \times T$ matrices L' and R' with

$$L'R' = A, \qquad L'L'^{\top} = LL^{\top}, \qquad \Delta_2 R' \le \Delta_2 R. \tag{H.24}$$

Here $\Delta_2 R$ is the sensitivity when each record takes part in one step. When a record takes part at several steps $\tau_1, \dots, \tau_k$, contributing $g_1, \dots, g_k$, the encoder's output changes by $\sum_i r_{\tau_i} g_i^{\top}$, where r_τ is column τ of R. The sensitivity of Equation 41.13 is the largest Frobenius norm of that change, over the allowed patterns and over all g_i of length at most C, divided by C. The same inequality holds for it.

Step 3 of Section 41.4 proves that a record that takes part in one step stays μ-Gaussian differential privacy (GDP) when the inputs are chosen adaptively. In Section 41.7, step 3, a record takes part at several steps, and its later contributions g_i may depend on outputs it has already influenced. The chapter there says that such adaptive choices cannot do worse than the largest change over fixed g_i, and it cites Denisov et al. (2022, Theorem 2.1). This section proves that claim for Gaussian noise. With a lower-triangular R, a fixed participation pattern, and the sensitivity of Equation 41.13, the release is μ-GDP with $\mu = \Delta_2 R / s$, however the contributions are chosen.

Recall what μ-GDP means. The neighbouring datasets differ by adding or removing one record: D is the dataset without the record and $D' = D \cup \{x\}$ the dataset with it. Let P be the distribution of all the outputs on D, when the record is absent, and Q their distribution on D', when it is present. The release is μ-GDP when telling P from Q is no easier than telling $\mathcal{N}(0,1)$ from $\mathcal{N}(\mu,1)$. The best trade-off between the two errors of a test for that normal pair is a curve called G_μ. By the Neyman–Pearson lemma, how easy that is depends only on the **privacy loss** $L_{D,D'} = \ln(p/q)$, the log of the ratio of the two densities at the output, written with its pair of datasets because L alone is the decoder on this page, and on its distribution under P and under Q (f-DP and Gaussian DP). For the normal pair the privacy loss is normal, $\mathcal{N}(\mu^2/2, \mu^2)$ under P.

H.5.2. The idea

For the triangular factors, the release depends on the decoder L only through the covariance $LL^\top$ of its noise Lz. Running Gram–Schmidt on the rows of L, in order, writes each row as a combination of the first few orthonormal directions, which is a lower-triangular matrix of coefficients. The orthonormal directions can then be moved into the encoder, where they cannot lengthen any column.

For adaptivity, release the rows of $Rx + z$ one at a time. Given what has been released so far, each new row is a Gaussian mechanism, and the record shifts its mean by some amount μ_j, measured in units of the noise. So the privacy loss of that row is a normal variable with mean $\mu_j^2/2$ and variance μ_j^2. The shifts depend on the past, because the record's later gradients do, but their squares always add up to at most μ^2. If they added up to exactly μ^2 on every path, the total privacy loss would be exactly $\mathcal{N}(\mu^2/2, \mu^2)$, the loss of a single Gaussian mechanism. To arrange that, imagine one extra output that tops the sum up to μ^2. Throwing that output away afterwards is post-processing, which cannot make privacy worse.

H.5.3. Derivation

Lower-triangular factors.

1. **The decoder has full rank.** A has rank T and $A = LR$, so L has rank T and $m \geq T$.
2. **Gram–Schmidt on the rows.** Orthonormalize the rows $\ell_1, \dots, \ell_T$ of L in order, giving orthonormal rows $o_1, \dots, o_T$, the rows of a $T \times m$ matrix O with $OO^\top = I$. By construction ℓ_t is a combination of $o_1, \dots, o_t$ only, so $L = L'O$ with L' lower-triangular, and invertible because L has rank T.
3. **The new encoder.** Set $R' = OR$. Then $L'R' = L'OR = LR = A$, and $R' = L'^{-1}A$ is lower-triangular as a product of lower-triangular matrices. The noise covariance is unchanged, because $L'L'^\top = L'OO^\top L'^\top = LL^\top$. So $L'z'$, with z' of size $T \times d$, has the same distribution as Lz, and the release has the same distribution.
4. **No more sensitivity.** A matrix with orthonormal rows does not lengthen vectors: $\|Ov\|^2 = \sum_t \langle o_t, v\rangle^2 \leq \|v\|^2$, by Bessel's inequality, because the o_t are orthonormal. Each column of R' is O times the matching column of R, so $\Delta_2 R' \leq \Delta_2 R$. For several participations, the change $\sum_i r_{\tau_i} g_i^\top$ becomes $O \sum_i r_{\tau_i} g_i^\top$, whose Frobenius norm is no larger for the same reason. This gives Equation H.24.

Adaptive participations. Take R lower-triangular of size $T \times T$, noise z with independent $\mathcal{N}(0, \varsigma^2)$ entries where $\varsigma = sC$, and release Y_j, row j of $Rx + z$, at step j. The record takes part at fixed steps $\tau_1 < \cdots < \tau_k$, and its contribution g_i at step τ_i may depend on $Y_1, \dots, Y_{\tau_i - 1}$. The other records' gradients at step t are functions of $Y_1, \dots, Y_{t-1}$, the same functions with and without the record.

1. **Each row is a Gaussian mechanism given the past.** Given $Y_1, \dots, Y_{j-1}$, the mean of Y_j is the same function of the past under P and Q, except that under Q it is shifted by $\Delta_j = \sum_i R_{j\tau_i} g_i^\top$. Only participations with $\tau_i \leq j$ contribute, because R is lower-triangular, and their g_i are already fixed by the past.

2. **The privacy loss adds up.** The density of all outputs is the product of the conditional densities, so the privacy loss is a sum $L_{D,D'} = \sum_j L_j$ of the privacy losses L_j of the single rows. For one row, the normal densities give $L_j = \frac{\|\Delta_j\|^2}{2\varsigma^2} - \frac{\langle \Delta_j, z_j \rangle}{\varsigma^2}$, with $z_j = Y_j$ minus its mean under P. Under P, given the past, z_j is normal with independent coordinates, so L_j is normal with mean $\mu_j^2/2$ and variance μ_j^2, where $\mu_j = \|\Delta_j\|/\varsigma$.
3. **The shifts are bounded on every path.** The squared shifts add up to $\sum_j \|\Delta_j\|^2 = \|\sum_i r_{\tau_i} g_i^\top\|_F^2$, the change in Rx. The g_i have length at most C, so this is at most $(\Delta_2 R)^2 C^2$ by the definition Equation 41.13, whatever values the g_i took. Dividing by ς^2, $\sum_j \mu_j^2 \le \mu^2$ with $\mu = \Delta_2 R/s$.
4. **Top up to exactly μ^2.** Add one more output Y_{T+1}, normal with variance 1, whose mean is 0 under P and $\mu_{T+1} = \sqrt{\mu^2 - \sum_{j \le T} \mu_j^2}$ under Q. Its shift depends on the past, which is allowed, because the argument below conditions on the past at every row. Now $\sum_j \mu_j^2 = \mu^2$ exactly on every path. The original release is the padded one with Y_{T+1} thrown away, and by post-processing it is at least as private.
5. **The total loss is exactly normal under P.** The tool is the moment generating function, the average of $e^{\lambda L_{D,D'}}$ for a real number λ. A normal variable with mean a and variance b has $\mathbb{E}[e^{\lambda N}] = e^{\lambda a + \lambda^2 b/2}$. So, given the past, step 2 gives

$$\mathbb{E}\big[e^{\lambda L_j}\big] = e^{c\mu_j^2}, \qquad c = \frac{\lambda + \lambda^2}{2}. \tag{H.25}$$

   In other words, the factor $e^{\lambda L_j - c\mu_j^2}$ has average 1 given the past, whatever μ_j the past chose. Multiply these factors over all rows, averaging the last one first, then the one before, and so on: each average is 1, so the product has average 1. The product is $e^{\lambda L_{D,D'} - c\sum_j \mu_j^2}$, and $\sum_j \mu_j^2 = \mu^2$ is a constant on every path, so

$$\mathbb{E}_P\big[e^{\lambda L_{D,D'}}\big] = e^{c\mu^2} = \exp\Big(\lambda \frac{\mu^2}{2} + \lambda^2 \frac{\mu^2}{2}\Big). \tag{H.26}$$

   This is the moment generating function of a normal variable with mean $\mu^2/2$ and variance μ^2. A moment generating function that is finite for every λ determines the distribution, so $L_{D,D'} \sim \mathcal{N}(\mu^2/2, \mu^2)$ under P. Here the padding matters. Without it, the constant μ^2 would be the path-dependent $\sum_j \mu_j^2$, and it could not be taken out of the average.
6. **So is the loss under Q, and the release is μ-GDP.** The distribution of $L_{D,D'}$ under Q follows from that under P, because $q = e^{-L_{D,D'}} p$: for any set S of values, $\Pr_Q[L_{D,D'} \in S] = \mathbb{E}_P\big[e^{-L_{D,D'}}\, \mathbf{1}[L_{D,D'} \in S]\big]$. The single Gaussian mechanism with ratio μ has the same law of $L_{D,D'}$ under its P, hence under its Q too. By Neyman–Pearson, the two pairs have the same trade-off curve G_μ. The padded release is therefore exactly μ-GDP, and the release itself, by step 4, is μ-GDP.

H.5.4. Checking it

For the triangular factors, the script starts from the binary tree of Section 41.5 at $T = 64$, whose encoder has one row for each of its 127 nodes. Gram–Schmidt on the rows of its decoder gives 64×64 lower-triangular factors with $L'R' = A$ and $L'L'^\top = LL^\top$, both exactly. The sensitivity stays 2.6458, which is $\sqrt{7}$, because the first column of the tree's encoder already lies in the span

of the decoder's rows. So 64 noisy numbers can replace the tree's 127 node sums, with the same distribution of every released prefix sum.

For adaptivity, the script simulates the square-root encoder at $T = 8$, one coordinate, with $C = 1$ and $s = \Delta_2 R$, so that $\mu = 1$. The record takes part at steps 1 and 5, with $g_1 = 1$ and $g_2 = \tanh(Y_4)$, a contribution chosen from an output the record has already influenced. Over a million runs under P, the padded privacy loss has mean 0.4996 and variance 0.9985, against $\mu^2/2 = 0.5$ and $\mu^2 = 1$. Without the padding the loss has mean 0.2681 and variance 0.5207, smaller, because $|g_2| < 1$ keeps the total shift below its worst case. Figure H.9 shows both histograms against the normal density.

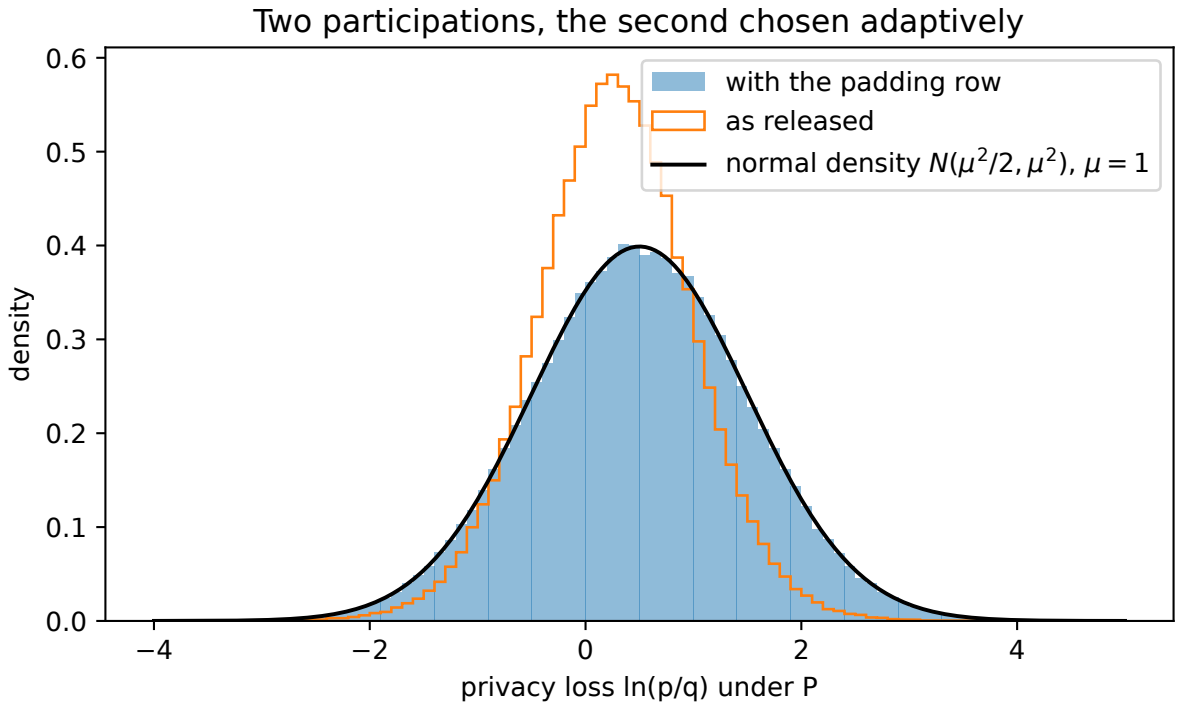

Figure H.9.: Histogram of the privacy loss $\ln(p/q)$ under P for a two-participation run of the square-root mechanism at $T = 8$, whose second contribution depends on an earlier output, with $\mu = 1$. Filled: with the padding row of step 4, which matches $\mathcal{N}(\mu^2/2, \mu^2)$ (black). Outline: the release itself, which is more concentrated, so more private.

H.5.5. What it does not cover

The adaptive proof assumes a square lower-triangular encoder released one row per step, a participation pattern fixed in advance, and Gaussian noise. The binary tree has more rows than steps. It fits after ordering its rows by the step at which each node is complete, and then the same argument applies with several rows released at some steps. Denisov et al. (2022, Theorem 2.1) prove a more general statement, which also covers (ε, δ) guarantees and non-Gaussian losses, and that version stays cited.

H.6. Code

The script `code/appendix-derivations/apx_matrices.py` checks each derivation numerically and draws the figures. For the Wishart mean it simulates Gaussian and 0/1 matrices, checks the regression identity of step 4 and the χ^2 average of step 6. For the smallest singular value it measures $s_{\min}$, the share of good queries and the number of queries the proof needs. For the prefix-sum matrix it checks the eigenvectors and singular values, the duality, the monotonicity of a_k and b_k for $k < 10^6$, and the sandwich up to $T = 10^6$. It also runs the fixed-point iteration, checks every condition of the optimum, and checks the triangular reduction and the adaptive privacy loss. Run it with

```
uv run python code/appendix-derivations/apx_matrices.py
```

Table H.6 collects the main numbers it prints with the default seed.

Table H.6.: The main numbers printed by the script.

Check	Result
m times average inverse diagonal, $n = 50$, $m = 100$: predicted, Gaussian, 0/1	2.041, 2.041, 2.000
$\mathbb{E}[1/\chi^2_{11}]$: Monte Carlo against 1/9	0.1112 against 0.1111
$s_{\min}(A)/\sqrt{m}$ at $n = 500$, $m = 2000$: simulated, asymptotic, proved	0.2558, 0.25, 0.0714
Queries the proof needs at $n = 100$, $\beta = 0.01$	115,627
Closed-form singular values against numerical, $T = 256$	2.7×10^{-15}
Square root against lower bound, $T = 100$ and 10^4	1.089 and 1.056
Optimal RMSE at $T = 100$ and 256, iterations	2.2355 (155), 2.5244 (193)
Adaptive privacy loss, padded: mean and variance	0.4996 and 0.9985

Every bound holds, and the simulations agree with the exact statements to within their noise. The two bounds that are far from tight are the smallest-singular-value floor, by a factor of three to six in $s_{\min}$ and much more in the number of queries, and the band of Equation H.12, which is wide at small T even though its ratio tends to 1.

I. Pseudorandom functions and learning with errors

This appendix proves two results that Cryptography basics states without a full proof. The first is that the GGM tree, named after Goldreich, Goldwasser and Micali, is a pseudorandom function (PRF) whenever the pseudorandom generator (PRG) it is built from is secure. The second is about learning with errors (LWE), a problem in which a secret vector is hidden behind noisy linear equations. When the arithmetic is done modulo a prime, an algorithm that can only *recognize* such equations can be turned into one that *finds* the secret. Both proofs are reductions: each turns an algorithm that solves one problem into an algorithm that solves another. Both also rest on the same move. The new algorithm takes the input it must judge, called its challenge, and uses it to build exactly the situation the old algorithm expects to see. So the heart of each proof is a check that two distributions are identical. Table I.1 lists where each result comes from.

Table I.1.: The two derivations in this appendix and the chapter section that states each one.

Derivation	Where the chapter states it	What the chapter gives
Section I.1: the GGM tree is a PRF, with advantage at most nQ times the PRG's	Section 8.6.4	A proof sketch, citing Goldreich for the full proof
Section I.2: search LWE reduces to decision LWE for prime p polynomial in d	Section 8.9, Definition	One sentence describing Regev's idea

The notation is the chapter's, with two letters changed. The security parameter λ is the length of keys and seeds in bits, and U_k stands for the uniform distribution on strings of k bits. An **adversary** is an algorithm that tries to break a scheme, usually by asking it questions called queries; it is written $\mathcal{A}$, and a second adversary built from it in a reduction is written $\mathcal{B}$. The number of queries Q and a bound ν on an advantage get letters of their own. Cryptography texts often write these q and ε, but in this book q is a sampling rate and ε a privacy parameter. The modulus in learning with errors is p.

A **distinguisher** receives input from one of two distributions, its two "worlds", and outputs a bit. Its **advantage** is the absolute difference between how often it outputs 1 in the two worlds. A procedure is **efficient** if its running time grows at most polynomially in λ, and a quantity is **negligible** if it shrinks faster than one over any polynomial in λ.

I.1. The GGM tree is a pseudorandom function

I.1.1. What the chapter uses

A pseudorandom generator stretches a short random seed into a longer string that efficient algorithms cannot tell from random. Here the generator doubles the length: $G\colon \{0,1\}^{\lambda} \to \{0,1\}^{2\lambda}$. Write its output as a left half $G_0(s)$ followed by a right half $G_1(s)$, each as long as the seed, so that $G(s) = (G_0(s), G_1(s))$. A PRG distinguisher $\mathcal{B}$ receives one 2λ-bit string and outputs a bit, and its advantage is

$$\mathrm{Adv}_{\mathrm{PRG}}(\mathcal{B}) = \big|\Pr[\mathcal{B}(G(U_\lambda)) = 1] - \Pr[\mathcal{B}(U_{2\lambda}) = 1]\big|. \tag{I.1}$$

The GGM tree turns G into a keyed function on n-bit inputs. Picture a binary tree of depth n in which every node carries a λ-bit **label**. The root's label is the key k. A node's left child gets the left half G_0 of G applied to the node's label, and its right child gets the right half G_1. An input $x = x_1 x_2 \cdots x_n$ is then read as directions from the root to a leaf. At level i, the bit x_i says go left if it is 0 and right if it is 1, and the output is the label of the leaf you reach,

$$F_k(x) = G_{x_n}\big(\cdots G_{x_2}(G_{x_1}(k))\cdots\big). \tag{I.2}$$

A node is named by the bits that lead to it, so node 01 is the right child of the left child of the root, and its **depth** is the length of its name.

In the PRF game, a fair coin decides what sits inside a box. It is either F_k with a uniform key, or a truly random function f from n-bit inputs to λ-bit outputs, which gives each input an independent uniform output. An adversary $\mathcal{A}$ sends up to Q queries, each chosen after seeing the answers to the earlier ones, and then outputs a bit. The box that answers the queries is called an oracle, and $\mathcal{A}^{O}$ means $\mathcal{A}$ run with oracle O. The adversary's advantage is

$$\mathrm{Adv}_{\mathrm{PRF}}(\mathcal{A}) = \big|\Pr[\mathcal{A}^{F_k} = 1] - \Pr[\mathcal{A}^{f} = 1]\big|, \tag{I.3}$$

where the probabilities are also over the adversary's own random choices.

The result says that any such adversary can be turned into a PRG distinguisher whose advantage is smaller by exactly the factor nQ, and which is about as fast. Precisely, take any adversary $\mathcal{A}$ that makes at most Q queries. Then there is a PRG distinguisher $\mathcal{B}$ that runs $\mathcal{A}$ once and, apart from that, evaluates G fewer than nQ times, such that

$$\mathrm{Adv}_{\mathrm{PRF}}(\mathcal{A}) = nQ \cdot \mathrm{Adv}_{\mathrm{PRG}}(\mathcal{B}). \tag{I.4}$$

The running time matters because PRG security only limits fast distinguishers. So if no distinguisher with $\mathcal{B}$'s running time has PRG advantage above some ν, then no Q-query adversary has PRF advantage above $nQ\,\nu$, which is the chapter's $\mathrm{Adv}_{\mathrm{PRF}} \le nQ \cdot \mathrm{Adv}_{\mathrm{PRG}}$. The chapter gives a proof sketch and cites Goldreich, *Foundations of Cryptography*, Vol. 1, §3.6, for the full proof.

I.1.2. The idea

The proof walks from the real function to a random one in n steps, one level of the tree at a time. Each intermediate world is called a **hybrid**, because it is part real and part random. The j-th hybrid, H_j, gives every node at depth j a fresh uniform label and computes everything below it with G as usual. The first hybrid, H_0, is the real F_k, because the only node at depth 0 is the root and its uniform label is the key. The last, H_n, is a random function, because every leaf gets its own uniform label. Going from H_{j-1} to H_j changes a single thing. In H_{j-1}, the two children of a node at depth $j-1$ carry the two halves of G applied to a uniform label, while in H_j they carry two uniform labels. Telling these apart is the PRG's game of output against uniform string, played once for every node at depth $j-1$ that the adversary's queries pass through. Figure I.1 shows the four hybrids for $n = 3$ and three queries.

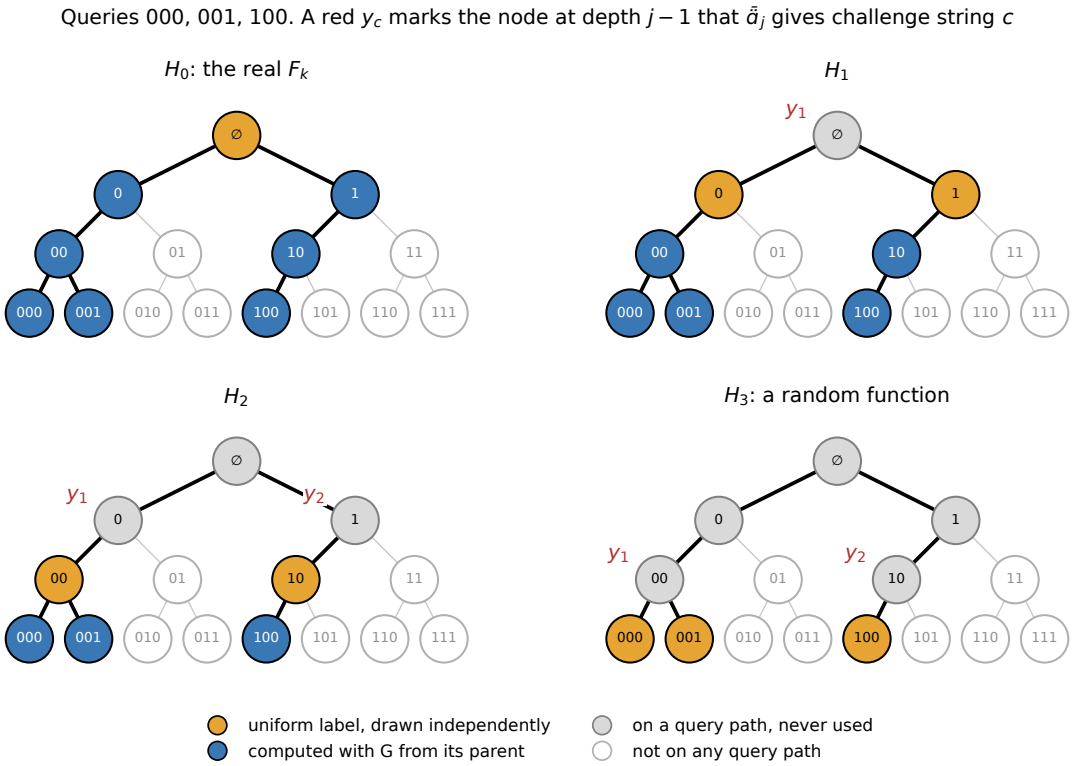

Figure I.1.: The GGM tree of depth 3 in the hybrids H_0 to H_3, for the queries 000, 001 and 100. Orange nodes get independent uniform labels, blue nodes are computed with G from their parent, and grey nodes lie on a query path but are never used. A red y_c marks the node at depth $j-1$ to which the reduction $\mathcal{B}_j$ assigns its c-th challenge string.

The subtle part is that the adversary chooses its queries as it goes. A reduction $\mathcal{B}_j$ that wants to use the adversary to break the PRG receives Q challenge strings, which are either all outputs of G on independent uniform seeds or all uniform. But it cannot know in advance which nodes at depth $j-1$ the queries will pass through. So it hands out its challenge strings like cloakroom tickets. The first time a query passes through a new node at depth $j-1$, that node gets the next unused string and keeps it for the rest of the game. Table I.2 follows $\mathcal{B}_2$ through the three queries of Figure I.1.

Table I.2.: How $\mathcal{B}_2$ assigns its challenge strings y_1, y_2, y_3 to the nodes at depth 1 as the queries arrive. The third string is never needed.

Query	Node at depth 1	First visit?	String used	Node at depth 2	Its label
000	0	yes	y_1	00	left half of y_1
001	0	no	y_1	00	left half of y_1
100	1	yes	y_2	10	left half of y_2

If each y_c is G applied to its own uniform seed, then the labels at depth 2 are halves of G applied to independent uniform labels at depth 1, which is H_1. If each y_c is uniform, the labels at depth 2 are uniform, which is H_2. The one thing left to check is that handing out values on first use gives the adversary the same distribution of answers as drawing them all in advance. It does, because a value nobody has looked at yet is still a fresh draw, and step 4 below proves this carefully.

I.1.3. Derivation

The proof has four parts. Steps 1 to 3 set up the hybrids and show that two neighbouring hybrids differ only in the distribution of one table. Steps 4 and 5 build the reduction $\mathcal{B}_j$, which judges Q strings at once, and show that it recreates either neighbour exactly. Steps 6 and 7 turn it into a distinguisher that judges a single string, and add up the levels. Step 8 restates the result for efficient adversaries.

1. **Define the hybrids.** For $j = 0, 1, \ldots, n$, hybrid H_j gives every node at depth j an independent uniform λ-bit label $L(x_1 \cdots x_j)$, all drawn before the game starts. It answers the query x by walking down from the depth-j node on its path:

$$H_j(x) = G_{x_n}(\cdots G_{x_{j+1}}(L(x_1 \cdots x_j)) \cdots). \tag{I.5}$$

   With $j = 0$ the only label is the root's, which is a uniform key, so H_0 is F_k. With $j = n$ the answer is the leaf's own label, independent and uniform for each input, so H_n is a random function. The table of 2^j labels can be huge, but that does not matter. The hybrids are thought experiments, and only the reduction has to be efficient.

2. **Split the advantage into levels.** Write $h_j = \Pr[\mathcal{A}^{H_j} = 1]$ for how often the adversary says 1 in hybrid H_j. In the sum $\sum_{j=1}^{n}(h_{j-1} - h_j)$, each intermediate h_j appears once with a plus sign and once with a minus sign, so the sum telescopes:

$$h_0 - h_n = \sum_{j=1}^{n}(h_{j-1} - h_j). \tag{I.6}$$

   The chapter calls this telescoping Fact 3, where it is used with absolute values. The left side is $\Pr[\mathcal{A}^{F_k} = 1] - \Pr[\mathcal{A}^{f} = 1]$, whose absolute value is $\mathrm{Adv}_{\mathrm{PRF}}(\mathcal{A})$.

3. **Write two neighbouring hybrids as one table.** Fix $j \geq 1$ and look at a node w at depth $j - 1$. In H_{j-1}, its two children $w0$ and $w1$ get the two halves of $G(L(w))$, so together they carry the string $G(L(w))$. Different nodes w have independent uniform labels, so these strings are independent, each distributed as $G(U_\lambda)$. In H_j, the children carry

two independent uniform labels, so together they carry a string distributed as $U_{2\lambda}$, again independently for each w. Below depth j both hybrids compute with G in the same way. So the two hybrids are one and the same world, except for the distribution P that the children's strings come from. In that world, a table T gives each node w at depth $j-1$ its own independent draw $T(w)$ from P. The query x is answered by taking the half of $T(x_1 \cdots x_{j-1})$ that bit x_j selects and walking down with G:

$$W_j^P(x) = G_{x_n}(\cdots G_{x_{j+1}}(\text{half } x_j \text{ of } T(x_1 \cdots x_{j-1}))\cdots). \tag{I.7}$$

With $P = G(U_\lambda)$ this world is H_{j-1}, and with $P = U_{2\lambda}$ it is H_j. For $j = 1$ the only node at depth 0 is the root, so the table has a single entry.

4. **Lazy sampling gives the same view.** There are two ways to fill the table T. In the *advance* version, every entry is drawn before the game starts. In the *lazy* version, each entry is drawn from P the first time a query needs it, and reused afterwards. The adversary's **view** is everything it sees: its own random choices (its coins) and all the answers it receives. The claim is that the view has the same distribution in both versions. Think of dice rolled earlier and hidden under cups: lifting a cup now shows a number that is exactly as random as rolling the die now, provided nobody peeked.

   The proof goes one query at a time. Call the **history** after i queries the adversary's coins together with the table entries used so far. Every answer, and therefore every next query, is a function of the history. If the next query needs an entry that was already used, both versions answer with that same entry, which is part of the history. If it needs a new entry, then in the advance version that entry was drawn independently of the other entries and of the adversary's coins, so given the history it is still distributed as P. In the lazy version it is a fresh draw from P, so the same holds. So in both versions, the history after $i+1$ queries is the history after i queries plus one entry with the same conditional distribution. The probability of a whole history is the product of these conditional probabilities, one per query (the chain rule), so the histories have the same distribution after every query. The same then holds for anything computed from them, including the adversary's output.

5. **Build $\mathcal{B}_j$, which judges Q strings at once.** The reduction $\mathcal{B}_j$ receives Q strings $y_1, \ldots, y_Q$ of 2λ bits each. They are drawn independently from one distribution P, which is either $G(U_\lambda)$ or $U_{2\lambda}$. It runs $\mathcal{A}$ and keeps a ticket table, which starts empty. When a query x arrives, $\mathcal{B}_j$ looks at the node $w = x_1 \cdots x_{j-1}$ at depth $j-1$ on its path, and if w has no ticket yet, gives it the next unused index c. It then answers with the half of y_c that x_j selects, walked down with G exactly as in step 3. At the end, $\mathcal{B}_j$ outputs whatever $\mathcal{A}$ outputs. Each query passes through one node at depth $j-1$, so at most Q nodes ever need a ticket and the strings never run out.

   Now compare this with step 4. The string y_c is first read when the c-th new node appears. Until then, everything $\mathcal{B}_j$ has done depends only on $y_1, \ldots, y_{c-1}$ and on $\mathcal{A}$'s coins, and y_c is independent of all of them. So $\mathcal{B}_j$ fills the table of step 3 lazily, in the sense of step 4, and $\mathcal{A}$'s view inside $\mathcal{B}_j$ is exactly its view in W_j^P. With step 3, this gives

$$\Pr\left[\mathcal{B}_j(G(U_\lambda)^Q) = 1\right] = h_{j-1}, \qquad \Pr\left[\mathcal{B}_j(U_{2\lambda}^Q) = 1\right] = h_j, \tag{I.8}$$

   where $G(U_\lambda)^Q$ means Q independent outputs of G on uniform seeds, and $U_{2\lambda}^Q$ means Q independent uniform strings.

6. **Go from Q strings to one.** The chapter's hybrid lemma for many samples does this, and here is its argument for this case. Write g_i for the probability that $\mathcal{B}_j$ outputs 1 on a list of Q independent strings whose first i are uniform and whose other $Q-i$ are outputs of G. The two ends are the cases of step 5: $g_0 = h_{j-1}$ (all from G) and $g_Q = h_j$ (all uniform). The mixed lists in between match no hybrid, and they do not need to. The one-string distinguisher $\mathcal{B}'_j$ takes a challenge string z and picks a position i uniformly from 1 to Q. It puts uniform strings before position i, puts z at position i, and after it puts outputs of G on seeds it draws itself, which is possible because G is public. Then it outputs $\mathcal{B}_j$'s answer on the whole list. If z comes from G, the list starts with $i-1$ uniform strings, so $\mathcal{B}'_j$ says 1 with probability g_{i-1}; if z is uniform, the probability is g_i. Averaging over i gives $\frac{1}{Q}\sum_{i=1}^{Q}(g_{i-1} - g_i)$, which telescopes as in step 2 to $\frac{1}{Q}(g_0 - g_Q)$:

$$\Pr[\mathcal{B}'_j(G(U_\lambda)) = 1] - \Pr[\mathcal{B}'_j(U_{2\lambda}) = 1] = \frac{1}{Q}\,(h_{j-1} - h_j). \tag{I.9}$$

7. **Pick the level at random and add up.** The final distinguisher $\mathcal{B}$ picks j uniformly from $\{1, \ldots, n\}$ and runs $\mathcal{B}'_j$. Averaging step 6 over j and using Equation I.6,

$$\Pr[\mathcal{B}(G(U_\lambda)) = 1] - \Pr[\mathcal{B}(U_{2\lambda}) = 1] = \frac{1}{n}\sum_{j=1}^{n}\frac{1}{Q}\,(h_{j-1} - h_j) = \frac{h_0 - h_n}{nQ}. \tag{I.10}$$

   Taking absolute values gives Equation I.4. As for the cost, $\mathcal{B}$ runs $\mathcal{A}$ once. It computes at most $Q-1$ outputs of G for the list, and at most $n-1$ evaluations of G per query to walk down the tree. That is at most $(Q-1) + Q(n-1) = nQ - 1$ evaluations, fewer than nQ.

8. **Conclude for efficient adversaries.** Suppose n and Q grow at most polynomially in λ. Then an efficient $\mathcal{A}$ gives an efficient $\mathcal{B}$. If $\mathcal{A}$'s advantage were not negligible, it would be at least λ^{-c} for some exponent c and infinitely many λ. Dividing by the polynomial nQ keeps it above one over a polynomial, so $\mathcal{B}$'s advantage $\mathrm{Adv}_{\mathrm{PRF}}(\mathcal{A})/(nQ)$ would not be negligible either, and G would not be a PRG. So if G is a PRG, the GGM tree is a PRF.

Adaptivity matters only in step 5. A reduction that fixed in advance which nodes get challenge strings would have to cover all 2^{j-1} nodes at depth $j-1$. That can be exponentially many strings, and the loss factor would grow with it, from Q to 2^{j-1}. The ticket rule lets the adversary's own queries decide where the Q strings go, and step 4 is why that changes nothing in what the adversary sees.

I.1.4. Checking it

The script runs the whole reduction on a toy with $\lambda = 8$, $n = 3$ and $Q = 3$. Its PRG is broken on purpose, so that every advantage is large enough to measure: $G(s) = (s, f(s))$ for a fixed random permutation f of the 8-bit strings. So the left half is the seed itself, and the right half is a public function of it. In the real F_k, every left step keeps the label and every right step applies f. So $F_k(000) = k$, $F_k(001) = f(k)$ and $F_k(100) = f(k)$, while $F_k(110) = f(f(k))$ because it takes two right steps.

The adversary uses these relations, and it chooses its third query adaptively so that the check also covers the subtle part of step 5. It asks 000 and then 001, and for its third query it asks 100 if the first answer starts with a 0 bit, and 110 otherwise. Check 1 asks whether the second

answer is f of the first. Check 2 asks whether the third answer is f of the first, after 100, or f applied twice to the first, after 110. The adversary flips a coin to choose one check, and outputs 1, meaning "random function", if that check fails. A uniform label passes a fixed equality only with probability 2^{-8}, so a check on labels that are independent fails with probability $1 - 2^{-8}$. Both checks pass in H_0, so $h_0 = 0$. In H_1 and H_2, the first two leaves still hang below one node and are computed from it with G, so check 1 passes. But check 2 compares labels from different branches of the tree, which are independent, so it fails with probability $1 - 2^{-8}$. That gives $h_1 = h_2 = \frac{1}{2}(1 - 2^{-8}) = 0.4980$. In H_3 both checks fail, so $h_3 = 1 - 2^{-8} = 0.9961$. Table I.3 compares these with simulation.

Table I.3.: How often the adversary says "random" in each hybrid, and in each reduction $\mathcal{B}_j$ fed outputs of the toy G or uniform strings (seed 0, 200,000 runs per entry).

j	Exact h_j	Simulated h_j	$\mathcal{B}_j$ on 3 outputs of G (should be h_{j-1})	$\mathcal{B}_j$ on 3 uniform strings (should be h_j)
0	0.0000	0.0000		
1	0.4980	0.4994	0.0000	0.5005
2	0.4980	0.4985	0.4979	0.4993
3	0.9961	0.9962	0.4983	0.9964

Each $\mathcal{B}_j$ lands on the hybrid that step 5 predicts, to within simulation noise of about 0.001, even though the adversary's third query depends on what it has seen. Figure I.2 draws the same comparison. The single-sample distinguisher $\mathcal{B}$ of step 7 says 1 with probability 0.5535 on outputs of G and 0.6641 on uniform strings. Its advantage is therefore 0.1105, against the predicted $0.9961/9 = 0.1107$. Multiplying back by $nQ = 9$ gives 0.995, which matches the adversary's PRF advantage $h_3 - h_0 = 0.9961$ as Equation I.4 says it should.

Since Equation I.4 is an equality, the factor nQ between the two advantages is lost inside $\mathcal{B}$ itself, in the averaging over levels and positions. The toy shows why. The adversary's rate jumps by 0.498 at levels 1 and 3 and does not move at level 2, but $\mathcal{B}$ spreads its effort evenly over all levels and all Q positions, most of which carry no signal. So the factor nQ comes from how the proof is organized, just like the factor for m samples in the chapter's hybrid lemma.

I.1.5. What it does not cover

The proof needs every input to have the same length n. With inputs of different lengths the GGM tree is not a PRF, because $F_k(0)$ is the label of the node that $F_k(00)$ hangs from. An adversary then checks whether $F_k(00) = G_0(F_k(0))$, which always holds for the real function and almost never for a random one. The proof also assumes that G is deterministic, because a node's label must give the same children every time a query passes through it. It assumes as well that G doubles its input exactly; a generator that stretches by only one bit can be applied repeatedly to its own output to reach double length. Finally, Equation I.4 compares advantages. To turn it into a concrete guarantee, such as "no attacker running for 2^{128} steps succeeds", you need a concrete bound on the advantage of PRG distinguishers with $\mathcal{B}$'s running time.

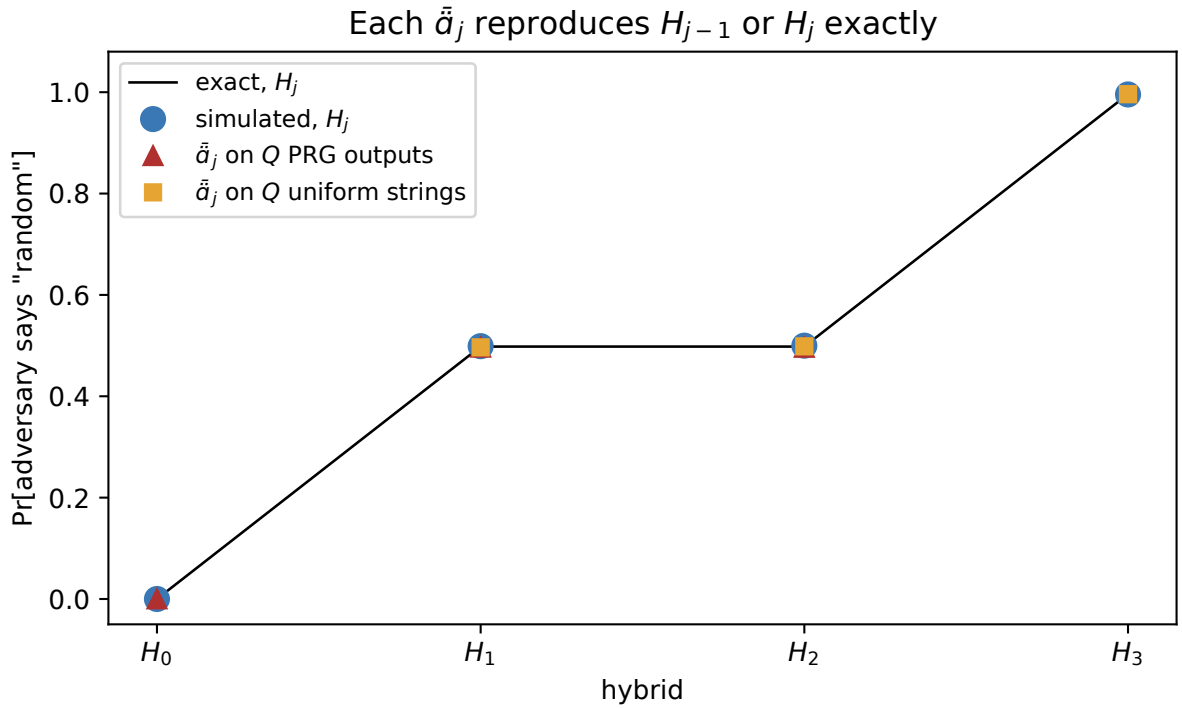

Figure I.2.: How often the toy adversary says "random" in the hybrids H_0 to H_3, exactly and by simulation, and in each reduction $\mathcal{B}_j$. Red triangles are $\mathcal{B}_j$ fed outputs of G, placed at H_{j-1}; orange squares are $\mathcal{B}_j$ fed uniform strings, placed at H_j. Every marker sits on the curve.

I.2. Search LWE reduces to decision LWE

I.2.1. What the chapter uses

Learning with errors hides a secret vector behind linear equations with small errors. Fix a dimension d, a modulus p and an error distribution χ on integers that are small compared with p. Write $\mathbb{Z}_p$ for the integers $0, \dots, p-1$ with arithmetic mod p, and $\mathbb{Z}_p^d$ for vectors of d such numbers. The secret s is a vector in $\mathbb{Z}_p^d$. An **LWE sample** is a pair made of a uniform random vector a in $\mathbb{Z}_p^d$ and a number b. To make b, draw an error e from χ and set

$$b = \langle a, s \rangle + e \bmod p, \qquad \langle a, s \rangle = \sum_{j=1}^{d} a_j s_j. \tag{I.11}$$

Every sample has its own fresh a and e, independent of the other samples, and the secret is the same in all of them.

Search LWE asks for s, given as many samples as the algorithm needs. **Decision LWE** asks whether m given pairs are LWE samples or uniform pairs in $\mathbb{Z}_p^d \times \mathbb{Z}_p$. The chapter shows that search is at least as hard as decision. For the converse it says only this: Regev, who introduced LWE, proves it for a prime p that is at most polynomial in d, by guessing the coordinates of s one at a time and testing each guess with the decision algorithm.

Here is that converse in a form this appendix proves. Assume that p is prime. Assume also that a decision algorithm $\mathcal{A}$, given m pairs, has advantage at least ν for every secret, where the probabilities are over the pairs and over $\mathcal{A}$'s own random choices:

$$\big|\Pr[\mathcal{A}(m \text{ LWE samples with secret } s) = 1] - \Pr[\mathcal{A}(m \text{ uniform pairs}) = 1]\big| \geq \nu \quad \text{for every } s \in \mathbb{Z}_p^d. \tag{I.12}$$

Then, for any failure probability β, there is a search algorithm that finds all of s with probability at least $1 - \beta$. It calls $\mathcal{A}$ at most $(dp+1)N$ times and uses $dpNm$ LWE samples, where the number of repetitions per test is

$$N = \left\lceil \frac{8}{\nu^2} \ln \frac{2(dp+1)}{\beta} \right\rceil. \tag{I.13}$$

The advantage ν is **noticeable** if it is at least one over some polynomial in d. In that case, and when p, m and $\mathcal{A}$'s running time are also polynomial in d, the search runs in polynomial time. The value of N comes from step 6 of the derivation.

I.2.2. The idea

The test for one guess works like this. Take an LWE sample and a guess g for the first coordinate s_1. Pick a random number r, add it to the first coordinate of a, and add rg to b. If the guess is right, the change to b is exactly the change to $\langle a, s \rangle$. So the new pair is again an LWE sample with the same secret and the same small error. If the guess is wrong, the error picks up the extra term $r(g - s_1)$. When p is prime, that term is a random multiple of a nonzero number, so it is uniform. It drowns the error, and together with the shifted first coordinate it makes the whole pair uniform. Feeding the new pairs to $\mathcal{A}$ therefore asks $\mathcal{A}$ "LWE or uniform?", and the true answer is "LWE" exactly when the guess is right. Repeating the test many times measures how

often $\mathcal{A}$ says 1, and comparing that rate with $\mathcal{A}$'s rate on uniform pairs, which the search draws itself, tells the right guess from the wrong ones. Trying all p guesses for each of the d coordinates recovers s.

Table I.4 makes the wrong-guess case concrete with $p = 5$, $s_1 = 3$ and error $e = 1$. After the change, the new b minus the inner product of the new a with s is $e + r(g - s_1) \bmod 5$. With the right guess $g = 3$ it stays at $e = 1$ for every r. With the wrong guess $g = 1$ it becomes $1 - 2r \bmod 5$, which takes each of the five values exactly once as r runs through $0, \ldots, 4$. Since r is uniform, the result is uniform.

Table I.4.: The value $b - \langle a, s \rangle$ after re-randomizing with guess g, for $p = 5$, $s_1 = 3$, $e = 1$ and each value of r. The wrong guess hits every element of $\mathbb{Z}_5$ once.

r	0	1	2	3	4
Right guess $g = 3$: $1 + 0 \cdot r$	1	1	1	1	1
Wrong guess $g = 1$: $1 - 2r \bmod 5$	1	4	2	0	3

I.2.3. Derivation

Fix a coordinate ℓ and a guess $g \in \mathbb{Z}_p$. Steps 1 to 4 show what one re-randomized sample looks like, and steps 5 to 8 turn this into a search with a failure probability you choose.

1. **Re-randomize.** Take an LWE sample (a, b) with $b = \langle a, s \rangle + e$. Draw a fresh r uniform in $\mathbb{Z}_p$, independent of everything else. Let a' be a with r added to its ℓ-th coordinate, and let $b' = b + rg \bmod p$. Adding r to a_ℓ adds rs_ℓ to the inner product, so $\langle a', s \rangle = \langle a, s \rangle + rs_\ell$. Subtracting this from b' leaves the **residual**

$$b' - \langle a', s \rangle = e + r(g - s_\ell) \bmod p. \tag{I.14}$$

2. **The new vector is still uniform.** For each fixed r, adding r to one coordinate is a bijection of $\mathbb{Z}_p^d$. By the chapter's Fact 4, a bijection maps the uniform distribution to itself. Since a is uniform and independent of r and e, the vector a' is uniform and independent of e.

3. **A right guess gives an LWE sample.** If $g = s_\ell$, the residual Equation I.14 is just e, so $b' = \langle a', s \rangle + e$. With step 2, a' is uniform and e is an independent draw from χ, so (a', b') is an LWE sample with the same secret s.

4. **A wrong guess gives a uniform pair.** Now let $c = g - s_\ell \neq 0$. This is where p must be prime. Every nonzero number mod a prime has an inverse; for example, $2 \cdot 3 = 6 \equiv 1 \pmod 5$. Fix the error e and write $v = e + rc$ for the residual. The map that sends (a, r) to (a', v) can be undone. From the residual you recover $r = (v - e)c^{-1}$, and then you recover a by subtracting r from coordinate ℓ of a'. So this map is a bijection of $\mathbb{Z}_p^d \times \mathbb{Z}_p$. The pair (a, r) is uniform there and independent of e, so by Fact 4 the pair (a', v) is uniform, whatever e is. Finally, $b' = \langle a', s \rangle + v$. The map from (a', v) to (a', b') is another bijection, undone by subtracting $\langle a', s \rangle$ from b'. So by Fact 4 once more, (a', b') is uniform on $\mathbb{Z}_p^d \times \mathbb{Z}_p$.

5. **The test feeds $\mathcal{A}$ exactly one of its two worlds.** Each re-randomized pair uses its own fresh sample and its own r, so m of them are independent. By steps 3 and 4, they are m LWE samples with secret s when the guess is right, and m uniform pairs when it is wrong. Write α_{LWE} and α_{U} for the probabilities that $\mathcal{A}$ outputs 1 in these two cases. Then a run of the test outputs 1 with probability α_{LWE} for the right guess and α_{U} for every wrong one, and $|\alpha_{\mathrm{LWE}} - \alpha_{\mathrm{U}}| \geq \nu$ by assumption.

6. **Estimate the rates.** The search does not know α_{LWE} or α_{U}, so it estimates them by repetition. For the baseline, it draws m uniform pairs itself, runs $\mathcal{A}$ on them, and repeats N times. The fraction of 1s is its estimate $\hat{\alpha}_{\mathrm{U}}$. For each coordinate ℓ and guess g, it repeats the test N times with fresh samples and fresh r, and the fraction of 1s is $\hat{\alpha}_{\ell,g}$. Each estimate is an average of N independent 0/1 values, so it concentrates around its mean. Hoeffding's inequality, from Concentration inequalities, says that such an average lands at least t away from its mean with probability at most $2e^{-2Nt^2}$. Step 7 needs every estimate within $\nu/4$, so take $t = \nu/4$, which gives $2e^{-N\nu^2/8}$. There are $dp + 1$ estimates in all. The union bound says that the chance that at least one of several events happens is at most the sum of their chances. So some estimate is off by $\nu/4$ or more with probability at most

$$2(dp + 1)\, e^{-N\nu^2/8} \leq \beta, \tag{I.15}$$

   Taking logarithms, this holds when $N\nu^2/8 \geq \ln(2(dp + 1)/\beta)$, which is Equation I.13.

7. **Decide each guess.** The search keeps the guess g for coordinate ℓ when $|\hat{\alpha}_{\ell,g} - \hat{\alpha}_{\mathrm{U}}| > \nu/2$. Suppose every estimate is within $\nu/4$ of its mean, which happens with probability at least $1 - \beta$. For the right guess, the true gap is at least ν and the two estimation errors together are less than $\nu/2$, so the measured gap is more than $\nu/2$ and the guess is kept. For a wrong guess the true gap is 0, so the measured gap is less than $\nu/2$ and the guess is dropped. So exactly one guess survives for each coordinate, and it is s_ℓ.

8. **Count the cost.** The search calls $\mathcal{A}$ N times for the baseline and N times for each of the dp pairs of coordinate and guess, which is $(dp + 1)N$ calls. Each test call uses m fresh LWE samples, so the search uses $dpNm$ samples. By Equation I.13, N grows like $1/\nu^2$ and only like the logarithm of dp/β. So the cost is polynomial in d when p, m and $1/\nu$ are. Even a failure probability as small as $\beta = 2^{-d}$ is affordable, because then $\ln(1/\beta) = d \ln 2$ is only linear in d.

Each assumption has its place. Primality is used in step 4, a polynomial p in step 8 (the search tries every element of $\mathbb{Z}_p$), a noticeable ν in step 8 as well, and "for every secret" in step 5. The coordinates are tested independently of one another, which is the "one at a time" of the chapter.

I.2.4. Checking it

The script first checks steps 3 and 4 directly, with $d = 4$, $p = 97$ and errors drawn from a normal distribution with standard deviation 3, rounded to the nearest integer. It re-randomizes 20,000 samples with the right guess for s_1 and with a guess that is off by 1. Figure I.3 shows the residuals. With the right guess they form the narrow bump of the error, and 0.760 of them lie within 3 of zero, against the exact 0.757 for the rounded normal. With the wrong guess they are flat, and 0.071 of them lie within 3 of zero. A uniform residual lands on each of the 7 values from -3 to 3 with probability $1/97$, so the exact share is $7/97 = 0.072$.

The third panel shows why the modulus must be prime. With $p = 96$ and a guess off by 48, the term $48r \bmod 96$ is only ever 0 or 48, because $48r$ is a multiple of 96 when r is even. So the residual is the error, or the error shifted by half the modulus, and it forms two bumps instead of a flat line. A decision algorithm that looks for small residuals would accept this wrong guess about half as often as the right one, and the test of step 7 could keep it.

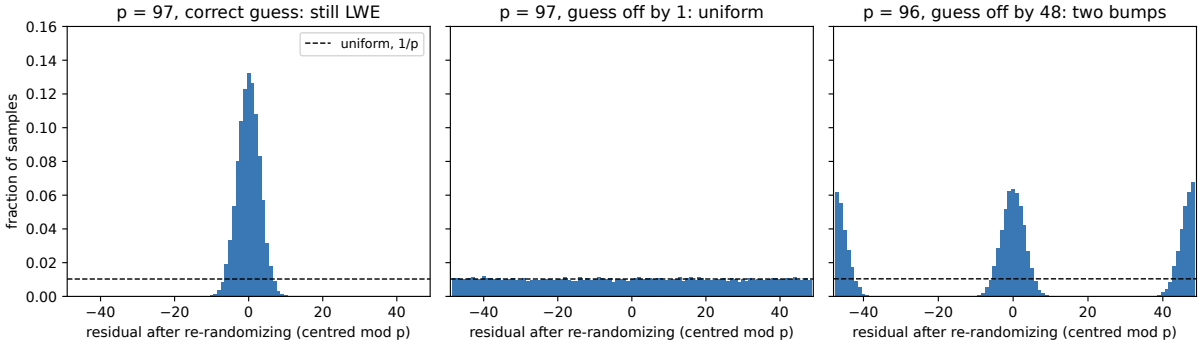

Figure I.3.: Histograms of the residual $b' - \langle a', s \rangle$ after re-randomizing 20,000 LWE samples ($d = 4$, rounded normal errors with standard deviation 3). Left: prime $p = 97$ and the right guess, which keeps the error's bump. Middle: $p = 97$ and a guess off by 1, which is uniform. Right: composite $p = 96$ and a guess off by 48, which leaves two bumps.

It then runs the whole search. A real decision algorithm for these parameters would be hard to write, so the script uses a stand-in. The stand-in sees one pair per call ($m = 1$) and is built with the secret, but the search treats it as a black box and never reads s. On 90% of calls it ignores its input and answers with a fair coin flip. On the other 10% it says 1 when the residual is within 3 of zero, which happens with probability 0.7567 for an LWE sample and 7/97 for a uniform pair. Its advantage is therefore $\nu = 0.1 \times (0.7567 - 7/97) = 0.0684$. With $\beta = 0.01$, Equation I.13 asks for $N = 19{,}230$ repetitions per test, which makes 7,480,470 calls to the stand-in in total.

The search recovers the secret $(6, 27, 27, 28)$ exactly. The smallest gap for a right guess is 0.0708, and the largest gap for a wrong one is 0.0166, both measured against the threshold $\nu/2 = 0.0342$. Figure I.4 shows a second run with another secret. Run on ten more random secrets, the search recovers every one of them.

The bound behind Equation I.13 is conservative. It asks every estimate to be within $\nu/4$ with probability $1 - \beta$ at once, but in practice the largest gap for a wrong guess, 0.0166, is only about half the threshold. The right guess clears the threshold with room to spare too. A search that stops testing once a guess is found, or that adds repetitions only for guesses near the threshold, would need fewer calls.

I.2.5. What it does not cover

The proof assumes that $\mathcal{A}$ works for every secret. Some decision algorithms work only on average over a random secret. The first step in handling them is to make the secret random: pick a uniform vector u and replace each b by $b + \langle a, u \rangle$, which gives samples with the random secret $s + u$. But for a given u the algorithm may still fail, so the search must try several u and check which ones work. Regev (2009) carries this out, and those details stay cited. The proof also

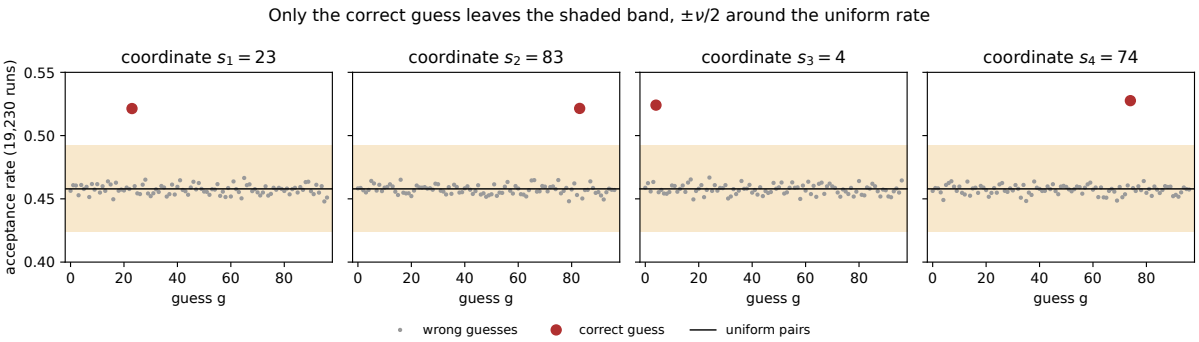

Figure I.4.: Acceptance rate of the stand-in decision algorithm on re-randomized samples, for every guess g of each of the four coordinates of a secret in $\mathbb{Z}_{97}^4$. Grey dots are wrong guesses, the red dot is the right one, the black line is the rate on uniform pairs and the shaded band is $\pm\nu/2$ around it.

assumes that a lower bound ν on $\mathcal{A}$'s advantage is known. Without one, the search can try $\nu = 1/2, 1/4, 1/8, \ldots$ in turn, which multiplies the cost by a logarithmic factor.

For moduli that are not prime, or are too large to try every guess, other reductions exist. Peikert (2009) handles moduli that are products of distinct small primes, and Micciancio & Mol (2011) give reductions that use no more samples than the decision algorithm, for a wide class of moduli. Brakerski, Langlois, Peikert, Regev & Stehlé (2013) show that decision LWE is hard for any modulus by relating moduli to one another rather than by guessing. These stay cited, because each needs lattice and number theory well beyond this appendix.

I.3. Code

The script apx_cryptography.py computes every number on this page and draws its figures. For the GGM tree it builds the toy PRG, runs the adaptive adversary in each hybrid, runs each reduction $\mathcal{B}_j$ on outputs of G and on uniform strings, and measures the single-sample distinguisher of step 7. For LWE it prints Table I.4, re-randomizes samples with right and wrong guesses, and runs the full search with the stand-in decision algorithm. From the repository root:

```
uv run python code/appendix-derivations/apx_cryptography.py
```

Table I.5.: The numbers the script prints (seed 0; 200,000 runs per GGM entry, 20,000 samples for the residuals).

Quantity	Value
GGM: exact h_0, h_1, h_2, h_3	0.0000, 0.4980, 0.4980, 0.9961
GGM: single-sample $\mathcal{B}$, rate on $G(U_\lambda)$ and on $U_{2\lambda}$	0.5535, 0.6641
GGM: advantage of $\mathcal{B}$, measured and predicted $\mathrm{Adv}_{\mathrm{PRF}}(\mathcal{A})/(nQ)$	0.1105, 0.1107

Quantity	Value
LWE: residual within 3 of zero, right guess (exact)	0.760 (0.757)
LWE: residual within 3 of zero, wrong guess (exact)	0.071 (0.072)
LWE search: ν, repetitions N, calls to the stand-in	0.0684, 19,230, 7,480,470
LWE search: smallest right gap, largest wrong gap, threshold $\nu/2$	0.0708, 0.0166, 0.0342
LWE search: random secrets recovered exactly	10 of 10

Two things are worth taking from these numbers. In the GGM check, the reductions recreate the hybrids exactly even against an adaptive adversary, so the factor nQ is lost only in the averaging of steps 6 and 7. In the LWE check, re-randomizing turns a right guess into LWE samples and a wrong one into exactly uniform pairs, and the only real cost is the number of repetitions needed to see a weak decision algorithm's small advantage.

J. Mechanisms and their limits

This appendix proves seven results that the chapters on differential privacy (DP) state about specific mechanisms but do not derive in full. Three of them are about what the slack δ of approximate DP means. The first shows that every (ε, δ)-DP pair of output distributions splits into an ε-DP pair and a leftover of mass δ, and so is a post-processing of the worst (ε, δ)-DP pair, called four-point randomized response. The second uses the same split to show that (ε, δ)-DP implies an approximate form of zero-concentrated differential privacy (zCDP). The third, the stability-based histogram, shows what the slack buys: an error that does not grow with the number of bins. The other four results pin down single mechanisms. One is a lower bound for estimating means of heavy-tailed data. Two are privacy proofs for selection: the sparse vector technique with several answers above the threshold, and Gumbel top-c selection. The last is a check that the "alarm" mechanism, which the group-privacy chapter uses to show its bound is tight, really is (ε, δ)-DP.

The derivations share one habit. Each proof fixes a neighbouring pair, writes down the two output distributions, and then compares them directly: it splits them into parts, changes variables in the noise, or bounds them one outcome at a time. Table J.1 maps each derivation to the chapter section that states or uses it.

Table J.1.: The derivations of this appendix and the chapter sections that rely on them.

Derivation	Where the chapter states or uses it
Every (ε, δ) pair is post-processed four-point randomized response	Section 21.4 (Table 21.3, Equation 21.15), Section 21.5
(ε, δ)-DP implies δ-approximate $(\varepsilon^2/2)$-zCDP	Section 31.7
The stability-based histogram	Section 27.1, Section 28.3
A lower bound for heavy-tailed means	Section 28.5
Sparse vector with c answers above	Section 22.6
Gumbel top-c is the exponential mechanism without replacement	Section 22.5
The alarm mechanism is (ε, δ)-DP	Section 19.2

J.1. Every approximate-DP pair is post-processed four-point randomized response

J.1.1. What the chapter uses

Take a mechanism that is (ε, δ)-DP, fix two neighbouring datasets D and D', and write P and Q for the distributions of its output on them. For now the outputs are discrete, with probabilities $p(y)$ and $q(y)$ at an output y; the last part of this section extends the argument to densities. Approximate DP says that the hockey-stick divergence is at most δ in both directions. That divergence is the mass of one distribution that sticks out above e^ε times the other, as in Equation 18.13, so

$$E_{e^\varepsilon}(P\|Q) = \sum_y \big(p(y) - e^\varepsilon q(y)\big)_+ \le \delta, \qquad E_{e^\varepsilon}(Q\|P) = \sum_y \big(q(y) - e^\varepsilon p(y)\big)_+ \le \delta. \tag{J.1}$$

Here the positive part $(x)_+$ equals x when x is positive and 0 otherwise.

The **four-point pair** $(P^\star, Q^\star)$ of Table 21.3 is the worst such pair, in the sense that every test tells it apart as well as (ε, δ)-DP allows. It has four outputs: "flag D", 0, 1 and "flag D'". With probability δ it announces the dataset, by "flag D" on D or "flag D'" on D'. Otherwise it runs randomized response at level ε, which reports 0 with probability $t = e^\varepsilon/(1+e^\varepsilon)$ on D and $1-t$ on D', and reports 1 otherwise. So $P^\star$ gives the four outputs the probabilities δ, $(1-\delta)t$, $(1-\delta)(1-t)$ and 0, and $Q^\star$ gives them 0, $(1-\delta)(1-t)$, $(1-\delta)t$ and δ. A **channel** K is a table of probabilities $K(y \mid z)$ that turns an input z into an output y. The claim is that some channel produces the pair (P, Q) from the four-point pair:

$$p(y) = \sum_z P^\star(z)K(y \mid z), \qquad q(y) = \sum_z Q^\star(z)K(y \mid z) \qquad \text{for every output } y. \tag{J.2}$$

The composition chapter derives the channel for $\delta = 0$ (Equation 21.12). For $\delta > 0$ it explains why a channel must exist, through Blackwell's theorem (a pair that is at least as hard to test as another at every level is a post-processing of it), and cites Kairouz, Oh & Viswanath (2015) for its construction. Optimal composition Equation 21.15, advanced composition with $\delta > 0$, and basic composition with $\delta > 0$ in Section 21.5 all rest on this channel.

J.1.2. The idea

Split each distribution into two parts. The two **pure parts**, one inside P and one inside Q, are chosen so that at every output each is at most e^ε times the other. The **leftover** of each distribution is everything else, and the split is arranged so that it has mass exactly δ. The pure parts then form an ε-DP pair, so the chapter's $\delta = 0$ channel produces them from plain randomized response. The leftovers are what the flags are for: the channel turns "flag D" into a draw from P's leftover, and "flag D'" into a draw from Q's.

The only care needed is in the masses. The four-point pair gives each side exactly $1 - \delta$ of plain randomized response, so the two pure parts must both have mass exactly $1 - \delta$. The obvious pure parts, $\min\{p, e^\varepsilon q\}$ and $\min\{q, e^\varepsilon p\}$, can have different masses. So the proof first moves the heavier one down to the lighter one's mass, by mixing in a scaled copy of the other one so that the factor e^ε survives, and then scales both down to $1 - \delta$.

A small case shows every step. Take three outputs with $P = (0.6, 0.3, 0.1)$, $Q = (0.2, 0.3, 0.5)$ and $e^{\varepsilon} = 2$. The mass of P above $2Q$ is $0.6 - 0.4 = 0.2$, and the mass of Q above $2P$ is $0.5 - 0.2 = 0.3$, so the pair is $(\ln 2, 0.3)$-DP, with δ the larger of the two. Table J.2 follows the construction.

Table J.2.: The construction on three outputs with $e^{\varepsilon} = 2$ and $\delta = 0.3$.

	Output 1	Output 2	Output 3	Total
p	0.6	0.3	0.1	1
q	0.2	0.3	0.5	1
$m_P = \min\{p, 2q\}$	0.4	0.3	0.1	$A = 0.8$
$m_Q = \min\{q, 2p\}$	0.2	0.3	0.2	$B = 0.7$
$\hat{m}_P$, the heavier part moved down to mass B	1/3	4/15	1/10	0.7
$\hat{m}_Q = m_Q$	0.2	0.3	0.2	0.7
$R_D = (p - \hat{m}_P)/0.3$	8/9	1/9	0	1
$R_{D'} = (q - \hat{m}_Q)/0.3$	0	0	1	1

The rows m_P and m_Q are the first guesses for the pure parts, with masses A and B. The heavier one, m_P, is moved down by step 4 of the derivation below: it is mixed with $m_Q/e^{\varepsilon} = m_Q/2$, with weight $\omega^* = \frac{2}{9}$ on $m_Q/2$, chosen so that the mass falls to B. So on output 1 the row $\hat{m}_P$ is $\frac{7}{9} \times 0.4 + \frac{2}{9} \times 0.1 = \frac{1}{3}$. The lighter mass $B = 0.7$ is already $1 - \delta$, so no further scaling is needed, and both pure parts end with mass 0.7. They also stay within a factor 2 of each other on every output, because the ratios $\hat{m}_P/\hat{m}_Q$ are $\frac{5}{3}$, $\frac{8}{9}$ and $\frac{1}{2}$. What is left over has mass 0.3 on each side, so dividing it by $\delta = 0.3$ gives two distributions. The section's checks below confirm that the channel built from these rows gives back P and Q exactly.

J.1.3. Derivation

Assume $0 < \delta < 1$ and $\varepsilon > 0$. Write $\gamma = e^{\varepsilon}$ to keep the formulas short.

1. **Pure parts.** Define, for every output y,

$$m_P(y) = \min\{p(y), \gamma q(y)\}, \qquad m_Q(y) = \min\{q(y), \gamma p(y)\}. \tag{J.3}$$

   Each is non-negative and at most its own distribution, $m_P \le p$ and $m_Q \le q$.
2. **They are within a factor γ.** The claim is $m_P \le \gamma m_Q$ at every output. The minimum m_P is at most γq by definition. To compare it with $\gamma m_Q = \min\{\gamma q, \gamma \cdot \gamma p\}$, note that it is also at most p, which is at most $\gamma^2 p$ because $\gamma \ge 1$. So m_P is at most both γq and $\gamma \cdot \gamma p$, and hence at most γ times the smaller one, which is γm_Q. Swapping the roles gives $m_Q \le \gamma m_P$.
3. **Their masses.** At each output, $p - \min\{p, \gamma q\} = (p - \gamma q)_+$: either the minimum is p and both sides are 0, or the minimum is $\gamma q < p$ and both sides are $p - \gamma q$. Summing over outputs, the mass of m_P is

$$A = \sum_y m_P(y) = 1 - E_\gamma(P \| Q) \ge 1 - \delta, \tag{J.4}$$

and in the same way the mass of m_Q is $B = 1 - E_\gamma(Q\|P) \geq 1 - \delta$.

4. **Move the heavier part down.** Say $A \geq B$; otherwise swap the names P and Q. For a weight ω between 0 and 1, mix m_P with the scaled-down $\gamma^{-1} m_Q$:

$$m_P^\omega = (1-\omega)\, m_P + \omega\, \gamma^{-1} m_Q. \tag{J.5}$$

Three properties hold for every ω, because each holds for both pieces of the mix, and a mix of two numbers lies between them. First, the mix fits inside p: $m_P \leq p$ by step 1, and $\gamma^{-1} m_Q \leq \gamma^{-1}\gamma p = p$ because $m_Q \leq \gamma p$. Second, it is at most γm_Q: $m_P \leq \gamma m_Q$ by step 2, and $\gamma^{-1} m_Q \leq \gamma m_Q$ because $\gamma \geq 1$. Third, it is at least $\gamma^{-1} m_Q$, which is the reverse bound $m_Q \leq \gamma m_P^\omega$. This holds because step 2 gives $m_Q \leq \gamma m_P$, that is $m_P \geq \gamma^{-1} m_Q$, and the second piece equals $\gamma^{-1} m_Q$. The mass of the mix is $(1-\omega)A + \omega\gamma^{-1}B$. It falls in a straight line from A at $\omega = 0$ to $\gamma^{-1}B$ at $\omega = 1$, and $\gamma^{-1}B \leq B \leq A$. So it passes through B, at

$$\omega^* = \frac{A - B}{A - \gamma^{-1} B} \tag{J.6}$$

(and $\omega^* = 0$ when $A = B$). Now $m_P^{\omega^*}$ and m_Q both have mass B.

5. **Scale both to mass $1 - \delta$.** Multiply both by $(1-\delta)/B$, which is at most 1 by step 3:

$$\hat{m}_P = \frac{1-\delta}{B}\, m_P^{\omega^*}, \qquad \hat{m}_Q = \frac{1-\delta}{B}\, m_Q. \tag{J.7}$$

Scaling both by the same factor keeps the ratio bounds of step 4 between $m_P^{\omega^*}$ and m_Q, and scaling down keeps $\hat{m}_P \leq p$ and $\hat{m}_Q \leq q$. Dividing by $1 - \delta$ then gives two distributions,

$$\bar{P} = \frac{\hat{m}_P}{1-\delta}, \qquad \bar{Q} = \frac{\hat{m}_Q}{1-\delta}, \tag{J.8}$$

with $\bar{P}(y) \leq \gamma \bar{Q}(y)$ and $\bar{Q}(y) \leq \gamma \bar{P}(y)$ at every output. So $(\bar{P}, \bar{Q})$ is an ε-DP pair.

6. **The leftovers are distributions.** Define the leftovers $R_D = (p - \hat{m}_P)/\delta$ and $R_{D'} = (q - \hat{m}_Q)/\delta$. Each is non-negative because of step 5, and each sums to $(1 - (1-\delta))/\delta = 1$, so each is a distribution. Rearranging the definitions gives the split

$$P = (1-\delta)\bar{P} + \delta R_D, \qquad Q = (1-\delta)\bar{Q} + \delta R_{D'}. \tag{J.9}$$

7. **The channel.** The channel sends "flag D" to R_D and "flag D'" to $R_{D'}$. It sends the reports 0 and 1 to the two rows of the $\delta = 0$ channel Equation 21.12, built for the pure pair $(\bar{P}, \bar{Q})$:

$$K(y \mid 0) = \frac{\gamma \bar{P}(y) - \bar{Q}(y)}{\gamma - 1}, \qquad K(y \mid 1) = \frac{\gamma \bar{Q}(y) - \bar{P}(y)}{\gamma - 1}. \tag{J.10}$$

The composition chapter shows that these rows are distributions when the pair is ε-DP: each entry is non-negative because no output is more than γ times likelier under one side, and each row sums to $(\gamma - 1)/(\gamma - 1) = 1$. It also shows that mixing the rows with weights t and $1 - t$ gives $\bar{P}$, and with weights $1 - t$ and t gives $\bar{Q}$.

8. **Check Equation J.2.** Feed $P^\star$ through K, one input at a time. The input "flag D" has probability δ, and the channel sends it to R_D. The reports 0 and 1 have probabilities $(1-\delta)t$ and $(1-\delta)(1-t)$, so by step 7 their rows mix to $(1-\delta)\bar{P}$. The input "flag D'" has probability 0 under $P^\star$ and adds nothing. So the total is $\delta R_D + (1-\delta)\bar{P}$, which is P by Equation J.9. The same steps with $Q^\star$, whose report 1 has probability $(1-\delta)t$, give $(1-\delta)\bar{Q} + \delta R_{D'} = Q$.

J.1.4. Checking it

The script runs the construction on three kinds of pairs: the small example, many random pairs, and a binned normal pair. On the small example of Table J.2 it finds $\omega^* = 0.2222$ and the channel rows $K(\cdot \mid 0) = (0.6667, 0.3333, 0)$ and $K(\cdot \mid 1) = (0.0952, 0.4762, 0.4286)$. Feeding $P^\star$ and $Q^\star$ through them returns $(0.6, 0.3, 0.1)$ and $(0.2, 0.3, 0.5)$. It then draws 2,000 random pairs for each of three settings: 3 outputs at $\varepsilon = 0.5$, 8 outputs at $\varepsilon = 1$ and 20 outputs at $\varepsilon = 2$. A quarter of the pairs have an output that only one side can produce. Such an output has an infinite privacy loss, so all of its mass must go into the leftover. Each pair gets its own exact δ. Over all 6,000 pairs, $P^\star K$ and $Q^\star K$ differ from P and Q by at most 2.2×10^{-16}, and every ratio bound of step 5 holds to within rounding. The smallest channel entry is -1.4×10^{-13}, which is rounding too: the leftover rows divide a difference by δ, and δ is sometimes small.

Figure J.1 shows the split on a larger pair. P is a normal distribution with mean 0 and standard deviation 1, Q one with mean 1 and standard deviation 0.8, each reported in eight bins. At $\varepsilon = 1$ the two hockey-stick divergences are 0.2259 and 0.0844, so $\delta = 0.2259$. The red leftover of P sits in the left bins, where p exceeds $e^\varepsilon q$, while the leftover of Q sits on the right, where q exceeds $e^\varepsilon p$. In both panels the blue pure parts stay under the dashed line.

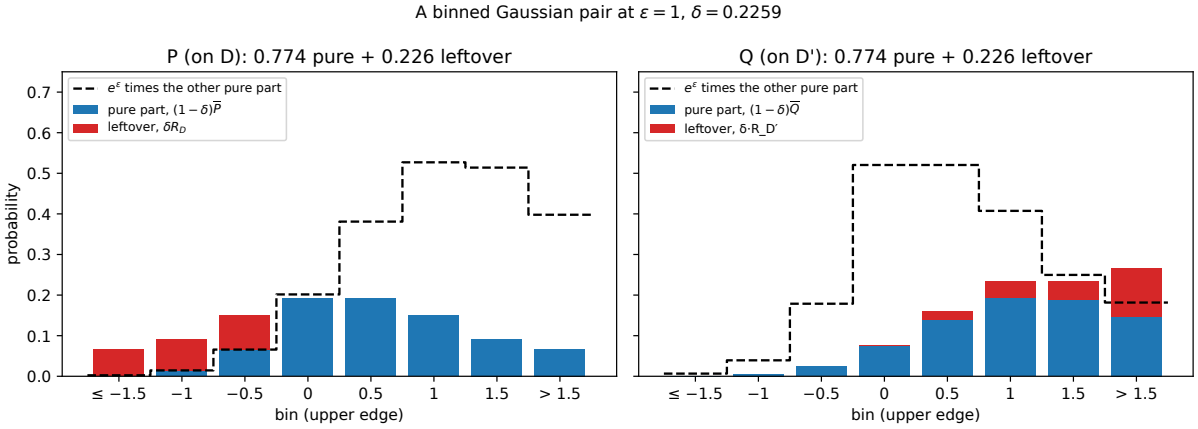

Figure J.1.: The split of Equation J.9 for a pair of binned normal distributions at $\varepsilon = 1$, $\delta = 0.2259$. Blue: the pure parts $(1-\delta)\overline{P}$ and $(1-\delta)\overline{Q}$. Red: the leftovers δR_D and $\delta R_{D'}$. Dashed: e^ε times the other side's pure part, which each blue bar must stay under.

Figure J.2 shows the same pair as hypothesis tests. On the left are trade-off curves: for each false positive rate x, the smallest false negative rate any test reaches. The pair's curve lies above the boundary $f_{\varepsilon,\delta}(x) = \max\{0, 1 - \delta - e^\varepsilon x, e^{-\varepsilon}(1 - \delta - x)\}$ of Equation 18.18, which is exactly the curve of the four-point pair. Its pure part lies above the higher boundary $f_{\varepsilon,0}$ of plain randomized response, because removing the leftover removes the outputs that tests can exploit. On the right is step 4. Here Q's first pure part is the heavier one, with mass $B = 0.9156$ against $A = 0.7741$. So step 4 runs with the roles of P and Q swapped: Q's part is mixed down, and it reaches A at $\omega^* = 0.2243$.

The result is exact, not a bound, so there is no slack to measure. The construction is not unique, because other splits work too. But no split can use a δ below the pair's own: every split needs a leftover of mass at least $\max\{E_\gamma(P\|Q), E_\gamma(Q\|P)\}$, because a leftover smaller than the mass sticking out above γ times the other side would leave some of that mass in the pure part.

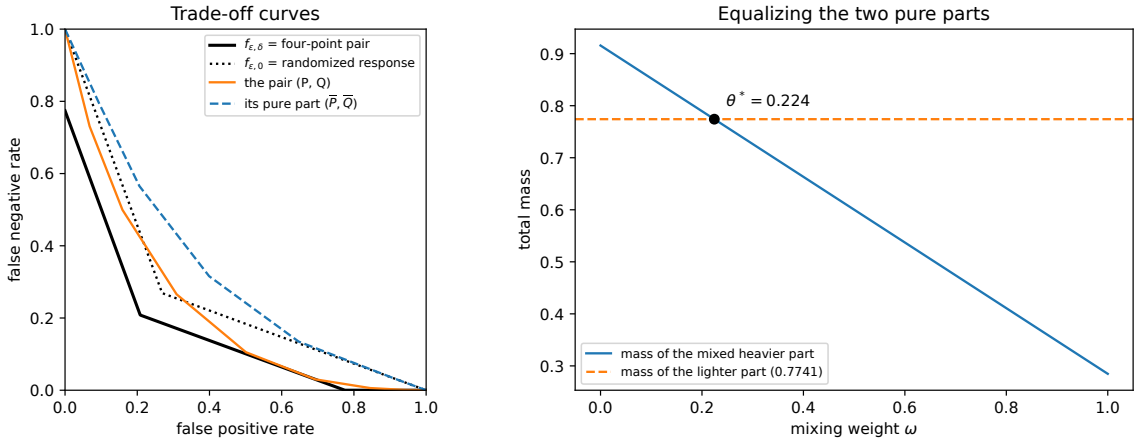

Figure J.2.: Left: trade-off curves of the binned normal pair (orange) and of its pure part (blue dashed), against the boundaries $f_{\varepsilon,\delta}$ (black), attained by the four-point pair, and $f_{\varepsilon,0}$ (dotted), attained by randomized response. Right: the mass of the mixed heavier pure part against the mixing weight ω; it falls in a straight line and meets the lighter part's mass at $\omega^* = 0.224$.

J.1.5. What it does not cover

The proof needs $\delta > 0$ to divide by in step 6, and the case $\delta = 0$ is the chapter's own derivation. It also needs $\varepsilon > 0$ to divide by $\gamma - 1$ in step 7. With $\varepsilon = 0$ the pure parts are equal, $\bar{P} = \bar{Q}$, randomized response reports 0 with probability $\frac{1}{2}$ on both sides, and both rows of the channel are simply $\bar{P}$.

Continuous outputs need one change. Replace the probabilities $p(y)$ and $q(y)$ by densities with respect to a common reference distribution, for example $(P + Q)/2$. Both have densities between 0 and 2 with respect to it, so every quantity above is finite. Every step above works output by output, so it goes through with sums replaced by integrals.

J.2. Approximate DP implies approximate zCDP

J.2.1. What the chapter uses

Zero-concentrated differential privacy describes a mechanism by a slope ρ. It asks that the Rényi divergence D_α of every order $\alpha > 1$, between the outputs on neighbouring datasets, lie under the line $\rho\alpha$ through the origin (Equation 31.2). The approximate version allows this to fail on an event of probability at most δ. Precisely, a mechanism M is **δ-approximately ρ-zCDP** if every pair of neighbours $D \sim D'$ has an event E for the run on D and an event E' for the run on D' with the following two properties. (The events may depend on how the run produced its output, as the idea below explains, and $M(D)|_E$ is the output distribution conditioned on E.) Each event has probability at least $1 - \delta$, and for every order $\alpha > 1$,

$$D_\alpha(M(D)|_E \,\|\, M(D')|_{E'}) \le \rho\alpha \qquad \text{and} \qquad D_\alpha(M(D')|_{E'} \,\|\, M(D)|_E) \le \rho\alpha. \tag{J.11}$$

The chapter states in Section 31.7 that an (ε, δ)-DP mechanism is δ-approximately $(\varepsilon^2/2)$-zCDP (Bun & Steinke 2016, Proposition 1.13). As the reason, it says only that any (ε, δ)-DP pair decomposes so that "with probability $1 - \delta$ it behaves like an ε-DP pair". It also states that approximate zCDP composes, with slack $\delta_1 + \delta_2 - \delta_1\delta_2$ for two steps (their Lemma 8.2), and it uses both facts in an example pipeline that mixes stability-based steps with Gaussian steps.

J.2.2. The idea

The decomposition is Equation J.9 of the previous section. It says that you can produce $M(D)$ in two stages. First flip a coin that says "pure" with probability $1 - \delta$. If it does, draw the output from the pure part $\bar{P}$, and otherwise draw it from the leftover R_D. The output then has exactly the distribution $P = (1 - \delta)\bar{P} + \delta R_D$, so this two-stage run is the same mechanism. Do the same on D' with $\bar{Q}$ and $R_{D'}$. Now let E and E' be the events that the coins say "pure". Conditioned on them, the outputs have distributions $\bar{P}$ and $\bar{Q}$, an ε-DP pair, and the chapter has already shown that every ε-DP pair is $(\varepsilon^2/2)$-zCDP.

Note that these events are about how the output was produced, not only about the output itself. That is enough for the chapter, because its conversion from approximate zCDP back to (ε, δ)-DP uses E only through its probability and through the conditional distribution.

J.2.3. Derivation

1. **Split the pair.** Fix neighbours $D \sim D'$, with output distributions P and Q. Because the mechanism is (ε, δ)-DP, both hockey-stick divergences are at most δ. For $0 < \delta < 1$ and $\varepsilon > 0$, the previous section then gives Equation J.9, with $(\bar{P}, \bar{Q})$ an ε-DP pair. If $\delta = 0$, take $\bar{P} = P$ and $\bar{Q} = Q$; if $\varepsilon = 0$, the previous section's last part covers it; and $\delta = 1$ makes the claim empty.
2. **Realize the mechanism in two stages.** Run $M(D)$ by drawing a coin C that equals "pure" with probability $1 - \delta$, then an output from $\bar{P}$ if C is "pure" and from R_D otherwise. The output has distribution $(1 - \delta)\bar{P} + \delta R_D = P$. Run $M(D')$ the same way with $\bar{Q}$ and $R_{D'}$.
3. **Pick the events.** Let E be "C is pure" in the run on D, and E' the same in the run on D'. Each has probability exactly $1 - \delta$. Conditioned on E the output is drawn from $\bar{P}$, and conditioned on E' from $\bar{Q}$.
4. **Apply the pure-DP bound.** The pair $(\bar{P}, \bar{Q})$ is ε-DP, so by Equation 31.6 of Section 31.4,

$$D_\alpha(\bar{P} \| \bar{Q}) \le \frac{\alpha\varepsilon^2}{2} \qquad \text{and} \qquad D_\alpha(\bar{Q} \| \bar{P}) \le \frac{\alpha\varepsilon^2}{2} \qquad \text{for every } \alpha > 1. \tag{J.12}$$

   That chapter proves it with Hoeffding's lemma. The privacy loss of an ε-DP pair lies in $[-\varepsilon, \varepsilon]$, and a Rényi divergence is the logarithm of an exponential moment of the privacy loss. Hoeffding's lemma bounds that moment by a normal one, and the result is the line $\alpha\varepsilon^2/2$. Steps 3 and 4 together are the definition with $\rho = \varepsilon^2/2$. The sharper Equation 31.7 gives $\rho = \varepsilon \tanh(\varepsilon/2)$ the same way.

Composition, in the case the chapter uses. The pipeline of Section 31.7 mixes steps that are $(\varepsilon_i, \delta_i)$-DP with steps that are ρ_i-zCDP, each chosen after seeing the earlier outputs. For a zCDP step take $\delta_i = 0$ and the coin always "pure". For an $(\varepsilon_i, \delta_i)$-DP step take $\rho_i = \varepsilon_i^2/2$ and the two-stage run of step 2, built for the mechanism that the earlier outputs (the history) selected.

5. **The coins ignore the history.** Whatever the earlier outputs were, step i's coin says "pure" with probability exactly $1-\delta_i$. So the event "every coin says pure" has probability $\prod_i(1-\delta_i) = 1-\delta_a$, which defines the slack δ_a.
6. **Condition on all coins.** The probability of a sequence of outputs together with "every coin says pure" is a product over steps of $(1-\delta_i)$ times the pure distribution of step i given the history. Dividing by $\prod_i(1-\delta_i)$ leaves the product of the pure distributions. So conditioned on all coins being pure, the run is an adaptive composition of the pure parts, on D and on D' alike.
7. **Add the slopes.** Each pure part is ρ_i-zCDP for every history. Rényi divergences of an adaptive composition add, even when each step is chosen from the earlier outputs (Fact 2 of Concentrated differential privacy), so the conditioned run is $(\sum_i \rho_i)$-zCDP. The whole pipeline is therefore δ_a-approximately $(\sum_i \rho_i)$-zCDP, with $\delta_a = 1 - \prod_i(1-\delta_i)$. For two steps that is $\delta_1 + \delta_2 - \delta_1\delta_2$.

J.2.4. Checking it

The script computes the Rényi divergences of the pure parts from the previous section on a grid of orders from 1.001 to 20.9, in both directions. For the three-output example, with $\varepsilon = \ln 2$ and $\rho = \varepsilon^2/2 = 0.2402$, the largest value of $D_\alpha/(\alpha\rho)$ is 0.4275. For the binned normal pair, with $\rho = 0.5$, it is 0.4306. Both are well under 1, the most the bound allows, and the slack has two sources. First, the Rényi divergence of an ε-DP pair never exceeds ε, so as α grows its curve flattens while the line $\alpha\varepsilon^2/2$ keeps rising. Second, these pure parts are milder than randomized response, the worst ε-DP pair.

J.2.5. What it does not cover

The events here depend on the coin that chooses between the pure part and the leftover, not only on the output. If an event had to be a set of outputs, the argument would not apply as it stands, because the leftover and the pure part can share outputs. The chapter's derivation in Section 31.7 uses the events only through their probabilities and conditional distributions, so it holds for these events.

The composition argument above needs each good event to have probability exactly $1-\delta_i$ given any history, which is what the two-stage run provides. Bun & Steinke's Lemma 8.2 covers general approximately-zCDP steps, whose good events only have probability at least $1-\delta_i$ and may depend on the history. That general case stays cited. For the pipelines of the chapter, which mix (ε, δ)-DP steps with zCDP steps, the special case is all that is used.

J.3. The stability-based histogram

J.3.1. What the chapter uses

A histogram over a universe of N bins releases a count for each bin. Under pure DP, the packing argument of Section 27.1 shows that the ℓ_∞ error, the largest error over the bins, must grow like $\ln N/\varepsilon$ (Equation 27.5). Under approximate DP, the chapter says, "the stability-based histogram

(Vadhan 2017) adds noise only to the bins that are non-empty … its error does not grow with N at all". It gives no proof. In Section 28.3, the same mechanism locates the data roughly before a mean is estimated, without any bound on where the data might be.

The **stability-based histogram** with parameters ε and δ works on a dataset of n records. Each record falls in one bin, and c_x is the number of records in bin x. The mechanism compares noisy counts with a threshold, set to

$$\tau = 1 + \frac{\ln\left(1/(2\delta)\right)}{\varepsilon}. \tag{J.13}$$

For every bin with $c_x \geq 1$, it draws a fresh Laplace noise $Z_x \sim \mathrm{Lap}(1/\varepsilon)$, and it releases the pair $(x, c_x + Z_x)$ if the noisy count exceeds τ. It releases nothing else, and a bin that is not released is read as 0. The chapter needs two claims about it. The first is privacy: under add/remove neighbours, where D' adds or removes one record, the mechanism is (ε, δ)-DP. The second is accuracy. Suppose k bins are non-empty, and allow a failure probability β. Then with probability at least $1 - \beta$ every bin's estimate is within

$$\tau + \frac{\ln(k/\beta)}{\varepsilon} = 1 + \frac{\ln\left(1/(2\delta)\right) + \ln(k/\beta)}{\varepsilon} \tag{J.14}$$

of its true count. Since $k \leq n$, this is of order $(\ln(1/\delta) + \ln(n/\beta))/\varepsilon$, with no N in it.

J.3.2. The idea

Adding one record changes one bin, from count c to $c + 1$, and two cases can happen. If the bin already had records, both datasets put Laplace noise on it. That is the ordinary Laplace mechanism on a count, which is ε-DP, and the threshold only decides what to print, so it changes nothing. If the bin was empty, the smaller dataset never even looks at it, so it cannot be released. The larger dataset releases it only if a count of 1 plus noise clears τ, and the threshold is set so that this happens with probability exactly δ. So apart from an event of probability δ, the two runs print the same thing. That is the argument of Section 18.8 for the mechanism that releases each record with probability δ.

Accuracy comes from the same threshold. A bin that is not released has a count below about τ, so reading it as 0 costs at most about τ. A released bin has the usual Laplace error. Only the k non-empty bins have any noise at all, so the union bound runs over k bins, not over N.

J.3.3. Derivation

Privacy. Fix a dataset D and add one record, in bin x, to get D'.

1. **Only bin x differs.** Every other bin has the same count in D and D'. Its noise is drawn the same way, independently of bin x, so its part of the output has the same distribution on both sides.
2. **Bin x was non-empty.** Then $c_x(D) \geq 1$, and both runs add $\mathrm{Lap}(1/\varepsilon)$ to a count that changes by 1. That is the Laplace mechanism with sensitivity 1, which is ε-DP. Comparing the noisy count with τ is a function of it, which is post-processing, so bin x's part of the output is ε-DP.

3. **Bin x was empty.** On D nothing about bin x is ever printed, while on D' bin x has count 1 and is printed exactly when $1 + Z_x > \tau$. A $\mathrm{Lap}(1/\varepsilon)$ variable exceeds a level $s \geq 0$ with probability $\frac{1}{2}e^{-\varepsilon s}$. Here the level is $\tau - 1$, which is $\ln(1/(2\delta))/\varepsilon$ by Equation J.13, so bin x is printed with probability

$$\Pr[Z_x > \tau - 1] = \tfrac{1}{2}e^{-\ln(1/(2\delta))} = \delta. \tag{J.15}$$

4. **Couple the two runs in the empty case.** Run the mechanism on D' by first running it on D with the same noise, then drawing Z_x for the new bin. The two outputs differ only if bin x is printed, which has probability δ. So for any set S of outputs, $\Pr[M(D') \in S] \leq \Pr[M(D) \in S] + \delta$. In the other direction, the outputs agree whenever bin x is not printed. That depends only on Z_x, which is drawn independently of everything else, so the outputs agree with probability $1 - \delta$ whatever $M(D)$ printed, and $\Pr[M(D') \in S] \geq (1 - \delta)\Pr[M(D) \in S] \geq \Pr[M(D) \in S] - \delta$. Both directions are $(0, \delta)$-DP.
5. **Put the bins back together.** Step 4 already compares whole outputs, but step 2 compares only bin x's part. To finish step 2, fix the output w of all the other bins. For each w, bin x's part satisfies the ε-DP inequality. The other bins' output w has the same distribution on D and D', so averaging the inequality over w with these common weights keeps it. Either way the pair satisfies (ε, δ)-DP, in both orders.

Accuracy. Let the k non-empty bins have noises Z_x.

6. **Error of one bin.** An empty bin is never printed and its estimate 0 is exact. A printed bin has error $|Z_x|$. A non-empty bin that is not printed has $c_x + Z_x \leq \tau$, so its error, the count c_x itself, is at most $\tau - Z_x \leq \tau + |Z_x|$. Either way the error is at most $\tau + |Z_x|$.
7. **All k noises at once.** A $\mathrm{Lap}(1/\varepsilon)$ variable exceeds s in absolute value with probability $e^{-\varepsilon s}$. The chance that at least one of k events happens is at most the sum of their chances (the union bound), so

$$\Pr\left[\max_x |Z_x| > s\right] \leq ke^{-\varepsilon s}. \tag{J.16}$$

   The right side equals β at $s = \ln(k/\beta)/\varepsilon$. Together with step 6, this shows that the ℓ_∞ error is at most Equation J.14 with probability at least $1 - \beta$.

J.3.4. Checking it

Take $\varepsilon = 1$ and $\delta = 10^{-6}$, so $\tau = 1 + \ln(5 \times 10^5) = 14.1224$. Figure J.3 shows the probability that a bin with true count c is printed. Below τ it falls by a factor e^ε for each record removed, and at $c = 1$ it is exactly 10^{-6}. That point is the whole δ the mechanism spends.

For accuracy, take $k = 10$ non-empty bins and $\beta = 0.05$. The bound Equation J.14 is $14.1224 + \ln 200 = 19.4207$. The script also computes the exact 95% quantile of the error when all ten bins hold the same count, and takes the worst count. The worst is a count of 18. Each such bin is suppressed with probability $\frac{1}{2}e^{-(18-\tau)} = 0.0104$, and then its whole count is the error. With ten bins, at least one is suppressed with probability about 0.1, which is more than 0.05, so the 95% quantile is exactly 18. A simulation of 200,000 runs at that count gives the same 18, so the bound is loose by about 1.4 records. The union bound costs little, and the slack has two small sources. A bin is suppressed only when its noise is negative, so only one of the two Laplace tails matters, which is worth $\ln 2 = 0.69$. And counts are whole numbers, so the worst count cannot sit exactly where the bound puts it.

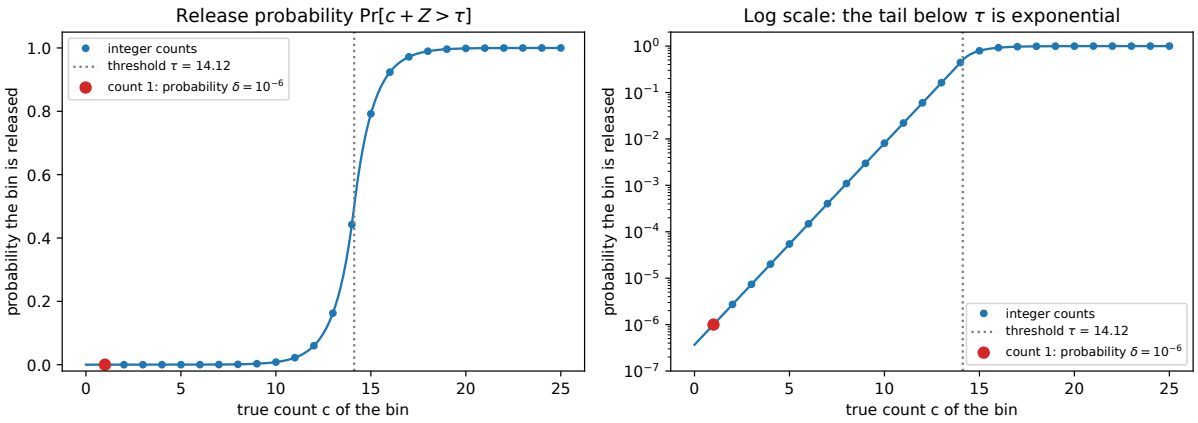

Figure J.3.: The probability that the stability-based histogram prints a bin, against the bin's true count, at $\varepsilon = 1$ and $\delta = 10^{-6}$, on a linear scale (left) and a log scale (right). The dotted line is the threshold $\tau = 14.12$. At count 1 the probability is exactly δ, which is all the privacy that empty bins cost.

Figure J.4 compares the error with pure DP as the universe grows. The Laplace histogram must add noise to all N bins. All N noises stay below s in size with probability $(1 - e^{-\varepsilon s})^N$, so setting this to 0.95 gives the exact 95% error, $-\ln(1 - 0.95^{1/N})/\varepsilon$, which is 16.79 at $N = 10^6$ and 30.60 at $N = 10^{12}$. The stability-based histogram stays at 19.42 for every N. It beats the Laplace histogram from $N = 1.394 \times 10^7$. It even falls below the packing lower bound Equation 27.5, $\frac{1}{2}(\ln(0.95N)/\varepsilon - 1)$, which holds for every pure-DP mechanism, but only from $N = 2.114 \times 10^{17}$, because $\ln(1/\delta)$ is a large constant.

J.3.5. What it does not cover

The proof is for add/remove neighbours, which is the relation of the lower-bounds chapter. Under replace neighbours, as in Section 28.3, one record leaves one bin and joins another. Each of the two bins behaves as in step 2 or step 4, independently, and basic composition gives $(2\varepsilon, 2\delta)$-DP. So run the mechanism with $\varepsilon/2$ and $\delta/2$.

The threshold Equation J.13 is the smallest that makes step 3 cost exactly δ. A larger threshold is also private, at the price of a larger error. The bound counts only bins that hold data. A universe with N bins, or even infinitely many, never enters, because the mechanism never draws noise for an empty bin.

J.4. A lower bound for heavy-tailed means

J.4.1. What the chapter uses

Section 28.5 estimates the mean of data whose variance is at most σ^2, from n records, under replace neighbours. It clips each record to an interval narrower than the data's spread, accepting a bias, and reaches an error a with about $\sigma^2/a^2 + 8\sqrt{2}\,\sigma^2/(a^2\varepsilon)$ records, by Equation 28.15. It

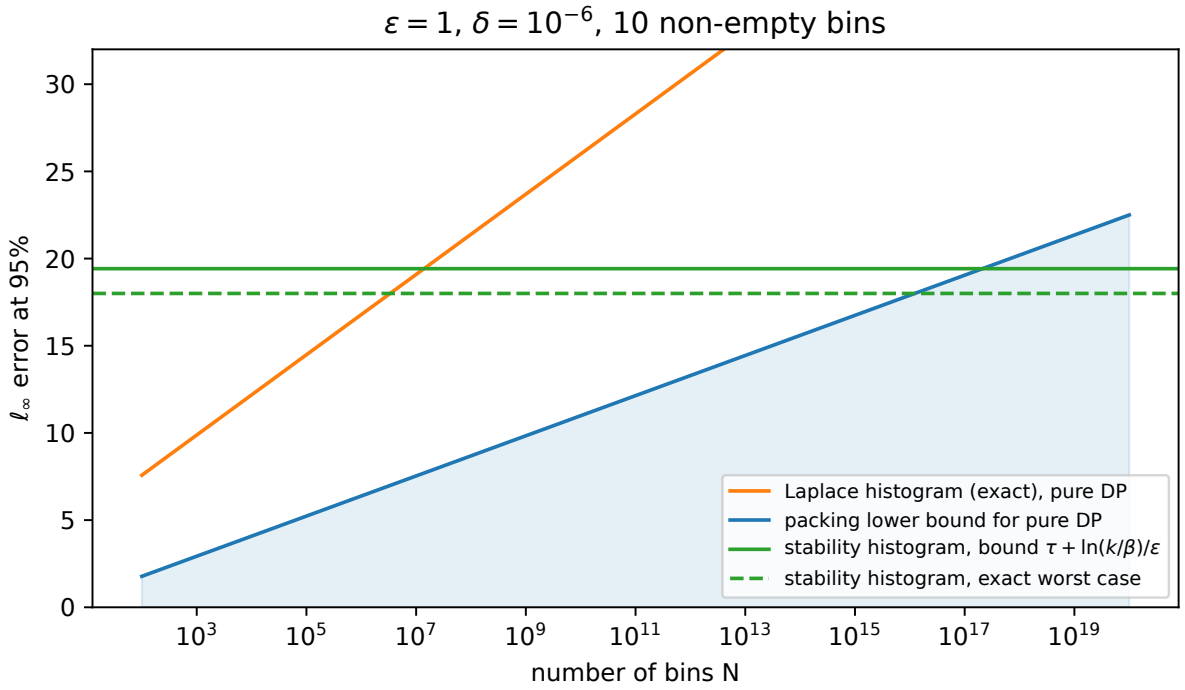

Figure J.4.: The ℓ_∞ error at the 95% level against the number of bins N, at $\varepsilon = 1$, for data in 10 non-empty bins. Orange: the Laplace histogram (exact), a pure-DP mechanism. Blue: the packing lower bound for every pure-DP mechanism, with the impossible region shaded. Green: the stability-based histogram with $\delta = 10^{-6}$, its bound (solid) and its exact worst case (dashed), neither of which depends on N.

then says that "Kamath, Singhal & Ullman (2020) show that this is unavoidable", and that if the k-th moment $\mathbb{E}|X-\mu|^k$ is bounded the cost falls to about $1/(\varepsilon a^{k/(k-1)})$ records. It gives no proof.

This section proves the claim for mechanisms that are pure ε-DP. Fix a whole number $k \geq 2$ and a bound m_k on the k-th central moment, the average of $|X-\mu|^k$ for a record X with mean μ. For the variance, $k=2$ and $m_2 = \sigma^2$. The data may come from any distribution that satisfies

$$\mathbb{E}|X-\mu|^k \leq m_k. \tag{J.17}$$

Suppose an ε-DP mechanism M takes n records from such a distribution and returns an estimate within less than a of μ with probability at least $1-\beta$. The probability is over both the data and the mechanism's noise, and the target error must satisfy $a \leq m_k^{1/k}/2$. Then

$$n \geq \frac{\ln\left((1-\beta)/\beta\right)}{\ln\left(1+p(e^{\varepsilon}-1)\right)} \geq \frac{\ln\left((1-\beta)/\beta\right)}{p(e^{\varepsilon}-1)}, \qquad p = \frac{(2a)^{k/(k-1)}}{m_k^{1/(k-1)}}. \tag{J.18}$$

For the variance, with $k=2$, the simpler bound reads

$$n \geq \frac{\sigma^2 \ln\left((1-\beta)/\beta\right)}{4a^2(e^{\varepsilon}-1)}. \tag{J.19}$$

For small ε, $e^{\varepsilon}-1$ is close to ε, so this is of order $\sigma^2/(a^2\varepsilon)$, the rate of the chapter's estimator. For general k, with the moment bound m_k held fixed, it is of order $1/(\varepsilon a^{k/(k-1)})$.

J.4.2. The idea

Build two distributions that a good estimator must tell apart but that DP says it cannot. The first, P_0, puts all its mass at 0, so its mean is 0. The second, P_1, is the same except that a small probability p moves to a far point v. Its mean is pv, which we set to $2a$. An accurate estimator must answer below a on data from P_0 and above a on data from P_1. The far point lets the mean move by $2a$ while the moment stays within its bound, because the mass out there is tiny.

Now look at the data. A sample from P_0 is all zeros. A sample from P_1 is all zeros except for about np records equal to v, so it is only about np replacements away from the all-zeros sample. Group privacy says that ε-DP outputs on datasets J replacements apart differ by at most a factor $e^{J\varepsilon}$. If np is small, the two samples look too much alike for the estimator to answer differently, so n must be at least about $1/(p\varepsilon)$. The more spread the moment bound allows, the farther the point v can be, the smaller p becomes, and the larger n must be.

Figure J.5 draws the two distributions for $k=2$, $\sigma=1$ and $a=0.15$.

J.4.3. Derivation

1. **The far point.** Let P_1 put probability p on a value $v>0$ and $1-p$ on 0, with $pv = 2a$ and $pv^k = m_k$. (Step 2 shows that pv^k bounds the central moment.) Dividing the second equation by the first gives $v^{k-1} = m_k/(2a)$, so

$$v = \left(\frac{m_k}{2a}\right)^{1/(k-1)}, \qquad p = \frac{2a}{v} = \frac{(2a)^{k/(k-1)}}{m_k^{1/(k-1)}}. \tag{J.20}$$

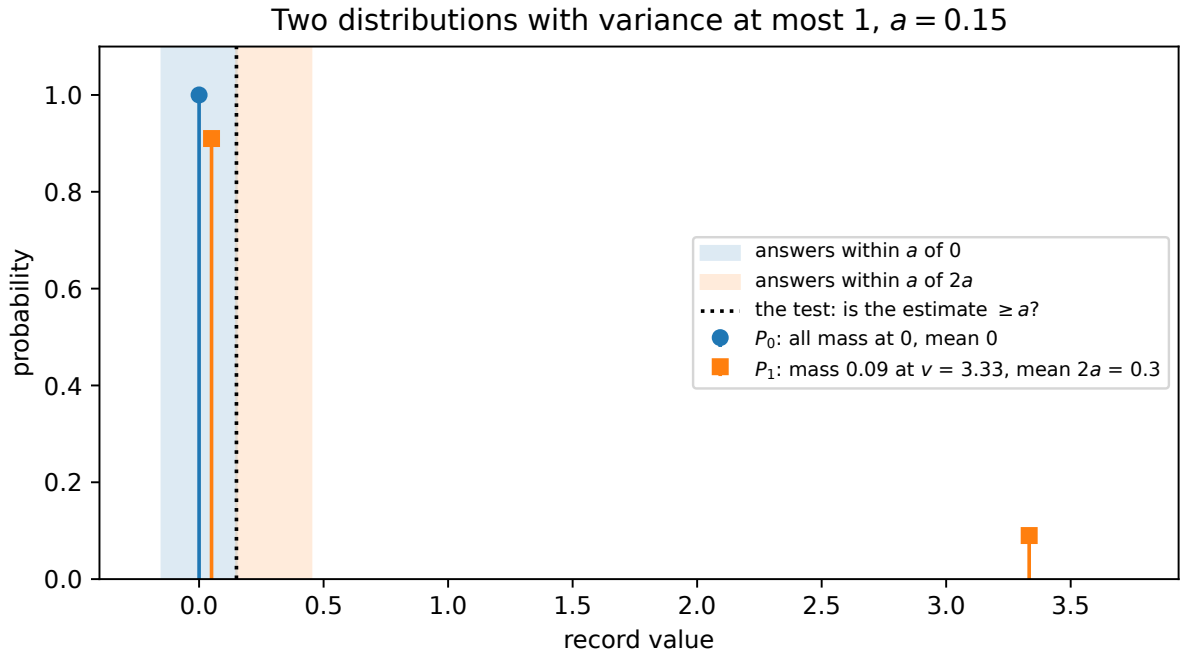

Figure J.5.: The two distributions of the lower bound for variance at most 1 and $a = 0.15$. P_0 (blue) puts all its mass at 0. P_1 (orange, its stem at 0 drawn slightly to the right) moves mass $p = 0.09$ to $v = 3.33$, which shifts the mean to $2a = 0.3$. An estimator accurate to a must answer in the blue band on P_0 and in the orange band on P_1, so the test "is the estimate at least a?" separates them.

For p to be a probability you need $v \geq 2a$, which is $m_k \geq (2a)^k$, the condition $a \leq m_k^{1/k}/2$. For $k = 2$ this is $v = \sigma^2/(2a)$ and $p = 4a^2/\sigma^2$.

2. P_1 **meets the moment bound.** Its mean is $\mu = pv$. The value 0 is at distance pv from it and the value v at distance $(1-p)v$, so

$$\mathbb{E}|X - \mu|^k = (1-p)(pv)^k + p\big((1-p)v\big)^k = p(1-p)v^k\big(p^{k-1} + (1-p)^{k-1}\big). \tag{J.21}$$

   Both p and $1-p$ lie in $[0,1]$, and raising such a number to the power $k-1 \geq 1$ cannot increase it. So the last bracket is at most $p + (1-p) = 1$, and the moment is at most $p(1-p)v^k \leq pv^k = m_k$. P_0 has moment 0.
3. **The datasets.** A sample of n records from P_0 is the all-zeros dataset D_0. A sample D_1 from P_1 has some number J of records equal to v, where J follows a binomial distribution with n trials and success probability p. You get D_1 from D_0 by replacing J records, so the two are at distance J.
4. **The test.** Let S be the event "the estimate is at least a". On P_0 the mean is 0, and an estimate within less than a of it is below a. So accuracy on P_0 gives $\Pr[M(D_0) \in S] \leq \beta$. On P_1 the mean is $2a$, and an estimate within less than a of it is above a. So accuracy on P_1, averaged over the random dataset D_1, gives $\mathbb{E}\Pr[M(D_1) \in S] \geq 1 - \beta$.
5. **Group privacy.** For pure DP, two datasets at distance J satisfy $\Pr[M(D_1) \in S] \leq e^{J\varepsilon}\Pr[M(D_0) \in S]$ (Equation 19.6 with $\delta = 0$). The reason is that the privacy loss adds up along the path of J single replacements, at most ε per step. With step 4, $\Pr[M(D_1) \in S] \leq e^{J\varepsilon}\beta$ for every possible D_1.
6. **Average over the datasets.** Combining steps 4 and 5 gives $1 - \beta \leq \beta\,\mathbb{E}[e^{\varepsilon J}]$. Each of the n records independently contributes a factor e^ε with probability p and 1 otherwise, so the average of $e^{\varepsilon J}$ is $(1 - p + pe^\varepsilon)^n$. Hence

$$1 - \beta \leq \beta\big(1 + p(e^\varepsilon - 1)\big)^n. \tag{J.22}$$

7. **Solve for n.** Take logarithms and divide by $\ln(1 + p(e^\varepsilon - 1))$ to get the first bound of Equation J.18. Since $\ln(1+x) \leq x$, the denominator is at most $p(e^\varepsilon - 1)$, which gives the second, simpler bound.

J.4.4. Checking it

Take a variance bound $\sigma^2 = 1$ and $\varepsilon = 1$, and ask for error $a = 0.05$ with failure probability $\beta = 0.05$. Step 1 gives $v = 10$ and $p = 0.01$, and the variance of P_1 is 0.99, within the bound. Equation J.18 then says that every ε-DP estimator needs at least 172.8 records, or 171.4 by the simpler form. The chapter's clipped mean reaches a root-mean-square error of 0.05 with 7,616 records, by Equation 28.15. The two use different measures of error and the lower bound's constants are loose, so the gap of a factor 44 says little. What matters is the rate. Lighter tails make the bound smaller. With a k-th moment bound of 1 and the same a, it falls to 55.6 records for $k = 3$ and to 38.4 for $k = 4$. For data in $[0,1]$ the far point can be at most 1, so the same argument with $v = 1$ and $p = 2a$ gives 18.6. The script also checks step 2 on a grid of a for $k = 2, 3, 4, 6$, and the largest k-th central moment of P_1 never exceeds 1. It comes closest at the smallest a, where it prints as 1.0000.

Figure J.6 plots these bounds against a on log–log axes. For $k = 2$ the lower bound and the chapter's estimator both have slope -2, so they differ by a constant factor at every a. A larger k gives a smaller slope, $-k/(k-1)$, which approaches -1, the slope of bounded data.

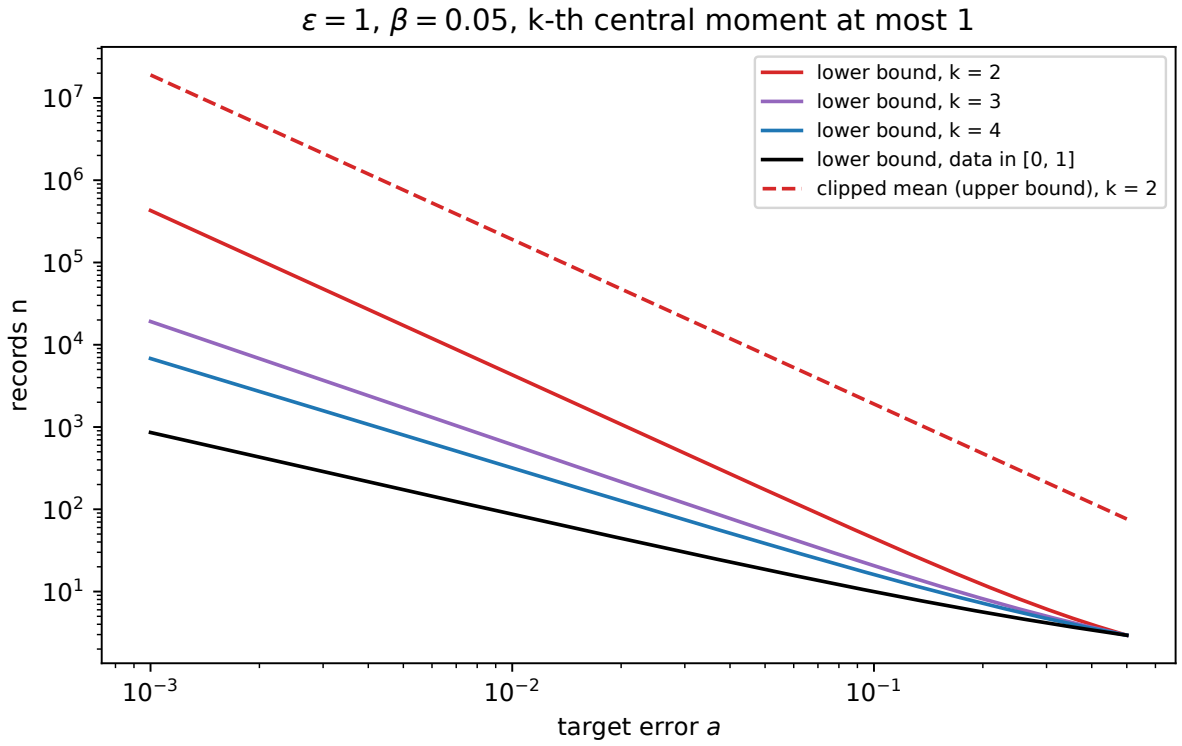

Figure J.6.: Records needed for error a at $\varepsilon = 1$, $\beta = 0.05$, on log–log axes, with k-th central moment at most 1. Solid: the lower bound Equation J.18 for $k = 2$, 3 and 4, and the same argument for data in $[0, 1]$. Dashed: the chapter's clipped mean Equation 28.15 for $k = 2$, which reaches root-mean-square error a. The $k = 2$ lines are parallel, so the chapter's estimator has the optimal rate.

J.4.5. What it does not cover

The proof needs pure DP. Step 5 multiplies by $e^{J\varepsilon}$, and under approximate DP group privacy adds a slack that grows like $e^{J\varepsilon}\delta$, which ruins the averaging in step 6 once J is large. Lower bounds under approximate DP need different tools and are not proved here, and Kamath, Singhal & Ullman (2020) is the place to start. The bound is also only the privacy part of the cost. The sampling part, about σ^2/a^2 records, comes from the usual non-private lower bounds.

J.5. Sparse vector with c answers above

J.5.1. What the chapter uses

Section 22.6 proves that AboveThreshold, which halts at the first query above a noisy threshold, is $(\varepsilon_1 + \varepsilon_2)$-DP, where ε_1 is the budget spent on the threshold's noise and ε_2 the budget spent on the queries' noise. To find c queries above the threshold, it says, "Lyu, Su & Li's Algorithm 1 keeps one threshold noise and uses $\nu_i \sim \mathrm{Lap}(2c\Delta/\varepsilon_2)$, so that the c shifts together cost e^{ε_2}". It gives no proof. The algorithm takes a dataset D, queries $f_1, f_2, \ldots$ of sensitivity Δ that may be chosen adaptively, a threshold τ and budgets $\varepsilon_1, \varepsilon_2 > 0$.

1. Draw the threshold noise $\xi \sim \mathrm{Lap}(\Delta/\varepsilon_1)$ once.
2. For each query i, draw fresh noise $\nu_i \sim \mathrm{Lap}(2c\Delta/\varepsilon_2)$. If $f_i(D) + \nu_i \geq \tau + \xi$, output $\top$, and halt if this is the c-th $\top$. Otherwise output $\bot$.

The claim is that this is $(\varepsilon_1 + \varepsilon_2)$-DP for any number of queries. If the queries are monotone, meaning one record moves all of them the same way, noise $\nu_i \sim \mathrm{Lap}(c\Delta/\varepsilon_2)$ suffices.

J.5.2. The idea

The proof is the chapter's AboveThreshold proof with c answers $\top$ instead of one. Every $\bot$ answer says that its noisy query is below the noisy threshold. As in the chapter, all of them together are one condition: the largest noisy $\bot$ query is below the threshold. The proof compares the two datasets by a change of variables in the noise. If the threshold noise on D' is shifted by the amount the largest $\bot$ query moved, at most Δ, that condition holds on D' exactly when it held on D. A Laplace density changes by at most a factor e^{ε_1} under such a shift, however many $\bot$ answers there are. Each $\top$ answer needs its own noise shifted to stay above the shifted threshold, by at most 2Δ: Δ for its own query's move and Δ for the threshold's. With noise scale $2c\Delta/\varepsilon_2$, one such shift costs $e^{\varepsilon_2/c}$. There are at most c of them, because the run halts at the c-th, so together they cost e^{ε_2}.

J.5.3. Derivation

The proof reuses four facts of the selection chapter. Pure DP can be checked one output at a time (Proposition 18.1). Noise drawn the same way on both datasets can be fixed and averaged over at the end (Lemma 22.1). A Laplace density with scale b changes by at most a factor $e^{|s|/b}$ when shifted by s (Lemma 22.3). And a maximum of numbers that each move by at most Δ moves by at most Δ (Lemma 22.2). Fix neighbours $D \sim D'$.

1. **Fix an output and the $\perp$ noises.** An output is a sequence of answers that ends either at the c-th $\top$ or at the end of the stream. Let B be the positions of its $\perp$ answers and A those of its $\top$ answers, so A has at most c elements. Fix the noises ν_i for $i \in B$. By Fact 2 it is enough to bound the conditional probability, because these noises do not depend on the data. The queries are fixed too, since each can depend only on earlier answers, which the output fixes.
2. **Write the output as conditions on ξ and the $\top$ noises.** Let $g(D) = \max_{i \in B} (f_i(D) + \nu_i)$ be the largest noisy $\perp$ query. All $\perp$ answers happen exactly when $g(D) < \tau + \xi$. Each $\top$ answer $i \in A$ happens when $f_i(D) + \nu_i \geq \tau + \xi$. Write p_ξ and p_ν for the Laplace densities of the threshold noise and of a query noise. The probability of the output is the integral of these densities over the region where all the conditions hold:

$$\int p_\xi(r)\, \mathbf{1}[g(D) < \tau + r] \prod_{i \in A} \Big(p_\nu(v_i)\, \mathbf{1}[f_i(D) + v_i \geq \tau + r] \Big)\, \mathrm{d}r \prod_{i \in A} \mathrm{d}v_i. \tag{J.23}$$

3. **Shift the noises.** Substitute $r = r' + g(D) - g(D')$ and, for each $i \in A$, $v_i = v_i' + (g(D) - g(D')) - (f_i(D) - f_i(D'))$. The first condition becomes $g(D') < \tau + r'$, and each $\top$ condition becomes $f_i(D') + v_i' \geq \tau + r'$. These are exactly the conditions for D'. The substitution is a translation, so it does not change the volume element. Only the densities change: they are now evaluated at shifted points.
4. **Size of the shifts.** The ν_i for $i \in B$ are fixed, so g is a maximum of numbers that each move by at most Δ, and $|g(D) - g(D')| \leq \Delta$ by Fact 4. Each $\top$ shift is a difference of two terms of size at most Δ, so it is at most 2Δ. If there are no $\perp$ answers, there is no g: shift r by 0 and each v_i by $-(f_i(D) - f_i(D'))$, at most Δ.
5. **Pay for the shifts.** By Fact 3, the threshold noise, with scale Δ/ε_1 and shift at most Δ, costs a factor at most e^{ε_1}. Each $\top$ noise, with scale $2c\Delta/\varepsilon_2$ and shift at most 2Δ, costs at most $e^{2\Delta\varepsilon_2/(2c\Delta)} = e^{\varepsilon_2/c}$. There are at most c of them, so together they cost at most e^{ε_2}. Pulling the factors out of the integral leaves the integral for D':

$$\Pr[\text{output} \mid D, \nu_B] \leq e^{\varepsilon_1 + \varepsilon_2} \Pr[\text{output} \mid D', \nu_B]. \tag{J.24}$$

6. **Collect.** Fact 2 removes the conditioning on ν_B, and Fact 1 turns the bound for every output into $(\varepsilon_1 + \varepsilon_2)$-DP.

Monotone queries. If all queries move the same way, by at most Δ, then g moves the same way as each f_i, also by at most Δ (Fact 4). The $\top$ shift in step 3 is the difference of two numbers of the same sign, each at most Δ in size, so it is at most Δ. With noise scale $c\Delta/\varepsilon_2$ each shift costs $e^{\varepsilon_2/c}$, and the rest is unchanged.

J.5.4. Checking it

The script computes the exact privacy loss of one output on one neighbouring pair, by integrating over the threshold noise on a fine grid, as the selection chapter's script does. The pair extends the counterexample of the selection chapter. On D the first m queries have value 0 and the last c have value 1, while on D' the first m have value 1 and the last c have value 0, with $\Delta = 1$, $\tau = 0$ and $\varepsilon_1 = \varepsilon_2 = 0.5$. The output is m answers $\perp$ followed by c answers $\top$, which is complete because the run halts at the c-th $\top$. On this pair every shift in step 4 can approach its largest size.

Figure J.7 shows the loss against m. For $c = 1$ it is 0.3958 at $m = 1$ and 0.9940 at $m = 10$, which are the chapter's AboveThreshold values. More answers above make the loss climb more slowly, so for $c = 4$ it is only 0.2670 at $m = 1$ and 0.7602 at $m = 10$. But for every c it reaches 1.0000, which is $\varepsilon_1 + \varepsilon_2$, by $m = 40$, and it never goes above, so the bound is tight. The dashed curve shows why the noise must grow with c. With $\nu_i \sim \mathrm{Lap}(2\Delta/\varepsilon_2)$ and $c = 4$, each $\top$ costs a full e^{ε_2}, and the loss reaches $2.5000 = \varepsilon_1 + 4\varepsilon_2$.

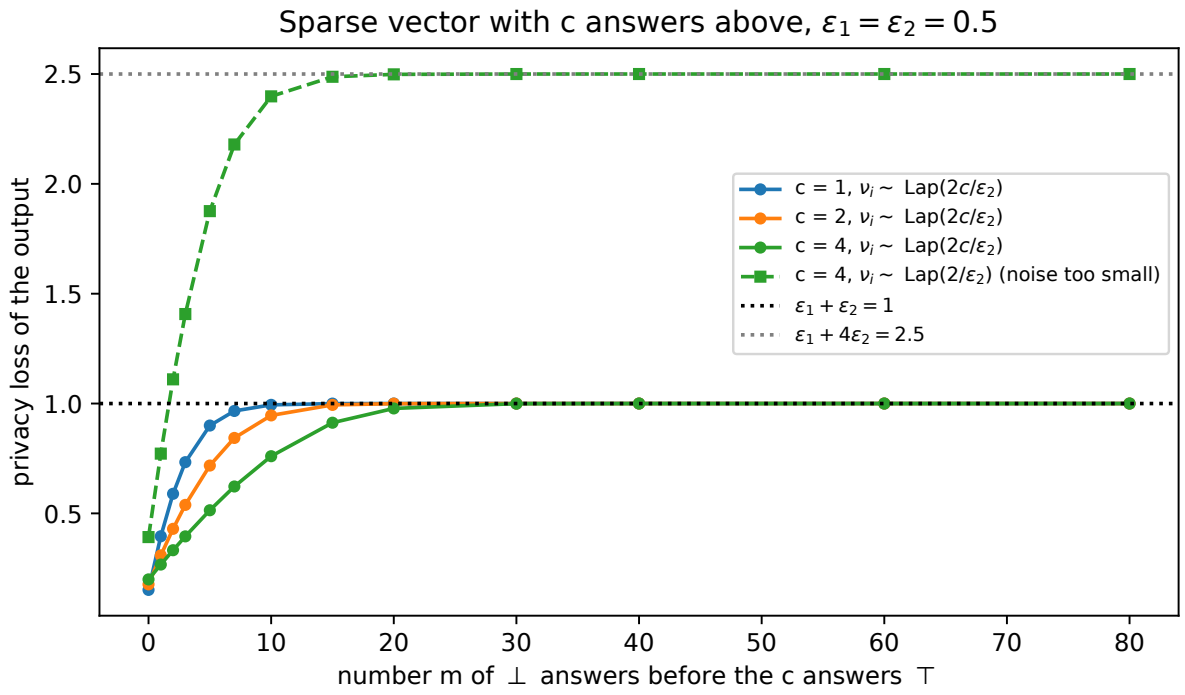

Figure J.7.: The exact privacy loss of the output "m answers $\perp$, then c answers $\top$" on a worst-case neighbouring pair, against m, with $\varepsilon_1 = \varepsilon_2 = 0.5$. With query noise $\mathrm{Lap}(2c/\varepsilon_2)$ the loss approaches $\varepsilon_1 + \varepsilon_2 = 1$ from below for $c = 1$, 2 and 4. With noise $\mathrm{Lap}(2/\varepsilon_2)$ that does not grow with c (dashed, $c = 4$), it approaches $\varepsilon_1 + 4\varepsilon_2 = 2.5$.

J.6. Gumbel top-c is the exponential mechanism without replacement

J.6.1. What the chapter uses

Section 22.5 proves the Gumbel-max trick Equation 22.12. Add independent Gumbel noise of scale κ to each score u_r and take the largest. Then candidate i wins with probability $e^{u_i/\kappa} / \sum_r e^{u_r/\kappa}$, which is the exponential mechanism Equation 22.2 when $\kappa = 2\Delta/\varepsilon$. (The chapter writes this scale β. Here it is κ, because β is a failure probability elsewhere on this page.) The chapter then states without proof that "taking the c largest of $u_r + G_r$ gives the same distribution as running the exponential mechanism c times, removing each winner (Durfee & Rogers 2019)", so its privacy is $c\varepsilon$.

Write $\lambda_r = e^{u_r/\kappa}$ for the weight of candidate r. The claim is that for any distinct candidates

$i_1, \dots, i_c$,

$$\Pr\left[\text{the top } c \text{ of } u_r + G_r, \text{ in order, are } i_1, \dots, i_c\right] = \prod_{j=1}^{c} \frac{\lambda_{i_j}}{\sum_{r \notin \{i_1, \dots, i_{j-1}\}} \lambda_r}. \tag{J.25}$$

Each factor is the probability that the exponential mechanism, run on the candidates not yet chosen, picks i_j.

J.6.2. The idea

Turn each noisy score into a waiting time, so that a higher score means an earlier arrival. The time $E_r = e^{-(u_r+G_r)/\kappa}$ does this, because e^{-x} falls as x rises. For Gumbel noise these times turn out to be independent exponential variables, and candidate r's time has rate λ_r: on average it arrives after $1/\lambda_r$. The top c noisy scores are then the first c arrivals of a race.

Exponential races have a simple rule. The chance that r arrives first is its share of the total rate, $\lambda_r / \sum_s \lambda_s$. And exponential waiting times have no memory: once one candidate has arrived, the others' remaining waits are fresh exponential times with the same rates. So the race restarts among the rest, and the next arrival is again picked in proportion to the rates. For example, with rates 3, 2 and 1, the first candidate wins the first round with probability 3/6. The race then restarts between the other two, and the second candidate wins it with probability 2/3. The ordered pair (first, second) therefore has probability $\frac{3}{6} \cdot \frac{2}{3} = \frac{1}{3}$.

J.6.3. Derivation

1. **Arrival times are exponential.** The Gumbel distribution with scale κ has cumulative distribution function $\Pr[G \le g] = \exp(-e^{-g/\kappa})$. For $s > 0$, $E_r > s$ means $u_r + G_r < -\kappa \ln s$, that is $G_r < -\kappa \ln s - u_r$. So

   $$\Pr[E_r > s] = \exp\left(-e^{\ln s + u_r/\kappa}\right) = \exp(-s\lambda_r). \tag{J.26}$$

   That is the survival function of an exponential variable with rate λ_r. The E_r are independent because the G_r are.
2. **Order reverses.** The map $x \mapsto e^{-x/\kappa}$ is decreasing, so the largest noisy score has the smallest arrival time. The top c noisy scores, in decreasing order, are the first c arrivals, in order.
3. **The first arrival.** Let $\Lambda = \sum_r \lambda_r$. Candidate i arrives first at a time near s when E_i is near s and every other E_r exceeds s. Integrating over s,

   $$\Pr[i \text{ first}] = \int_0^\infty \lambda_i e^{-\lambda_i s} \prod_{r \ne i} e^{-\lambda_r s} \, \mathrm{d}s = \int_0^\infty \lambda_i e^{-\Lambda s} \, \mathrm{d}s = \frac{\lambda_i}{\Lambda}. \tag{J.27}$$

4. **No memory.** Given $E_r > s$, the extra wait $E_r - s$ exceeds x with probability $e^{-\lambda_r(s+x)}/e^{-\lambda_r s} = e^{-\lambda_r x}$. So it is again exponential with rate λ_r, whatever s is. The other candidates' times are independent of E_i, so given that i arrives first at time s, their extra waits are independent exponentials with their own rates, and their order does not depend on s.

5. **Restart the race.** By step 4, the probability that i arrives first and the rest arrive in a given order is the integral of step 3 times the probability of that order in a race among the others alone. That is λ_i/Λ times a race with i removed. Applying this c times gives Equation J.25.
6. **The same as c exponential mechanisms.** Round j of the exponential mechanism without replacement picks i_j with probability λ_{i_j} over the sum of the remaining weights. That is the j-th factor of Equation J.25, so the two procedures have the same distribution of ordered outputs.
7. **Privacy.** Each round is the exponential mechanism on a set of candidates fixed by the earlier outputs, with scores of sensitivity Δ, so each is ε-DP. Basic composition, which holds even when each step depends on the earlier outputs (Section 19.3), makes the c rounds $c\varepsilon$-DP. Releasing the top c as an unordered set is post-processing of the ordered list, so it is $c\varepsilon$-DP too.

J.6.4. Checking it

Take six candidates with scores $(4, 3, 3, 1, 0, 0)$ and scale $\kappa = 2$, the chapter's five candidates with a sixth. Equation J.25 gives probabilities for all 30 ordered pairs, and they sum to 1. For candidate 1 followed by candidate 2 it gives 0.1313, and in a million draws of Gumbel noise the top two came out in that order with frequency 0.1313. Over all 30 pairs the largest difference between frequency and formula is 0.0003, about the sampling error of a million draws. Step 1 is checked separately: the average arrival time of each candidate, times its rate, is 1 to within 0.001, as it must be for an exponential variable.

Figure J.8 shows the 30 pairs from a fresh run, and Figure J.9 shows the race. Each curve is the probability that a candidate has not yet arrived by time s. A higher score gives a steeper curve and an earlier typical arrival. One draw's arrivals are marked with their rank, and the first two are the top two noisy scores.

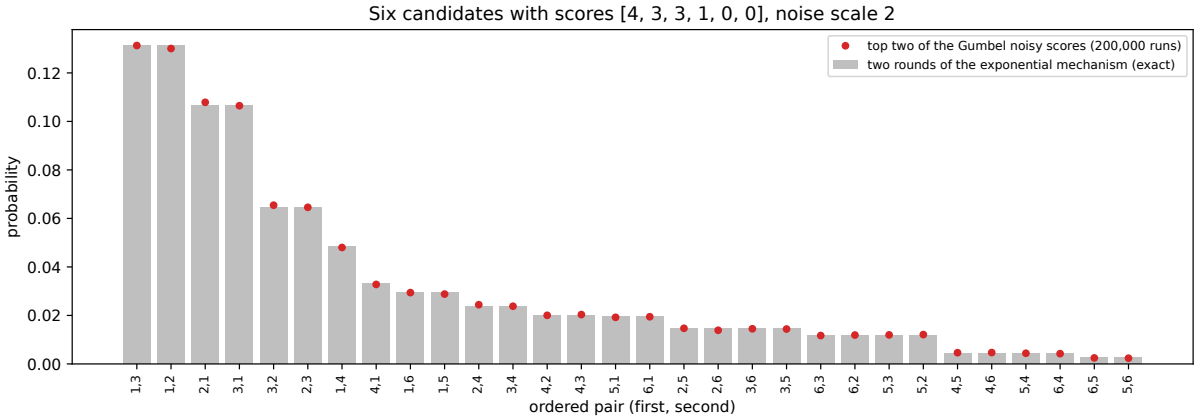

Figure J.8.: Probabilities of the 30 ordered pairs (first, second) for six candidates with scores $(4, 3, 3, 1, 0, 0)$ and Gumbel scale 2. Grey bars: two rounds of the exponential mechanism, Equation J.25. Red dots: frequencies of the top two noisy scores in 200,000 runs.

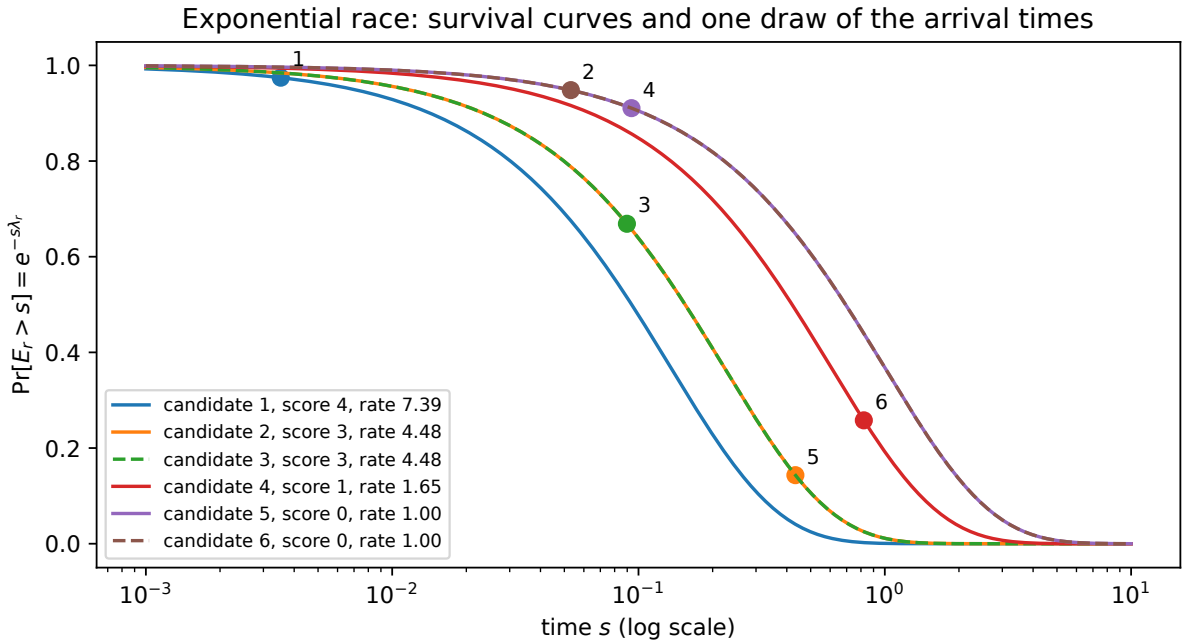

Figure J.9.: The exponential race for the same six candidates. Each curve is $\Pr[E_r > s] = e^{-s\lambda_r}$ with rate $\lambda_r = e^{u_r/2}$, on a log time axis; tied candidates share a curve (one dashed). The dots are one draw of the arrival times $E_r = e^{-(u_r+G_r)/2}$, numbered in order of arrival.

J.7. The alarm mechanism is (ε, δ)-DP, with one condition

J.7.1. What the chapter uses

Section 19.2 shows that the group-privacy bound Equation 19.6 is attained, using a mechanism whose input is a count, where neighbouring counts differ by 1. The mechanism has a parameter K, the largest group it is built for, and on a count $c \le K$ it outputs "alarm" with probability

$$a_c = \delta \sum_{j=0}^{K-c-1} e^{j\varepsilon} = \delta \, \frac{e^{(K-c)\varepsilon} - 1}{e^{\varepsilon} - 1}, \tag{J.28}$$

and "quiet" otherwise. Above K it always outputs "quiet", so $a_c = 0$ for $c \ge K$. The chapter shows that the event "alarm" meets the definition with equality, and states the condition on K under which the other events are also within (ε, δ). This section proves that condition.

For $\varepsilon > 0$ and $K \ge 1$, the alarm mechanism is (ε, δ)-DP if and only if

$$a_0 \le \frac{e^{\varepsilon} + \delta}{e^{\varepsilon} + 1}. \tag{J.29}$$

Since a_0 grows with K, this caps K.

J.7.2. The idea

There are only two outputs, so there are only two events to check, "alarm" and "quiet", each in both orders of a pair of neighbouring counts. The alarm probabilities fall as the count rises, by the rule $a_c = e^{\varepsilon} a_{c+1} + \delta$. Three of the four checks then hold for any K. The fourth asks that "quiet" on the higher count is not too much likelier than on the lower one. If a_0 is close to 1, "quiet" is rare on count 0. Since $a_1 = (a_0 - \delta)/e^{\varepsilon}$ is smaller by about a factor e^{ε}, "quiet" is much more common on count 1, and the ratio of the two "quiet" probabilities breaks the bound.

J.7.3. Derivation

Fix neighbouring counts c and $c+1$. The alarm probability has fewer terms at $c+1$, so $a_c \geq a_{c+1}$. For $c \geq K$ both are 0, the two output distributions are equal, and there is nothing to check. So take $c \leq K-1$, where splitting off the first term of the sum gives

$$a_c = e^{\varepsilon} a_{c+1} + \delta. \tag{J.30}$$

The empty event has probability 0 on both sides, and the event "alarm or quiet" has probability 1 on both sides, which is at most $e^{\varepsilon} + \delta$. So both pass, and four checks remain.

1. **"Alarm", count c against $c+1$.** The definition asks $a_c \leq e^{\varepsilon} a_{c+1} + \delta$. This holds with equality, by the rule above.
2. **"Alarm", count $c+1$ against c.** It asks $a_{c+1} \leq e^{\varepsilon} a_c + \delta$, which holds because $a_{c+1} \leq a_c$.
3. **"Quiet", count c against $c+1$.** It asks $1 - a_c \leq e^{\varepsilon}(1 - a_{c+1}) + \delta$. This holds because $1 - a_c \leq 1 - a_{c+1}$ and $1 - a_{c+1} \geq 0$.
4. **"Quiet", count $c+1$ against c.** It asks $1 - a_{c+1} \leq e^{\varepsilon}(1 - a_c) + \delta$. Substitute the rule for a_c. The right side becomes $e^{\varepsilon} - e^{2\varepsilon} a_{c+1} - (e^{\varepsilon} - 1)\delta$. Moving terms across, the check becomes $(e^{2\varepsilon} - 1)a_{c+1} \leq (e^{\varepsilon} - 1)(1 - \delta)$. Since $e^{2\varepsilon} - 1 = (e^{\varepsilon} - 1)(e^{\varepsilon} + 1)$ and $e^{\varepsilon} - 1 > 0$, it is

$$a_{c+1} \leq \frac{1 - \delta}{e^{\varepsilon} + 1}. \tag{J.31}$$

5. **The worst pair.** The largest a_{c+1} with $c \leq K-1$ is a_1, so all checks pass exactly when $a_1 \leq (1 - \delta)/(e^{\varepsilon} + 1)$. By the rule, $a_0 = e^{\varepsilon} a_1 + \delta$, and this condition is the same as $a_0 \leq (e^{\varepsilon}(1 - \delta) + \delta(e^{\varepsilon} + 1))/(e^{\varepsilon} + 1)$. The numerator simplifies to $e^{\varepsilon} + \delta$, which gives Equation J.29. The right side of Equation J.29 is below 1, so the condition also makes a_0 a valid probability.

At the cap the pair of counts 0 and 1 is exactly the four-point pair of Section J.1, with "flag D" merged into report 0 and "flag D'" merged into report 1. Then $a_0 = \delta + (1 - \delta)t$ and $a_1 = (1 - \delta)(1 - t)$, with $t = e^{\varepsilon}/(1 + e^{\varepsilon})$, as extreme as (ε, δ)-DP allows.

J.7.4. Checking it

In the chapter's example, $\varepsilon = 0.5$, $\delta = 10^{-5}$ and $K = 10$. The cap is $(e^{0.5} + 10^{-5})/(e^{0.5} + 1) = 0.6225$, and $a_0 = 2.272 \times 10^{-3}$, far below it. So the chapter's mechanism is $(0.5, 10^{-5})$-DP, and the script's check over every event agrees: the largest amount by which any event exceeds the bound is 2.5×10^{-20}, which is rounding on the event that holds with equality. The largest allowed size

at these parameters is $K = 21$, where $a_0 = 0.5598$. At $K = 22$, $a_0 = 0.9229$ is still a probability, but the event "quiet" on counts 1 against 0 exceeds the bound by 0.3132. So the condition is real, and it does not follow from $a_0 \le 1$.

J.7.5. What it does not cover

The derivation divides by $e^\varepsilon - 1$ in step 4, so it needs $\varepsilon > 0$. At $\varepsilon = 0$ the rule reads $a_c = a_{c+1} + \delta$, check 4 asks $a_c - a_{c+1} \le \delta$, which holds with equality, and the only condition left is $a_0 \le 1$.

J.8. Code

The script apx_mechanisms.py computes every number on this page and draws its figures. It builds the four-point channel and checks it on 6,000 random pairs. It computes the stability-based histogram's error exactly and by simulation, and the sparse vector technique's privacy loss by numerical integration. It also evaluates the heavy-tail lower bound, compares Gumbel top-two selection with the exponential mechanism, and checks every event of the alarm mechanism. From the repository root:

```
uv run python code/appendix-derivations/apx_mechanisms.py
```

Table J.3 shows the output with seed 0.

Table J.3.: The script's output with seed 0.

Check	Result
Four-point channel, three-output example	$\omega^* = 0.2222$; $P^\star K = (0.6, 0.3, 0.1)$ and $Q^\star K = (0.2, 0.3, 0.5)$ exactly
Four-point channel, binned normal pair at $\varepsilon = 1$	$\delta = 0.2259$; masses 0.7741 and 0.9156; $\omega^* = 0.2243$
Four-point channel, 6,000 random pairs	reproduces P and Q to 2.2×10^{-16}; smallest channel entry -1.4×10^{-13} (rounding)
Pure parts as zCDP	largest $D_\alpha/(\alpha\varepsilon^2/2)$ is 0.4275 and 0.4306
Stability-based histogram, $\varepsilon = 1$, $\delta = 10^{-6}$, 10 bins	$\tau = 14.1224$; error bound 19.4207; exact worst 18.0000, simulated 18.0000
Laplace histogram over N bins	16.7857 at $N = 10^6$, 30.6012 at $N = 10^{12}$; above the stability bound from $N = 1.394 \times 10^7$
Heavy-tail lower bound, $a = 0.05$	172.8 records for $k = 2$, 55.6 for $k = 3$, 38.4 for $k = 4$, 18.6 for bounded data; the clipped mean uses 7,616
Sparse vector, $c = 1, 2, 4$	loss 0.9940, 0.9459, 0.7602 at $m = 10$; 1.0000 at $m = 40$; 2.5000 with noise that ignores c
Gumbel top two, six candidates	largest difference from Equation J.25 0.0003 over 30 pairs, from 10^6 draws

Check	Result
Alarm mechanism, $\varepsilon = 0.5$, $\delta = 10^{-5}$	cap 0.6225; $a_0 = 2.272 \times 10^{-3}$ at $K = 10$; largest K is 21; at $K = 22$ an event fails by 0.3132

tests/test_appendix_mechanisms.py checks that the output still matches this table.

What to take from it. The four-point construction is exact: it reproduces every pair to rounding, including pairs whose outputs only one side can produce. The stability-based histogram's error is flat in N, and its bound is within about 1.4 records of the exact worst case, so what approximate DP costs here is the constant $\ln(1/\delta)/\varepsilon$, in place of a $\ln N$ that grows with the universe. The sparse vector proof is tight: on a worst-case pair the loss approaches $\varepsilon_1 + \varepsilon_2$ for every c, and noise that ignores c really does cost c times more. And the alarm mechanism's hidden condition matters at $K = 22$ but not at the chapter's $K = 10$.

K. Composition of trade-off functions

Two chapters of Part 4 compose differential privacy (DP) guarantees step by step. They are f-DP and Gaussian DP and Numerical accounting, and they lean on five results that they state but do not prove, and this appendix derives all five. Each result is about how well an attacker can tell two output distributions apart, which the chapters measure by a curve of the attacker's two kinds of error, the trade-off curve defined below.

The first result says that any curve with the four properties of a trade-off curve really is the curve of some pair of distributions. The next two say that running mechanisms one after another, even when each one is chosen after seeing the earlier outputs, leaks no more than running fixed, independent copies of the worst step. One of them says it with trade-off curves and the other with hockey-stick divergences, a second measure of the same leak. The last two are central limit theorems: when there are many small steps, the composed curve comes close to the curve of two normal distributions with the same variance. The first three results share one move. You take a test that an attacker runs on one pair of distributions and replace it, piece by piece, by a test on another pair that does at least as well. The central limit theorems instead follow the best tests of the composed pair and watch their errors approach those of the two normal distributions.

Table K.1 lists the five derivations and where the book states or uses each one. Each section restates the terms it needs, so the table only points the way.

Table K.1.: The derivations of this appendix and the chapter sections that state or use them.

Derivation	What it proves	Stated or used in
Section K.1	Every convex, non-increasing, continuous $f \le 1 - \alpha$ is the trade-off curve of a pair	Section 4.5, Section 32.3, Section 32.6
Section K.2	Composition of f-DP, adaptive steps included, and the tensor product is well defined	Section 32.6 (Equation 32.12)
Section K.3	Dominating pairs survive adaptive composition	Section 34.4, Section 34.5, Section 37.2
Section K.4	The f-DP central limit theorem with its Berry–Esseen band	Section 32.7 (Equation 32.14)
Section K.5	The central limit theorem for the Poisson-subsampled Gaussian	Section 32.8 (Equation 32.17), Section 34.8, Section 37.2

Notation. The notation is that of f-DP and Gaussian DP. A mechanism M runs either on a dataset D or on a neighbouring dataset D', written $D \sim D'$, which adds or removes one record (the results hold for any neighbouring relation). Write $P = M(D)$ for the distribution of its output on D and $Q = M(D')$ for the distribution on D'. Their densities, or probabilities for discrete outputs, are p and q.

A **test** ϕ looks at the output y and fires, deciding that the data was D', with probability $\phi(y)$. How often it fires on D is its type I error $\alpha = \mathbb{E}_P[\phi]$. How often it fires on D' is its **power** $\mathbb{E}_Q[\phi]$, and how often it stays silent there is its type II error $\beta = 1 - \mathbb{E}_Q[\phi]$.

The **trade-off function** $T(P, Q)$ gives, at each type I error α, the smallest type II error that any test with type I error at most α can reach. A **pair** always means such a pair of distributions (P, Q), and its curve means $T(P, Q)$. A mechanism is f-DP when the curve of every neighbouring pair lies on or above the curve f, so that no test does better than f allows. The privacy loss of an output measures how much more likely the output is on D than on D',

$$L(y) = \ln \frac{p(y)}{q(y)}. \tag{K.1}$$

One fact from Hypothesis testing carries most of the weight, so here it is once. The **Neyman–Pearson lemma** (Section 4.4) says that the best test at any type I error is a likelihood-ratio test. Such a test fires where q/p is above a threshold and stays silent where it is below. On outputs exactly at the threshold it may fire with any probability, and this coin flip is what lets the test spend its type I error exactly when the threshold outputs carry positive mass. For every $\alpha \in (0, 1]$ such a test exists with type I error exactly α, and its type II error is $T(P, Q)(\alpha)$. At $\alpha = 0$ the best test fires only on outputs that P never produces. In terms of the loss, $q/p = e^{-L}$, so the best tests fire when L is small.

K.1. Every trade-off function has a canonical pair

K.1.1. What the chapter uses

f-DP and Gaussian DP calls f a trade-off function when it is the curve $T(P, Q)$ of some pair (Section 32.3). Every such curve has four properties: it is non-increasing, convex and continuous, and it lies on or below the line $1 - \alpha$ of the test that ignores the output and fires at random. The composition theorem of the next section needs the converse. It starts from curves $f_1, \dots, f_k$, one per step, that are only known to have the four properties, and it needs a pair of distributions behind each one. The converse says that the four properties are enough, and it builds the pair.

Let $f\colon [0, 1] \to [0, 1]$ have the four properties. Let P_f be the uniform distribution on $[0, 1]$, and let Q_f put mass $f(1 - x)$ on each interval $[0, x]$,

$$Q_f([0, x]) = f(1 - x) \quad \text{for } x \in [0, 1]. \tag{K.2}$$

This may leave Q_f short of total mass 1. So Q_f also has an **atom**, a single point carrying positive probability, at a point outside $[0, 1]$, say at 2, and the atom carries the missing mass $1 - f(0)$. Then

$$T(P_f, Q_f) = f. \tag{K.3}$$

The pair (P_f, Q_f) is the **canonical pair** of f. Hypothesis testing already gives this construction in one paragraph of Section 4.5. The f-DP chapter cites only the forward statement, that every curve of a pair has the four properties. This section spells the converse out step by step, because the next section depends on it.

K.1.2. The idea

Take P_f uniform, so that a test which fires on an interval of length α has type I error exactly α. Then shape Q_f so that firing on the top interval $(1-\alpha, 1]$ misses exactly $f(\alpha)$ of Q_f. That forces the mass of Q_f below $1-\alpha$ to be $f(\alpha)$, which is the formula above. A value $f(0)$ below 1 means that some test reaches type II error $f(0) < 1$ with no type I error at all. So Q_f needs mass $1 - f(0)$ in a place where P_f has none, and the atom outside $[0, 1]$ supplies exactly that mass. What remains is to check that these top-interval tests are the best tests. Step 2 below shows that convexity makes the density of Q_f rise from left to right. Since P_f has the flat density 1, the likelihood ratio rises too, and the Neyman–Pearson lemma says the best tests fire where the ratio is highest, which is at the top.

A Gaussian example makes the construction concrete. The Gaussian curve G_μ is the curve of the normal distribution $\mathcal{N}(0, 1)$ against the normal distribution $\mathcal{N}(\mu, 1)$ with its mean shifted by μ. A mechanism whose neighbouring pairs all have curves on or above G_μ satisfies Gaussian differential privacy (GDP) with parameter μ, written μ-GDP. For $\mu = 1$ the canonical pair is easy to recognize. Let Z be standard normal and Φ its distribution function. Then P_f is the law, meaning the distribution, of $\Phi(Z)$, which is uniform on $[0, 1]$ because for every $x \in [0, 1]$

$$\Pr[\Phi(Z) \le x] = \Pr[Z \le \Phi^{-1}(x)] = x. \tag{K.4}$$

And Q_f is the law of $\Phi(Z + 1)$. Applying the increasing function Φ to both $\mathcal{N}(0, 1)$ and $\mathcal{N}(1, 1)$ is a one-to-one relabelling of the outputs, so it changes no test's errors and the pair still has curve G_1. Figure K.1 shows this pair and the test at $\alpha = 0.1$.

K.1.3. Derivation

1. **Q_f is a probability distribution.** Write $F(x) = f(1-x)$. As x grows, $1-x$ shrinks, and f is non-increasing, so F is non-decreasing. Property $f(\alpha) \le 1-\alpha$ at $\alpha = 1$ forces $f(1) = 0$, so $F(0) = 0$, and $F(1) = f(0) \le 1$. The atom adds the missing mass $1 - f(0)$, so the total is 1.
2. **Q_f has a non-decreasing density on $[0, 1]$.** This step uses three standard facts about a convex function, which are cited (Rockafellar 1970, §§23–24). It has a slope $f'(\alpha)$ at every point except at most countably many kinks, its slope never decreases as α grows, and it is the integral of its slope. So F has density $F'(x) = -f'(1-x)$, which is minus the slope of f at $1-x$. Now let x grow. Then $1-x$ shrinks, and because the slope of f never decreases as its argument grows, it can only fall, that is become more negative, as its argument shrinks. So $f'(1-x)$ can only become more negative, and the density $-f'(1-x)$ can only grow. At a kink the density has a jump, and either one-sided value can stand for it.
3. **The likelihood ratio is non-decreasing.** The density of P_f is 1 on $[0, 1]$, so the likelihood ratio q/p equals the density of Q_f there. At the atom, P_f has no mass, so the ratio is infinite.

4. **The top-interval tests are likelihood-ratio tests.** Fix $\alpha \in (0, 1]$ and let ϕ_α fire on the atom and on every $x > 1 - \alpha$. Take the threshold τ to be the density just to the left of $1 - \alpha$, which is well defined even when $1 - \alpha$ is a kink, because a non-decreasing function has a limit from each side. By step 3, the ratio is at least τ wherever ϕ_α fires and at most τ wherever it is silent. Outputs with ratio exactly τ are ties, and the lemma allows any behaviour on ties. So ϕ_α is a likelihood-ratio test, and no test with type I error at most α has a smaller type II error.
5. **Read off the errors.** The type I error of ϕ_α is the uniform mass of $(1 - \alpha, 1]$, which is α, since the atom has no P_f-mass. Its type II error is the Q_f-mass where it is silent, $Q_f([0, 1 - \alpha]) = F(1 - \alpha) = f(\alpha)$. So $T(P_f, Q_f)(\alpha) = f(\alpha)$ for $\alpha \in (0, 1]$. At $\alpha = 0$ the best test fires on the atom only, and it misses $F(1) = f(0)$.

K.1.4. Checking it

The script of this appendix, apx_composition.py, coarsens each canonical pair into 1000 equal cells of $[0, 1]$, plus the atom. It then computes the trade-off curve of this finite pair exactly, by sorting the cells by likelihood ratio. Reporting only the cell that the output fell in is post-processing, a function applied to the output, and no test can gain from seeing less, so the coarse curve can only lie above f. It still touches f at the cell edges, because a test that fires on the top cells fires on a top interval, and that test is still available with the same errors. For $f = G_1$ the largest gap is 2.0×10^{-3}, near $\alpha = 0$, where G_1 is steepest. The second example is the curve of an (ε, δ)-DP guarantee, which the chapter writes as a curve made of two straight lines,

$$f_{\varepsilon,\delta}(\alpha) = \max\left(0,\ 1 - \delta - e^{\varepsilon}\alpha,\ e^{-\varepsilon}(1 - \delta - \alpha)\right). \tag{K.5}$$

With $\varepsilon = 1$ and $\delta = 0.1$ its largest gap is 8.3×10^{-5}. Both gaps shrink as the cells shrink, which is what Equation K.3 predicts.

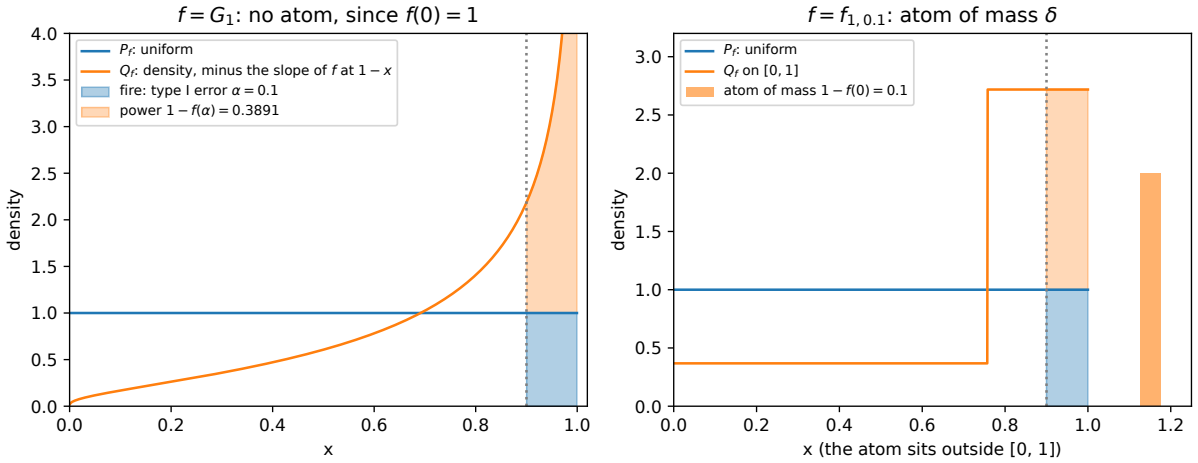

Figure K.1.: The canonical pair of two trade-off functions. Left: for $f = G_1$, the uniform P_f and the density of Q_f, which is minus the slope of f at $1 - x$; the test that fires on $(0.9, 1]$ has type I error 0.1 (blue area) and power $1 - G_1(0.1) = 0.3891$ (orange area). Right: for $f_{1,0.1}$, the density of Q_f steps from e^{-1} to e at $x = 1 - 0.2420$, and the missing mass $\delta = 0.1$ sits in an atom outside $[0, 1]$ that every good test fires on.

In Figure K.1 (right), the density of Q_f on $[0,1]$ has two levels, e^{-1} and e, which are minus the two slopes $-e^{-1}$ and $-e$ of $f_{1,0.1}$. The step sits at $1-\alpha^*$, where α^* is the corner of $f_{1,0.1}$, the point where its two lines meet. Setting $1-\delta-e\,\alpha = e^{-1}(1-\delta-\alpha)$ with $\delta = 0.1$ gives $\alpha^* = 0.9/(1+e) = 0.2420$. The atom carries the $\delta = 0.1$ of mass that a test can catch with no type I error.

K.2. Composition of f-DP, adaptive steps included

K.2.1. What the chapter uses

When an attacker sees the outputs of two mechanisms, it faces two joint distributions, one for D and one for D'. The simplest case is two independent mechanisms. Their joint output then has the **product** distribution $P \times P'$, under which the two coordinates are drawn independently, one from P and one from P'. The chapter defines the **tensor product** of two trade-off functions $f = T(P,Q)$ and $g = T(P',Q')$ as the curve of the product pair,

$$f \otimes g = T(P \times P', Q \times Q'). \tag{K.6}$$

The composition theorem then says that composing f_i-DP mechanisms gives an $f_1 \otimes \cdots \otimes f_k$-DP mechanism, even when each mechanism is chosen after seeing the earlier outputs. In symbols, suppose M_1 is f_1-DP and, for every value y_1 of its output, the second mechanism $M_2(\cdot\,; y_1)$ is f_2-DP. Then the pair of outputs (y_1, y_2) satisfies

$$T\big((M_1,M_2)(D),(M_1,M_2)(D')\big) \geq f_1 \otimes f_2 \quad \text{for all neighbours } D \sim D', \tag{K.7}$$

and the same holds for k steps with $f_1 \otimes \cdots \otimes f_k$. Section 32.6 states this theorem (Dong, Roth & Su 2022, Theorem 3.2) and leaves three gaps. The chapter proves the non-adaptive case through Blackwell's theorem, a cited result that compares two pairs through post-processing. For the adaptive case, the chapter reports that Dong et al. prove it "with the Neyman–Pearson lemma alone" and uses the result without a proof. Finally, the chapter cites without proof the fact that $f \otimes g$ does not depend on which pairs represent f and g (their Definition 3.1), which is what makes the tensor product well defined. This section proves the non-adaptive case, the adaptive case and this independence of the pairs, using only the Neyman–Pearson lemma.

K.2.2. The idea

Take the adaptive example of Rényi DP (Table 29.5), which uses randomized response, a mechanism that reports a person's bit truthfully with some keep-probability and flips it otherwise. One person's bit is 1 in D and 0 in D'. The first step keeps the bit with probability 0.75, and the second step's keep-probability depends on the first output, 0.75 if it was 1 and 0.6 if it was 0. Each step's curve lies on or above f, the curve of randomized response with keep-probability 0.75. The reason is that a keep-probability closer to $\frac{1}{2}$ makes the report closer to a fair coin, and so hides the bit better. So the theorem promises that the joint curve lies on or above $f \otimes f$, the curve of two independent runs with keep-probability 0.75. Table K.2 lists the four joint outputs.

Table K.2.: Two adaptive randomized responses: keep-probability 0.75, then 0.75 or 0.6 depending on y_1.

(y_1, y_2)	p, bit 1 (D)	q, bit 0 (D')	q/p
(1, 1)	0.5625	0.0625	0.111
(1, 0)	0.1875	0.1875	1
(0, 1)	0.15	0.3	2
(0, 0)	0.1	0.45	4.5

An attacker's joint test can be read one branch at a time, where a branch is one value of the first output. For each first output y_1, what the test does with y_2 is a test of the second step's pair on that branch. The plan is to swap each branch's pair for a fixed pair whose curve is exactly f, here randomized response with keep-probability 0.75 itself, and each branch's test for the best test of that fixed pair at the same type I error. The type I error does not change, and the type II error cannot grow, because f lies on or below that branch's curve. After the swap every branch uses the same fixed pair, so the second output no longer depends on the first, and the joint pair is a product. The first coordinate is then swapped in the same way, now one value of the second output at a time. The result is a test on the product pair that is at least as good as the attacker's test, so no attacker beats $f \otimes f$.

Here it is on one test. The test that fires only on $(0, 0)$ has type I error $p(0, 0) = 0.1$ and type II error $1 - 0.45 = 0.55$. On the branch $y_1 = 1$ it never fires, and on the branch $y_1 = 0$ it fires when $y_2 = 0$. That branch keeps the bit with probability 0.6, so the branch test fires with probability 0.4 on D and 0.6 on D'. The best test of the fixed pair at type I error 0.4 always fires on output 0, which has probability 0.25 on D and 0.75 on D'. To spend the remaining 0.15 of type I error, it also fires on output 1 with probability 0.2, since output 1 has probability 0.75 on D. That adds $0.2 \times 0.25 = 0.05$ of power, so the test's power is $0.75 + 0.05 = 0.8$, more than the branch test's 0.6.

Swapping it in, the joint type I error stays $0.25 \times 0.4 = 0.1$, since the first output is 0 with probability 0.25 on D. The power becomes $0.75 \times 0.8 = 0.6$, since the first output is 0 with probability 0.75 on D'. So the type II error drops from 0.55 to 0.4, which is exactly the value of $f \otimes f$ at 0.1. To check that value, take the best test of the product pair at type I error 0.1. It fires on $(0, 0)$, which costs 0.0625 of type I error and brings 0.5625 of power. It spends the remaining 0.0375 on the two mixed outputs, where $q/p = 1$, so they add 0.0375 of power, and the type II error is $1 - 0.6 = 0.4$.

K.2.3. Derivation

Write the two joint distributions with the first output's law and the second output's law given the first: $P(y_1, y_2) = P_1(y_1)P_2(y_2 \mid y_1)$ and $Q(y_1, y_2) = Q_1(y_1)Q_2(y_2 \mid y_1)$. The assumption is that $T(P_1, Q_1) \geq f_1$, and that $T(P_2(\cdot \mid y_1), Q_2(\cdot \mid y_1)) \geq f_2$ for every y_1. By Section K.1 there are pairs $(\tilde{P}_i, \tilde{Q}_i)$ with curve exactly f_i, for example the canonical pairs.

1. **The replacement step.** One pair can be swapped for another whose curve is lower, one test at a time. Suppose $T(P, Q) \geq T(\tilde{P}, \tilde{Q})$. Then for every test ϕ of P against Q there is a

test $\tilde{\phi}$ of $\tilde{P}$ against $\tilde{Q}$ with

$$\mathbb{E}_{\tilde{P}}[\tilde{\phi}] = \mathbb{E}_P[\phi] \qquad \text{and} \qquad 1 - \mathbb{E}_{\tilde{Q}}[\tilde{\phi}] \le 1 - \mathbb{E}_Q[\phi]. \tag{K.8}$$

In words, $\tilde{\phi}$ has the same type I error and a type II error no larger. To find it, let $\alpha = \mathbb{E}_P[\phi]$ and take $\tilde{\phi}$ to be the likelihood-ratio test of $\tilde{P}$ against $\tilde{Q}$ with type I error exactly α, which exists by the Neyman–Pearson lemma. For $\alpha = 0$ it is the test that fires on every output where $\tilde{p} = 0$, which is best because firing anywhere else would cost type I error. Its type II error is $T(\tilde{P}, \tilde{Q})(\alpha)$, which is at most $T(P, Q)(\alpha)$ by assumption. That is at most the type II error of ϕ, because ϕ is one of the tests the minimum in $T(P, Q)(\alpha)$ ranges over.

2. **Swap the second coordinate, one branch at a time.** Fix any joint test $\phi(y_1, y_2)$. For a fixed y_1, the function $\phi(y_1, \cdot)$ is a test of $P_2(\cdot \mid y_1)$ against $Q_2(\cdot \mid y_1)$, and that pair's curve is at least $f_2 = T(\tilde{P}_2, \tilde{Q}_2)$. Step 1 gives a test $\tilde{\phi}_{y_1}$ of $\tilde{P}_2$ against $\tilde{Q}_2$ with the same type I error on this branch and at least the same power. Now replace the second output too. Write z_2 for an output of the fixed pair, drawn from $\tilde{P}_2$ or $\tilde{Q}_2$ independently of y_1, and define the new joint test $\phi'(y_1, z_2) = \tilde{\phi}_{y_1}(z_2)$. It is a test of the pair $P_1 \times \tilde{P}_2$ against $Q_1 \times \tilde{Q}_2$, in which the second output no longer depends on the first.
3. **Average over the first output.** The joint type I error of ϕ is the average over $y_1 \sim P_1$ of the branch type I errors, and step 2 kept each of these. So ϕ' has the same joint type I error:
$$\mathbb{E}_{P_1 \times \tilde{P}_2}[\phi'] = \mathbb{E}_{y_1 \sim P_1}\big[\mathbb{E}_{\tilde{P}_2}\tilde{\phi}_{y_1}\big] = \mathbb{E}_{y_1 \sim P_1}\big[\mathbb{E}_{P_2(\cdot \mid y_1)}\phi(y_1, \cdot)\big] = \mathbb{E}_P[\phi]. \tag{K.9}$$
The joint power is the average over $y_1 \sim Q_1$ of the branch powers, and step 2 raised or kept each of them. So $\mathbb{E}_{Q_1 \times \tilde{Q}_2}[\phi'] \ge \mathbb{E}_Q[\phi]$, and the joint type II error did not grow.
4. **Swap the first coordinate.** The pair is now a product. So for each fixed z_2, the function $\phi'(\cdot, z_2)$ is a test of P_1 against Q_1, whatever z_2 is. Step 1, with $T(P_1, Q_1) \ge f_1 = T(\tilde{P}_1, \tilde{Q}_1)$, swaps it for a test of $\tilde{P}_1$ against $\tilde{Q}_1$ with the same type I error and at least the same power. Averaging over $z_2 \sim \tilde{P}_2$ and $z_2 \sim \tilde{Q}_2$, as in step 3, gives a test ϕ'' of $\tilde{P}_1 \times \tilde{P}_2$ against $\tilde{Q}_1 \times \tilde{Q}_2$ with the type I error of ϕ and a type II error no larger. The order of the two swaps matters. Before step 2 the first output and the second were dependent, so fixing the second output would have changed the distribution of the first, and the branch test would no longer be a test of P_1 against Q_1.
5. **Conclude.** Take any α and any joint test ϕ with type I error at most α. Steps 2 to 4 give a test ϕ'' on the product pair with the same type I error and a type II error no larger. So the type II error of ϕ is at least $T(\tilde{P}_1 \times \tilde{P}_2, \tilde{Q}_1 \times \tilde{Q}_2)$ evaluated at that type I error. Trade-off curves are non-increasing, so it is also at least that curve at α, which is $f_1 \otimes f_2(\alpha)$. This is Equation K.7.
6. **The tensor product does not depend on the pairs.** Steps 2 to 5 never used that $P_2(\cdot \mid y_1)$ changes with y_1. So they also prove the non-adaptive statement: if $T(P_i, Q_i) \ge T(\tilde{P}_i, \tilde{Q}_i)$ for $i = 1, 2$, then $T(P_1 \times P_2, Q_1 \times Q_2) \ge T(\tilde{P}_1 \times \tilde{P}_2, \tilde{Q}_1 \times \tilde{Q}_2)$. If both pairs have curve exactly f_i, the assumption holds in both directions, so the two product curves are each at least the other, and they are equal.
7. **Many steps, by induction.** The k-fold tensor product $f_1 \otimes \cdots \otimes f_k$ is the curve of the k-fold product pair, and step 6 shows that it does not depend on the pairs chosen. Suppose the first $k-1$ steps together are $f_1 \otimes \cdots \otimes f_{k-1}$-DP. That curve is the curve of the product pair $\tilde{P}_1 \times \cdots \times \tilde{P}_{k-1}$ against $\tilde{Q}_1 \times \cdots \times \tilde{Q}_{k-1}$. Treat the first $k-1$ outputs as one first output, and step k, chosen after seeing all of them, as the second step. Steps 2 to 5 then give the curve of $\tilde{P}_1 \times \cdots \times \tilde{P}_k$ against $\tilde{Q}_1 \times \cdots \times \tilde{Q}_k$, which is $f_1 \otimes \cdots \otimes f_k$.

K.2.4. Checking it

For the example of Table K.2, the script computes both curves exactly, by sorting the outputs by likelihood ratio. Each curve is made of straight pieces that meet at corners, written as (type I error, type II error). The adaptive pair's corners are at $(0.1, 0.55)$, $(0.25, 0.25)$ and $(0.4375, 0.0625)$, while the product's are at $(0.0625, 0.4375)$, $(0.25, 0.25)$ and $(0.4375, 0.0625)$. On a grid of 100,001 type I errors the adaptive curve is never below the product curve. The two touch from $\alpha = 0.25$ on and differ most, by 0.2812, at $\alpha = 0.0625$. The gap comes from the branch $y_1 = 0$, which keeps the bit only with probability 0.6 and so leaks less than the theorem charges for it.

The script also checks the replacement itself. It draws 20,000 random tests on the four joint outputs, with each $\phi(y_1, y_2)$ uniform on $[0, 1]$, and runs steps 2 and 4 on each one. No test had its type I error changed by more than 3.3×10^{-16}, which is rounding, and none had its type II error raised. On average the type II error fell by 0.4013, because random tests are far from optimal. Figure K.2 shows the replacement on single tests, and it shows that step 4 matters too. For example, the test that fires only on $(1, 1)$, the output most typical of D, has type II error 0.9375 at type I error 0.5625. Step 2 lowers the type II error to 0.7708, and step 4, which swaps the first coordinate for the best test of the fixed pair, lowers it to 0.1042.

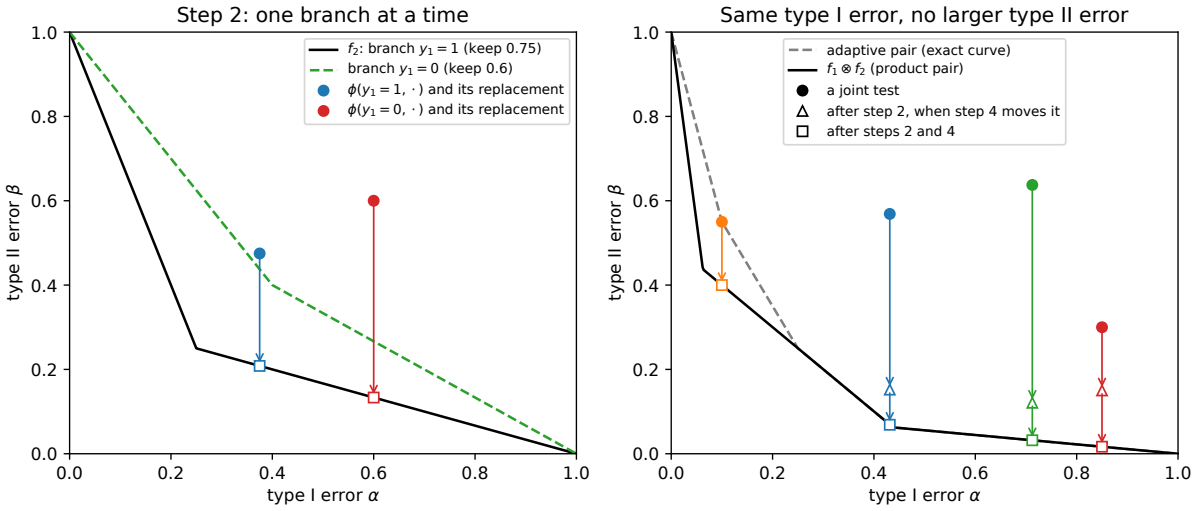

Figure K.2.: Test replacement for two adaptive randomized responses. Left: step 2 on each branch, where the attacker's test (dot) is swapped for the best test of the fixed pair with curve f_2 at the same type I error (square). On branch $y_1 = 1$ the branch pair is the fixed pair itself, and on branch $y_1 = 0$ (keep 0.6) its curve lies above f_2. Right: four joint tests on the adaptive pair, after step 2 (triangles, shown when step 4 moves them further) and after steps 2 and 4 (squares); each moves straight down, onto or above $f_1 \otimes f_2$. The adaptive pair's own curve (grey, dashed) lies above $f_1 \otimes f_2$.

K.2.5. What it does not cover

With continuous outputs there is a technical condition. Step 2 chooses one test per branch, and the averages in step 3 make sense only if the joint test ϕ' is a measurable function of (y_1, z_2), which roughly means that its averages are well defined. Choosing the canonical pair as $(\tilde{P}_2, \tilde{Q}_2)$

settles this. Its best test at type I error α is "fire when $z_2 > 1-\alpha$ or z_2 is the atom". So $\phi'(y_1, z_2)$ is that formula with α replaced by the branch's type I error, which is itself an average of ϕ over y_2 and so a measurable function of y_1. For finite outputs, as in the examples, there is nothing to check.

The proof does not use Blackwell's theorem, which the chapter cites for the non-adaptive case. Blackwell's theorem says more. The curve of one pair lies on or above the curve of another exactly when the first pair can be obtained by post-processing the second, that is by applying one random function to the outputs of both its distributions. That stronger statement stays cited. The chapter also claims that no better bound than $f_1 \otimes \cdots \otimes f_k$ holds in general, and this needs no new argument. Suppose the steps ignore each other's outputs, and each f_i is exactly the curve of some neighbouring pair of step i. Then the joint pair is that product pair, so its curve equals the tensor product, as the chapter shows in step 3 of its derivation.

K.3. Dominating pairs survive adaptive composition

K.3.1. What the chapter uses

Numerical accounting compares pairs through the **hockey-stick divergence** with a general weight $\gamma \geq 0$,

$$E_\gamma(P\|Q) = \sum_y \big(P(y) - \gamma Q(y)\big)_+, \tag{K.10}$$

where $P(y)$ and $Q(y)$ are the probabilities of output y and $(x)_+$ is x when x is positive and 0 otherwise. This section writes sums, so it assumes outputs that take finitely or countably many values, as in its examples. For continuous outputs every sum becomes an integral of densities, and nothing else changes. At the weight $\gamma = e^\varepsilon$ the divergence is the smallest δ for which the pair satisfies the (ε, δ)-DP inequality $P(S) \leq e^\varepsilon Q(S) + \delta$ for every set of outputs S.

A pair (P, Q) **dominates** a mechanism M if $E_\gamma(M(D)\|M(D')) \leq E_\gamma(P\|Q)$ for all neighbours and all $\gamma \geq 0$, so that every (ε, δ) statement true of the pair is true of the mechanism. The theorem used in Section 34.4 says that domination survives composition. Suppose the pair (P_i, Q_i) dominates step i for every value of the earlier outputs. Then for every $\gamma \geq 0$,

$$E_\gamma(M(D) \,\|\, M(D')) \leq E_\gamma(P_1 \times \cdots \times P_k \,\|\, Q_1 \times \cdots \times Q_k), \tag{K.11}$$

where M is the adaptive composition of the k steps. The chapter cites this theorem and does not prove it: "Its proof is in Zhu, Dong & Wang (2022, Theorem 10)." The numerical-accounting chapter works with the privacy loss distribution (PLD), the distribution of the privacy loss L when the output is drawn from P, and it rounds every loss up to a grid to get a pessimistic PLD that belongs to a pair dominating the mechanism. The theorem is what lets that pessimistic PLD bound adaptive runs, in step 6 of Section 34.5. It also makes the PLD accountants of Section 37.2 valid for the differentially private form of stochastic gradient descent (SGD), called DP-SGD, whose steps depend on the model so far.

K.3.2. The idea

Unlike the previous section, this section's tests ϕ fire for P, as in the numerical-accounting chapter. The reason is that $E_\gamma(P\|Q)$ rewards finding P, so a test that fires for P makes the formulas shorter. Think of E_γ as a best net gain. A test earns one unit each time it fires on a draw from P and pays γ each time it fires on a draw from Q. Its average gain is $\mathbb{E}_P[\phi] - \gamma\,\mathbb{E}_Q[\phi]$, and step 1 below shows that the best gain over all tests is $E_\gamma(P\|Q)$. Domination says that, whatever the price γ, the dominating pair offers at least the best gain the mechanism offers.

A picture turns this into the replacement step of Section K.2. Draw each test as a point in the plane, with how often it fires under Q across and how often it fires under P up. The points of all tests fill a region, and the region's upper edge g gives, for each budget c of firing under Q, the most firing under P that a test can reach. Step 2 shows that this edge is concave, bending downward like an arch, because mixing two tests gives a point on the segment between them.

Now take a line of slope γ that touches the edge from above without crossing it. It meets the vertical axis at height E_γ, because the height of a line of slope γ through a test's point is exactly that test's gain, and the touching line passes through the best test. A concave edge is the lowest of its touching lines, so the values E_γ at all slopes $\gamma \geq 0$ fix the edge. If the dominating pair has every intercept at least as high, its edge is everywhere at least as high, and its region contains the other one. So every test on the dominated pair has a counterpart on the dominating pair that fires at least as often under P and at most as often under Q.

That counterpart plays the role of the replacement step of Section K.2. There the counterpart had the same type I error and no larger type II error, and here it has two inequalities instead, one in each error. Both inequalities can only raise the gain $\mathbb{E}_P[\phi] - \gamma\,\mathbb{E}_Q[\phi]$, because $\gamma \geq 0$, so the branch-by-branch swap of the previous section goes through unchanged.

A small case shows the touching lines. Randomized response with keep-probability 0.75 has two outputs. The best tests fire first on the output that favours P, then on both. So the upper edge runs from $(0, 0)$ to $(0.25, 0.75)$ with slope 3, and then to $(1, 1)$ with slope $1/3$. A line of slope γ between $1/3$ and 3 touches the corner $(0.25, 0.75)$ and meets the vertical axis at $0.75 - 0.25\gamma$. The hockey-stick formula gives the same value, because $E_\gamma = (0.75 - 0.25\gamma)_+ + (0.25 - 0.75\gamma)_+$ and the second term is 0 once $\gamma \geq 1/3$. For example, the intercept and the formula both give 0.5 at $\gamma = 1$ and 0.25 at $\gamma = 2$.

K.3.3. Derivation

1. **The best gain is the hockey-stick divergence.** For every $\gamma \geq 0$,

$$E_\gamma(P\|Q) = \max_\phi \left(\mathbb{E}_P[\phi] - \gamma\,\mathbb{E}_Q[\phi]\right), \tag{K.12}$$

   where ϕ ranges over tests with values in $[0, 1]$. The gain is $\sum_y \phi(y)(P(y) - \gamma Q(y))$, and each term is largest when $\phi(y) = 1$ where $P(y) > \gamma Q(y)$ and $\phi(y) = 0$ elsewhere. That choice gives $\sum_y (P(y) - \gamma Q(y))_+$. This is Fact 3 of Divergences, on the best event, and it is also Equation 32.4 with the roles of the two distributions swapped.

2. **The upper edge of the region.** For a pair $(\tilde{P}, \tilde{Q})$ and $c \in [0,1]$, let

$$g(c) = \max\{\mathbb{E}_{\tilde{P}}[\tilde{\phi}] : \mathbb{E}_{\tilde{Q}}[\tilde{\phi}] \le c\}. \tag{K.13}$$

This is the Neyman–Pearson problem with the two distributions swapped, so the maximum is reached by a likelihood-ratio test that fires where $\tilde{p}/\tilde{q}$ is large. A bigger budget allows more tests, so g is non-decreasing. To see that g is concave, take tests $\tilde{\phi}_1$ and $\tilde{\phi}_2$ that reach g at budgets c_1 and c_2, and a weight $\lambda \in [0,1]$. The mixed test $\lambda\tilde{\phi}_1 + (1-\lambda)\tilde{\phi}_2$ mixes both of their averages (Hypothesis testing, the fact that mixing tests mixes their errors). So it fires under $\tilde{Q}$ at most $\lambda c_1 + (1-\lambda)c_2$ of the time and under $\tilde{P}$ exactly $\lambda g(c_1) + (1-\lambda)g(c_2)$ of the time. Then g at the mixed budget is at least the mixed value, which is what concave means.

3. **The edge is the lowest of its touching lines.** For every $c \in [0,1]$,

$$g(c) = \inf_{\gamma \ge 0} [E_\gamma(\tilde{P}\|\tilde{Q}) + \gamma c]. \tag{K.14}$$

The right side is never below $g(c)$. For any test with $\mathbb{E}_{\tilde{Q}}[\tilde{\phi}] \le c$, step 1 gives $\mathbb{E}_{\tilde{P}}[\tilde{\phi}] \le E_\gamma + \gamma\,\mathbb{E}_{\tilde{Q}}[\tilde{\phi}] \le E_\gamma + \gamma c$, because $\gamma \ge 0$. To see that the right side comes down to $g(c)$, use a line that touches g at c. For $0 < c < 1$, let γ^* be the slope of g just to the right of c. It is finite, because the slope of a concave function never increases, so it is at most the slope of the chord from 0 to c, which is at most $1/c$. It is at least 0 because g is non-decreasing. A concave function lies below each of its touching lines (Rockafellar 1970, §23), so $g(c') \le g(c) + \gamma^*(c' - c)$ for every c'. Now any test $\tilde{\phi}$ has $\mathbb{E}_{\tilde{P}}[\tilde{\phi}] \le g(c')$ with $c' = \mathbb{E}_{\tilde{Q}}[\tilde{\phi}]$, so its gain at price γ^* is at most $g(c') - \gamma^* c' \le g(c) - \gamma^* c$. By step 1, $E_{\gamma^*} + \gamma^* c \le g(c)$. The two ends of the budget need their own argument. At $c = 1$, the slope $\gamma^* = 0$ works, since $E_0 = 1 = g(1)$. At $c = 0$, the edge is $g(0) = \tilde{P}[\tilde{q} = 0]$, the mass that $\tilde{P}$ puts where $\tilde{Q}$ puts none. Then E_γ falls to exactly this value as $\gamma \to \infty$, because every output with $\tilde{q} > 0$ eventually contributes 0. So at $c = 0$ the infimum is reached only in the limit, which is why Equation K.14 uses inf rather than min.

4. **Domination puts one region inside the other.** Suppose $E_\gamma(P\|Q) \le E_\gamma(\tilde{P}\|\tilde{Q})$ for every $\gamma \ge 0$. Then for every test ϕ of P against Q there is a test $\tilde{\phi}$ of $\tilde{P}$ against $\tilde{Q}$ with

$$\mathbb{E}_{\tilde{P}}[\tilde{\phi}] \ge \mathbb{E}_P[\phi] \qquad \text{and} \qquad \mathbb{E}_{\tilde{Q}}[\tilde{\phi}] \le \mathbb{E}_Q[\phi]. \tag{K.15}$$

The reason: by step 1 and the assumption, $\mathbb{E}_P[\phi] \le E_\gamma(P\|Q) + \gamma\,\mathbb{E}_Q[\phi] \le E_\gamma(\tilde{P}\|\tilde{Q}) + \gamma\,\mathbb{E}_Q[\phi]$ for every $\gamma \ge 0$. Taking the smallest right side, Equation K.14 gives $\mathbb{E}_P[\phi] \le g(\mathbb{E}_Q[\phi])$. The test that reaches g at the budget $c = \mathbb{E}_Q[\phi]$ is the $\tilde{\phi}$ wanted.

5. **Swap branch by branch.** Take two adaptive steps. The letters P_i and Q_i already name the dominating pairs, so the run's own laws get new letters, A for the laws on D and B for those on D'. On D the first output has law A_1, and the second, given y_1, has law $A_2(\cdot \mid y_1)$. On D' the laws are B_1 and $B_2(\cdot \mid y_1)$. So the joint laws are $A_1(y_1)A_2(y_2 \mid y_1)$ and $B_1(y_1)B_2(y_2 \mid y_1)$. The fixed pair (P_2, Q_2) dominates $(A_2(\cdot \mid y_1), B_2(\cdot \mid y_1))$ on every branch, and (P_1, Q_1) dominates (A_1, B_1). Fix $\gamma \ge 0$ and a joint test ϕ. Its gain is

$$\sum_{y_1} \Big(A_1(y_1)\,\mathbb{E}_{A_2(\cdot|y_1)}\phi(y_1,\cdot) - \gamma\, B_1(y_1)\,\mathbb{E}_{B_2(\cdot|y_1)}\phi(y_1,\cdot) \Big). \tag{K.16}$$

On each branch, step 4 gives a test $\tilde{\phi}_{y_1}$ of P_2 against Q_2 that fires at least as often under P_2 and at most as often under Q_2. The weights $A_1(y_1)$ and $\gamma\, B_1(y_1)$ are not negative, so the swap raises the first part of each term or keeps it, and lowers the subtracted part or keeps it. So the gain does not fall, and the new test is a test of $A_1 \times P_2$ against $B_1 \times Q_2$.

That pair is a product, so for each fixed second output the test is a test of A_1 against B_1. Step 4 swaps each of these tests for a test of P_1 against Q_1 in the same way. The weights are now the probabilities of the second output under P_2 and γQ_2, which are again not negative. The result is a test of $P_1 \times P_2$ against $Q_1 \times Q_2$ with at least the gain of ϕ.

6. **Conclude, and induct.** Step 1 says that no test of the product pair gains more than E_γ of the product pair, so neither does ϕ. Step 1 also says that the best gain over joint tests ϕ is E_γ of the run's joint pair, so that divergence is at most E_γ of the product pair, which is Equation K.11 for two steps. Treating the first $k-1$ steps as one step, as in step 7 of Section K.2, extends it to k steps.

7. **The same theorem in the language of curves.** Domination at every $\gamma \geq 0$ turns out to be the same as an order between trade-off curves, and the proof goes both ways through step 4. To use the curves, switch back to tests that fire for Q, as in Section K.2, by reading $1-\phi$ and $1-\tilde{\phi}$, which fire exactly when ϕ and $\tilde{\phi}$ stay silent. First suppose that the pair $(\tilde{P}, \tilde{Q})$ dominates (P, Q). For any ϕ, step 4 gives a $\tilde{\phi}$, and the type I errors of $1-\phi$ and $1-\tilde{\phi}$ are $1-\mathbb{E}_P[\phi]$ and $1-\mathbb{E}_{\tilde{P}}[\tilde{\phi}]$, while their type II errors are $\mathbb{E}_Q[\phi]$ and $\mathbb{E}_{\tilde{Q}}[\tilde{\phi}]$. So the test $1-\tilde{\phi}$ is no worse in either error, and since trade-off curves are non-increasing this gives $T(P, Q) \geq T(\tilde{P}, \tilde{Q})$.

   Now suppose instead that $T(P, Q) \geq T(\tilde{P}, \tilde{Q})$. Take any test ϕ that fires for P. The replacement step of Section K.2, applied to $1-\phi$, gives a test χ of $\tilde{P}$ against $\tilde{Q}$ with the same type I error and a type II error no larger. Reading $\tilde{\phi} = 1-\chi$ back as a test that fires for P, it fires under $\tilde{P}$ exactly as often as ϕ fires under P, and under $\tilde{Q}$ at most as often as ϕ fires under Q. So its gain is at least that of ϕ at every $\gamma \geq 0$, and by step 1, $E_\gamma(P\|Q) \leq E_\gamma(\tilde{P}\|\tilde{Q})$.

   Together, the two directions say that domination at every $\gamma \geq 0$ is the same as $T(M(D), M(D')) \geq T(P, Q)$ for all neighbours. So the theorem of this section is the theorem of Section K.2, read through hockey-stick divergences.

K.3.4. Checking it

The three-step adaptive run of Adaptive composition (Table 36.5) is a good test case. The first step is randomized response with keep-probability 0.75. Then come a strong step (keep 0.75) and a weak step (keep 0.6), in an order set by the first output: if it is 1 the strong step comes second and the weak one third, and if it is 0 the order is reversed. Randomized response with keep-probability 0.75 dominates both kinds of step, so the theorem says the product of three such pairs dominates the run. The script checks E_γ of both at 502 values of γ in $[0, e^4]$, including 100 values below 1, and the product is never below the run. Table K.3 lists four of them.

Table K.3.: $\delta(\varepsilon) = E_{e^\varepsilon}(P\|Q)$ of the three-step adaptive run and of the product of its dominating pairs.

$\varepsilon = \ln\gamma$	0	1	2	3
Adaptive run, $\delta(\varepsilon)$	0.5750	0.3926	0.1528	0.0000
Product of three dominating pairs	0.6875	0.4190	0.3064	0.1080

The adaptive run's δ reaches 0 at its largest privacy loss. Along any path, the first step and the strong step each multiply the likelihood ratio by at most $0.75/0.25 = 3$, and the weak step by at most $0.6/0.4 = 1.5$. So the largest loss is $\ln(3 \times 3 \times 1.5) = \ln 13.5 = 2.6027$. The product's δ reaches 0 only at $3\ln 3 = 3.2958$, because it charges for three strong steps while no path of the run uses more than two (Figure K.3). The script also checks step 4 directly. Of 100,000 random tests on the run's eight transcripts, the possible triples of outputs, none lies above the product's upper edge g, and the closest comes within 0.0726 of it.

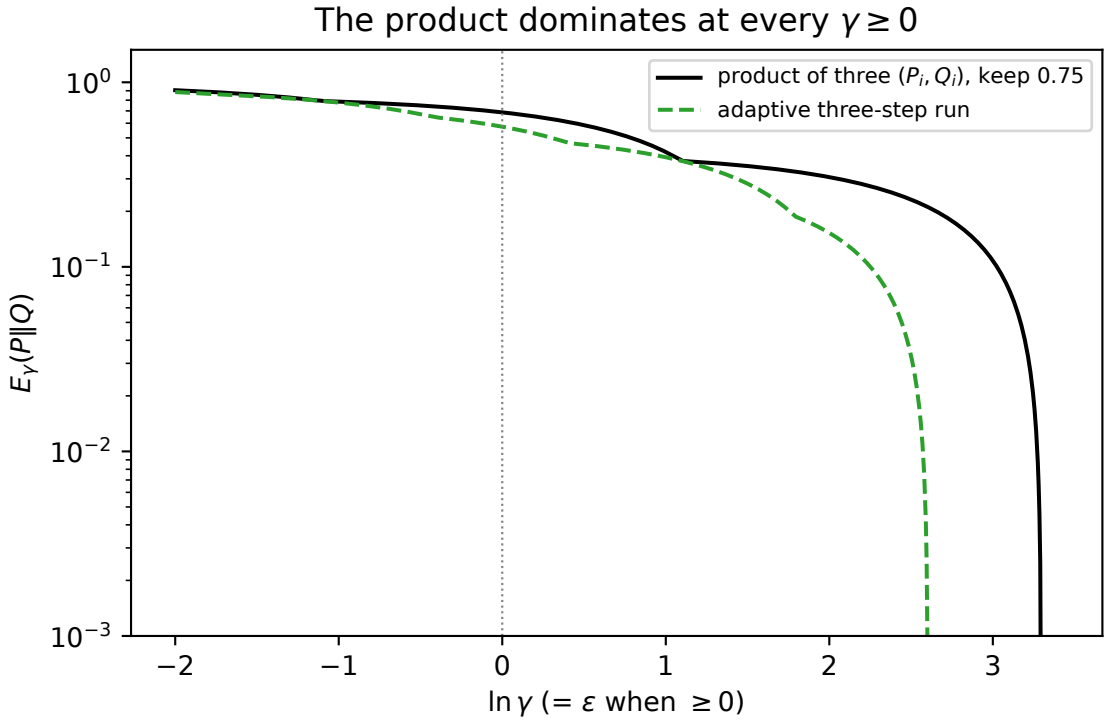

Figure K.3.: The hockey-stick divergence $E_\gamma(P\|Q)$ against $\ln\gamma$ for the three-step adaptive run (dashed) and for the product of three randomized responses with keep-probability 0.75 (solid). The product lies on or above the run at every $\gamma \geq 0$, including $\gamma < 1$ (left of the dotted line).

Figure K.4 draws the regions for a pair with a curved edge. The dominating pair has $P = \mathcal{N}(1, 1)$ and $Q = \mathcal{N}(0, 1)$, and the dominated pair has $P = \mathcal{N}(0.6, 1)$ and the same Q, so its region lies

inside. Three touching lines of the outer region, with slopes 0.5, 1 and e, meet the vertical axis at $E_\gamma = 0.5953$, 0.3829 and 0.1269. The inner pair's values are 0.5253, 0.2358 and 0.0190, all lower, as domination requires.

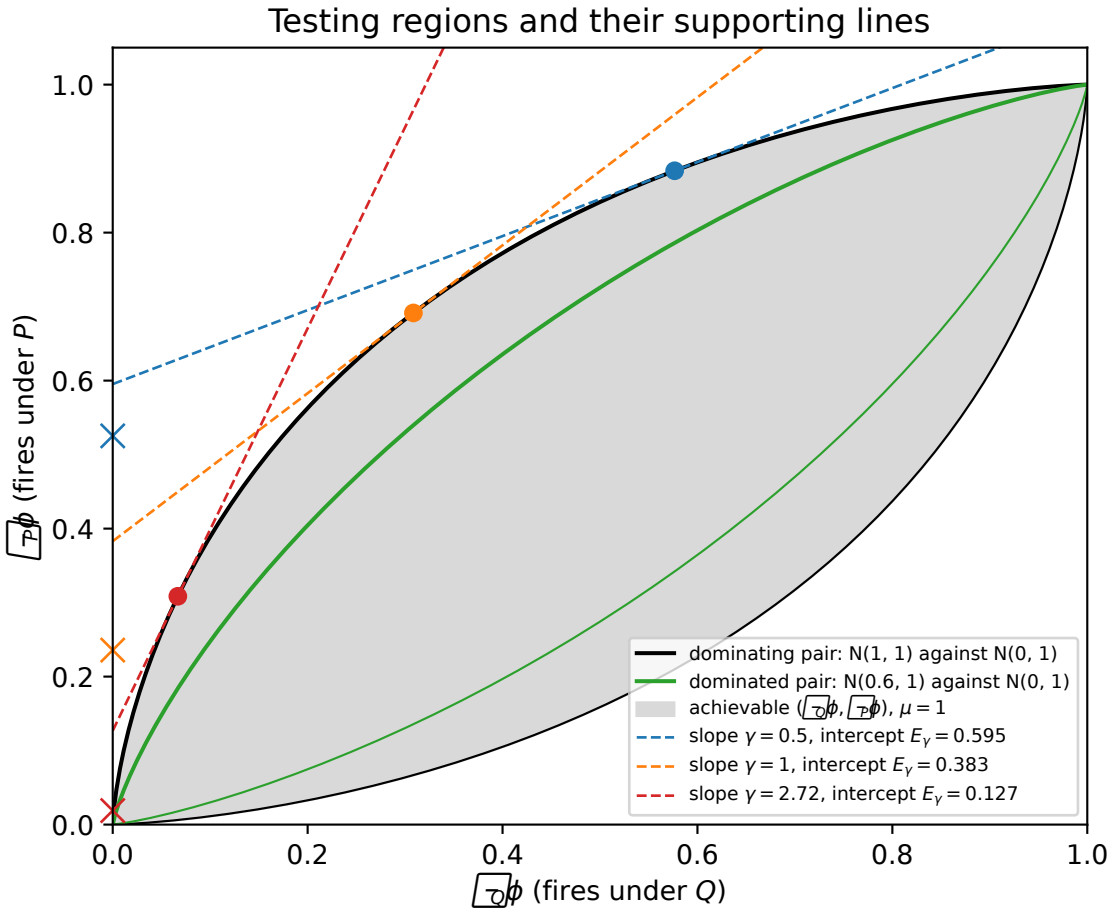

Figure K.4.: Testing regions in the plane of $(\mathbb{E}_Q\phi, \mathbb{E}_P\phi)$. The grey region holds every test of $\mathcal{N}(1,1)$ against $\mathcal{N}(0,1)$; the region of $\mathcal{N}(0.6,1)$ against $\mathcal{N}(0,1)$ (green) lies inside it. Each dashed line has slope γ and touches the outer edge at a dot; its height at 0 is E_γ of the outer pair. Crosses on the vertical axis mark E_γ of the inner pair, below each line.

K.3.5. What it does not cover

The theorem needs domination at every $\gamma \geq 0$, not only at $\gamma \geq 1$. In step 3 the touching line at a large budget c can have a slope below 1, so step 4 uses those values of γ. The values of E_γ below $\gamma = 1$ describe the reversed pair (Q, P), because

$$E_\gamma(P\|Q) = 1 - \gamma + \gamma\, E_{1/\gamma}(Q\|P). \tag{K.17}$$

To see it, split each term as $(P - \gamma Q)_+ = (P - \gamma Q) + (\gamma Q - P)_+$, and note that $(\gamma Q - P)_+ = \gamma(Q - P/\gamma)_+$. Summing over y, the first part gives $1 - \gamma$, since P and Q each sum to 1, and

the second gives $\gamma\, E_{1/\gamma}(Q\|P)$. So domination below $\gamma = 1$ is domination of the reversed pair at $1/\gamma > 1$. The theorem also assumes one fixed pair per step for every history. A pair that may change with the history is not covered, and that version stays with Zhu, Dong & Wang (2022).

K.4. The f-DP central limit theorem

K.4.1. What the chapter uses

f-DP and Gaussian DP states the central limit theorem (CLT) for composition in Section 32.7. The theorem describes the composed curve through a few averages of each step's privacy loss L_i, with the output drawn from P_i. The chapter computes these averages from the curve f_i alone, and step 1 below shows that they are moments of the loss. So read $\mathrm{kl}(f_i)$ as the mean of L_i, $\kappa_2(f_i)$ as its second moment $\mathbb{E}_P[L_i^2]$, $\kappa_3(f_i)$ as its third absolute moment $\mathbb{E}_P|L_i|^3$, and $\bar\kappa_3(f_i)$ as its third absolute moment about the mean, $\mathbb{E}_P|L_i - \mathbb{E}_P L_i|^3$. The theorem also assumes that every curve is symmetric, $f_i = T(P_i, Q_i) = T(Q_i, P_i)$, which means that telling D from D' is exactly as hard as telling D' from D.

Summing over the steps gives the moments of the composed loss $L = L_1 + \cdots + L_k$ under P. Its mean is $K = \sum_i \mathrm{kl}(f_i)$, and its variance is $V = \sum_i \kappa_2(f_i) - \sum_i \mathrm{kl}(f_i)^2$, each step's second moment minus its squared mean, summed. The chapter writes these sums as $\|\mathrm{kl}\|_1$ and $\|\kappa_2\|_1 - \|\mathrm{kl}\|_2^2$, and the summed third central moments as $\|\bar\kappa_3\|_1 = \sum_i \bar\kappa_3(f_i)$. With these it sets

$$\mu = \frac{2K}{\sqrt{V}}, \qquad w = \frac{0.56\,\|\bar\kappa_3\|_1}{V^{3/2}}, \tag{K.18}$$

where 0.56 is the constant of the Berry–Esseen theorem that step 3 states. In this section w is the width of a band. Dong, Roth & Su write it γ, which this book keeps for the level of the hockey-stick divergence. The band surrounds the Gaussian curve G_μ, the curve of $\mathcal{N}(0,1)$ against $\mathcal{N}(\mu,1)$, which is $G_\mu(\alpha) = \Phi(\Phi^{-1}(1-\alpha) - \mu)$ with Φ the standard normal distribution function. The theorem says that if $w < \frac{1}{2}$, then for all $\alpha \in [w, 1-w]$ the composed curve lies in the band

$$G_\mu(\alpha + w) - w \le f_1 \otimes \cdots \otimes f_k(\alpha) \le G_\mu(\alpha - w) + w. \tag{K.19}$$

This is Dong, Roth & Su (2022), Theorem 3.4.

The chapter also states a limit form for many steps that each leak little (their Theorem 3.5). Take, for each k, a fresh list of k symmetric curves. Suppose that as k grows the summed means tend to a limit, $\sum \mathrm{kl} \to K_\infty$, the largest mean tends to 0, the summed second moments tend to some $s^2 > 0$, and the summed third absolute moments tend to 0. Then the composed curve tends to $G_{2K_\infty/s}$. Their Theorem 3.6 applies this to steps that are ε_i-DP. The chapter explains why the theorem should hold and refers to Dong et al., Appendix D, for the proof. Its sketch explains in outline why $\mu = 2K/\sqrt{V}$ and why the curve is close to G_μ, and points here for the details. This section proves the band from the Berry–Esseen theorem, which stays cited, and shows that the argument forces the value $\mu = 2K/\sqrt{V}$ rather than choosing it.

K.4.2. The idea

The best test fires when the composed privacy loss L is below some threshold τ. Its type I error is $\Pr_P[L < \tau]$, a distribution function of L under P, and its power is $\Pr_Q[L < \tau]$, a distribution function of L under Q. The Berry–Esseen theorem, stated in step 3, says each is within w of a normal distribution function. Step 2 shows that symmetry makes the law of L under Q the mirror image of its law under P: mean $-K$ instead of K, with the same spread $\sqrt{V}$. So, measured in units of $\sqrt{V}$ from the mean under P, the two normal approximations are one curve and the same curve shifted left by $2K/\sqrt{V}$. Two normal curves one standard deviation wide and μ apart are exactly the Gaussian pair $\mathcal{N}(0,1)$ against $\mathcal{N}(\mu,1)$ behind G_μ. So each best test has a type I error within w, and a type II error within w, of the matching test of the Gaussian pair, and that is what the band says.

For an example, compose $k = 100$ randomized responses, each ε_0-DP with $\varepsilon_0 = 0.1$, so that each reports the bit truthfully with probability $e^{\varepsilon_0}/(1 + e^{\varepsilon_0})$. Each step's loss is then ± 0.1, and step 8 shows that its mean is $\varepsilon_0 \tanh(\varepsilon_0/2) = 0.1 \tanh(0.05) = 0.004996$. Its variance is $0.1^2 - 0.004996^2$, so over the 100 steps $K = 0.4996$, $V = 0.9975$ and $\mu = 2 \times 0.4996/\sqrt{0.9975} = 1.0004$. Figure K.6 (right) shows the two step-shaped distribution functions of $(L - K)/\sqrt{V}$, one under P and one shifted left by about 1 under Q.

K.4.3. Derivation

Let (P_i, Q_i) be pairs with curves f_i. By Section K.2, the composed curve $f_1 \otimes \cdots \otimes f_k$ is the curve of the product pair $P = \prod P_i$ against $Q = \prod Q_i$, whose privacy loss is $L = \sum_i L_i$ with independent terms.

1. **The functionals are moments of the loss.** The chapter computes kl, κ_2 and $\bar{\kappa}_3$ as integrals over $\alpha \in [0,1]$ of powers of $\ln|f'(\alpha)|$, and the link to the loss is the slope rule. Let $\tau(\alpha)$ be the threshold of the best test of size α, the point below which L has probability α under P. Moving that threshold to take in one more sliver of outputs near y raises the type I error by $p(y)\,\mathrm{d}y$ and lowers the type II error by $q(y)\,\mathrm{d}y$. So the curve's slope there is $-q/p = -e^{-\tau(\alpha)}$, and taking logs gives

$$-\ln|f'(\alpha)| = \tau(\alpha). \tag{K.20}$$

   The function τ is the inverse of the distribution function of L under P. So feeding a uniform α into τ draws a sample of L under P, just as feeding uniform random numbers into any inverse distribution function draws from that distribution. So averaging a function of $\tau(\alpha)$ over α uniform on $[0,1]$ averages that function of L under P. Applied to each step's curve f_i, this gives $\mathrm{kl}(f_i) = \mathbb{E}_P[L_i]$, $\kappa_2(f_i) = \mathbb{E}_P[L_i^2]$ and $\bar{\kappa}_3(f_i) = \mathbb{E}_P|L_i - \mathbb{E}_P L_i|^3$. Means and variances of independent terms add, so K and V are the mean and variance of L under P. The same step shows that the curve fixes the law of the loss under P, because it fixes the function $\tau(\alpha)$.

2. **Symmetry mirrors the law.** Swap the roles of P_i and Q_i. The swapped pair has privacy loss $\ln(q_i/p_i) = -L_i$, read under Q_i. Its curve is $T(Q_i, P_i) = f_i$, the same curve, so by step 1 its loss has the same law: $-L_i$ under Q_i has the law of L_i under P_i. Adding the independent steps, $-L$ under Q has the law of L under P. So under Q the loss has mean $-K$, variance V and the same third absolute central moments.

3. **Berry–Esseen under both laws.** The Berry–Esseen theorem bounds how far a standardized sum of independent terms can be from normal. Take such a sum S, and write m for its mean and V for its variance. Write ρ_3 for the sum of the third absolute central moments of its terms. Then for every x (Shevtsova 2010, with the constant 0.56)

$$\Big|\Pr\Big[\frac{S-m}{\sqrt{V}} \le x\Big] - \Phi(x)\Big| \le \frac{0.56\,\rho_3}{V^{3/2}}. \tag{K.21}$$

The same bound holds with $<$ in place of $\le$. To see it, let x rise towards a point x_0 from below. Then $\Pr[\cdot \le x]$ rises to $\Pr[\cdot < x_0]$, while $\Phi(x)$ moves continuously to $\Phi(x_0)$, so the bound survives the limit. Under P, with $S = L$, the right side is exactly the band width w defined above. Under Q the bound follows from step 2, which turns a statement about L under Q into one about $-L$ under P. For every y,

$$\Pr_Q\Big[\frac{L+K}{\sqrt{V}} < y\Big] = \Pr_P\Big[\frac{L-K}{\sqrt{V}} > -y\Big] = 1 - \Pr_P\Big[\frac{L-K}{\sqrt{V}} \le -y\Big], \tag{K.22}$$

which is within w of $1 - \Phi(-y) = \Phi(y)$, by the symmetry of the normal density.

4. **The errors of a best test.** By the Neyman–Pearson lemma, a best test fires when $L < \tau$ and, if L has an atom at τ, fires there with some probability λ. Its type I error α lies between $\Pr_P[L < \tau]$ and $\Pr_P[L \le \tau]$. Write $x = (\tau - K)/\sqrt{V}$ for the threshold in standard units under P. Both ends are within w of $\Phi(x)$ by step 3, so $|\alpha - \Phi(x)| \le w$. Its power lies between $\Pr_Q[L < \tau]$ and $\Pr_Q[L \le \tau]$. The event $L < \tau$ is the event $(L+K)/\sqrt{V} < x + 2K/\sqrt{V}$, so by step 3 the power is within w of $\Phi(x+\mu)$ with $\mu = 2K/\sqrt{V}$. In terms of the type II error $\beta = 1 - \text{power}$, and using $1 - \Phi(t) = \Phi(-t)$,

$$|\alpha - \Phi(x)| \le w, \qquad |\beta - \Phi(-x-\mu)| \le w. \tag{K.23}$$

This is where μ comes from. Under P and under Q the loss has the same spread, and its two means K and $-K$ are $2K/\sqrt{V}$ standard deviations apart. The Gaussian pair behind G_μ has exactly this picture, with means μ apart.

5. **Remove the threshold.** The Gaussian curve is $G_\mu(\alpha) = \Phi(-\Phi^{-1}(\alpha) - \mu)$, because $\Phi^{-1}(1-\alpha) = -\Phi^{-1}(\alpha)$. From $\Phi(x) \ge \alpha - w$ and the fact that Φ is increasing, $x \ge \Phi^{-1}(\alpha - w)$. Then $\Phi(-x-\mu) \le \Phi(-\Phi^{-1}(\alpha - w) - \mu) = G_\mu(\alpha - w)$, so $\beta \le G_\mu(\alpha - w) + w$. In the same way, $\Phi(x) \le \alpha + w$ gives $x \le \Phi^{-1}(\alpha + w)$ and $\beta \ge G_\mu(\alpha + w) - w$. The first bound needs $\alpha - w \ge 0$ and the second needs $\alpha + w \le 1$, so that Φ^{-1} is applied inside $[0,1]$, which is why the chapter states the band on $[w, 1-w]$. At the ends, where Φ^{-1} is infinite, the bound reads $\beta \le 1 + w$ or $\beta \ge -w$ and holds trivially.

6. **Every point of the curve.** For every type I error α, the Neyman–Pearson lemma gives a best test of size exactly α, and its type II error is the composed curve at α. Steps 4 and 5 apply to that test, so Equation K.19 holds at every $\alpha \in [w, 1-w]$.

7. **The limit form.** Take a triangular array, a fresh list of k symmetric curves for each k, with the chapter's four conditions. First, $V \to s^2$. Each mean kl_i is a Kullback–Leibler divergence and so cannot be negative, which means each squared mean is at most the largest mean times the mean. So $\sum_i \mathrm{kl}_i^2 \le \max_i \mathrm{kl}_i \sum_i \mathrm{kl}_i \to 0 \cdot K_\infty = 0$, and V has the same limit as $\sum_i \kappa_2$.

   Second, $w \to 0$, because a third absolute central moment is at most 8 times the third absolute moment. To see it, measure size by $\|X\|_3 = (\mathbb{E}|X|^3)^{1/3}$, which obeys the triangle

inequality. The mean m_i of L_i is at most $\|L_i\|_3$ in size, since an average is at most the average size and the average size is at most $\|L_i\|_3$. So $\|L_i - m_i\|_3 \le \|L_i\|_3 + |m_i| \le 2\|L_i\|_3$, and cubing gives the factor 8. Hence $\sum \bar{\kappa}_3 \le 8 \sum \kappa_3 \to 0$, so $w \to 0$ and $\mu \to 2K_\infty/s$.

Third, the band closes. Since μ converges, it stays below some bound $\mu_{\max}$. The function $(\mu, \alpha) \mapsto G_\mu(\alpha)$ is uniformly continuous on $[0, \mu_{\max}] \times [0, 1]$, so both edges of the band tend to $G_{2K_\infty/s}$ uniformly in α. Below $\alpha = w$, the composed curve and G_μ are both non-increasing and at most 1, so each lies between its value at w and 1. Both values at w tend to 1 as $w \to 0$, so the curve converges there too, and the same argument with 0 in place of 1 covers $\alpha > 1 - w$.

8. **Steps that are ε_i-DP.** Such a step is $f_{\varepsilon_i,0}$-DP, and the curve $f_{\varepsilon,0}$ is that of randomized response. Its loss is $+\varepsilon$ with probability $t = e^\varepsilon/(1+e^\varepsilon)$ and $-\varepsilon$ otherwise. So $\mathrm{kl} = \varepsilon(2t-1)$, and $2t - 1 = (e^\varepsilon - 1)/(e^\varepsilon + 1) = \tanh(\varepsilon/2)$. The loss always has size ε, so $\kappa_2 = \varepsilon^2$ and $\kappa_3 = \varepsilon^3$. For $x \ge 0$, $x - x^3/3 \le \tanh x \le x$, and with $x = \varepsilon/2$ this gives

$$\left|\varepsilon \tanh \frac{\varepsilon}{2} - \frac{\varepsilon^2}{2}\right| \le \frac{\varepsilon^4}{24}. \tag{K.24}$$

If $\sum \varepsilon_i^2 \to \mu^2$ and $\max \varepsilon_i \to 0$, then $\sum \mathrm{kl} \to \mu^2/2$, because the error is at most $\max \varepsilon_i^2 \sum \varepsilon_i^2/24 \to 0$. Also $\sum \kappa_2 \to \mu^2$ and $\sum \kappa_3 \le \max \varepsilon_i \sum \varepsilon_i^2 \to 0$. Step 7, with $K_\infty = \mu^2/2$ and $s = \mu$, gives the limit $G_{2(\mu^2/2)/\mu} = G_\mu$. By Section K.2 the composed mechanism is $\bigotimes f_{\varepsilon_i,0}$-DP, so its guarantee tends to μ-GDP.

K.4.4. Checking it

The script composes k randomized responses with $\varepsilon_0 = 1/\sqrt{k}$, exactly, from the binomial law of the number of truthful reports. Table K.4 compares the composed curve with the band. Its "room" columns give the smallest distance, over $\alpha \in [w, 1-w]$, between the curve and each edge of the band.

Table K.4.: The band of Equation K.19 for k randomized responses with $\varepsilon_0 = 1/\sqrt{k}$. The last column is the distance between the distribution function F of $(L-K)/\sqrt{V}$ under P and Φ, the quantity that Berry–Esseen bounds by w.

k	μ	w	Smallest room above the lower edge	Smallest room below the upper edge	$\max_\alpha \lvert f(\alpha) - G_\mu(\alpha)\rvert$	Actual $\sup_x \lvert F(x) - \Phi(x)\rvert$
10	1.0042	0.1837	0.2151	0.2420	0.0137	0.1331
100	1.0004	0.0562	0.0611	0.0647	0.0014	0.0405
1000	1.0000	0.0177	0.0187	0.0193	0.0001	0.0127

The exact curve always stays inside the band, with room to spare (Table K.4). The Berry–Esseen step is nearly sharp here. Dividing the last column by the w column gives about 0.72 at every k, so the distribution function of the loss really is 0.72 times w away from Φ, because it jumps at each of its $k+1$ values. The curve is much closer to G_μ than that, 0.0137 at $k = 10$ and 0.0001 at $k = 1000$. The reason is that a jump moves both errors of a test at once. Just past an atom of

the loss, both distribution functions overshoot their normal curves. So the type I error grows and the type II error shrinks together, and a point that moves right and down at once moves roughly along the falling curve G_μ rather than away from it. So the band is valid but wide, and its width shrinks only like $1/\sqrt{k}$. At $k = 1$, $w = 0.7663$ is above $\frac{1}{2}$ and the theorem says nothing.

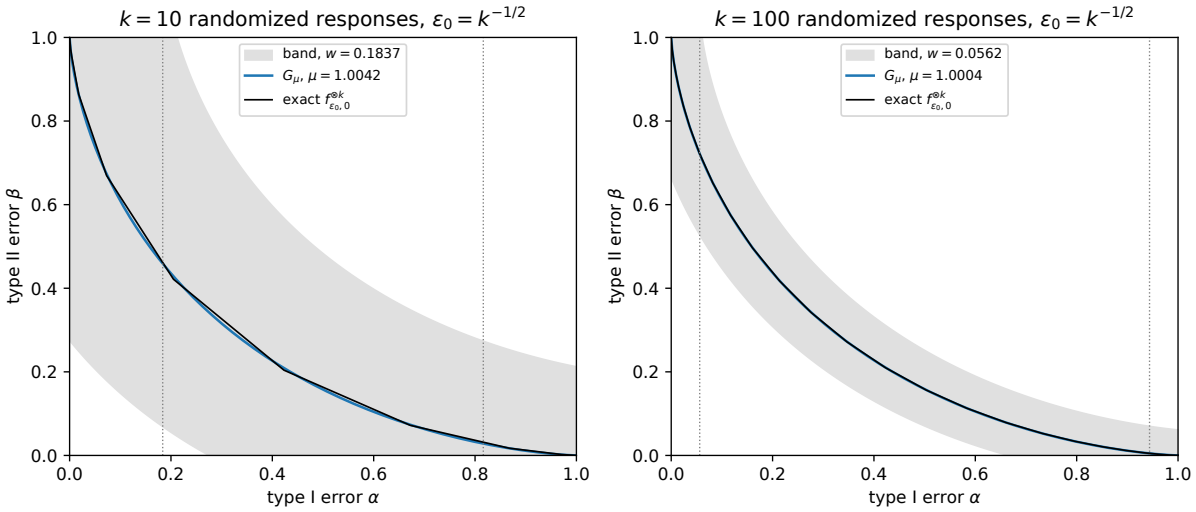

Figure K.5.: The band of the f-DP central limit theorem for k randomized responses with $\varepsilon_0 = k^{-1/2}$. Grey: the region between $G_\mu(\alpha + w) - w$ and $G_\mu(\alpha - w) + w$; blue: G_μ; black: the exact composed curve. Dotted lines mark $\alpha = w$ and $\alpha = 1 - w$, where the band starts to apply. Left: $k = 10$, $w = 0.1837$. Right: $k = 100$, $w = 0.0562$.

Figure K.6 shows steps 3 and 4. Each step function stays within w of its normal curve, and the shift between the two normal curves is the μ of the band in Figure K.5.

K.4.5. What it does not cover

The proof needs every f_i to be symmetric, because step 2 gets the law under Q from the law under P. Without symmetry the two laws have to be handled separately, as in Section K.5. The Berry–Esseen theorem and its constant 0.56 are cited (Shevtsova 2010). The central limit theorem itself, without a rate, is derived in Section E.3. The band is additive, so it says nothing useful about type I errors below w. Those are the errors that decide a small δ. The δ that goes with ε is the largest value of $1 - f(\alpha) - e^\varepsilon \alpha$ over α, and for a large ε the cost $e^\varepsilon \alpha$ pushes that largest value to a tiny α. This is why the chapter treats the CLT only as an approximation in the tails.

K.5. The central limit theorem for the subsampled Gaussian

K.5.1. What the chapter uses

Each step of DP-SGD forms a batch by Poisson subsampling, which includes each record independently with probability q, the sampling rate. It clips each record's gradient to the clipping norm and adds Gaussian noise whose standard deviation, in units of the clipping norm, is the noise

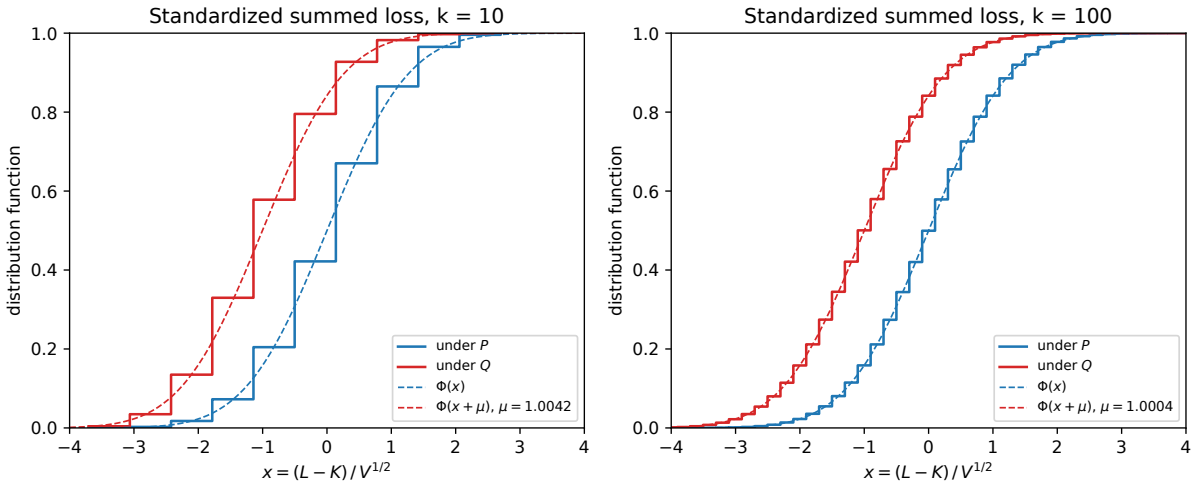

Figure K.6.: Distribution functions of the standardized composed loss $(L-K)/\sqrt{V}$ of k randomized responses, under P (blue steps) and under Q (red steps), against $\Phi(x)$ and $\Phi(x+\mu)$ (dashed). The law under Q is the mirror image of the law under P, shifted left by $\mu = 2K/\sqrt{V}$. Left: $k = 10$. Right: $k = 100$.

multiplier σ. The chapter uses add/remove neighbours, where D' is D with one target record added. The other records contribute the same to both outputs and can be subtracted, and the target record shifts the sum by at most one unit, and only when it lands in the batch. So one step reduces to the pair (Section 32.8)

$$P = \mathcal{N}(0, \sigma^2), \qquad Q = (1-q)\,\mathcal{N}(0, \sigma^2) + q\,\mathcal{N}(1, \sigma^2). \tag{K.25}$$

Under P the target record is absent, and under Q it is present and lands in the batch with probability q. This order of the two distributions is the **add direction**, and the reversed order (Q, P) is the **remove direction**. Since the letter q now names the sampling rate, this section writes the densities as $P(y)$ and $Q(y)$. The chapter states that if $k \to \infty$ and $q\sqrt{k} \to c$ with σ fixed, the k-fold composition is asymptotically μ-GDP with

$$\mu = q\sqrt{k(e^{1/\sigma^2} - 1)} \to c\sqrt{e^{1/\sigma^2} - 1}. \tag{K.26}$$

Write $v = e^{1/\sigma^2} - 1$, and write P^k and Q^k for the k-fold products of the pair. In the precise form proved here, with $c > 0$,

$$T(P^k, Q^k) \to G_{c\sqrt{v}} \quad \text{uniformly on } [0, 1]. \tag{K.27}$$

This is Bu, Dong, Long & Su (2020), Theorem 5.

The numerical-accounting chapter (Section 34.8) and Choosing an accountant (Section 37.2) use this formula as an approximation, but the chapter's derivation of it is labelled heuristic. It computes the leading terms of the mean and variance of one step's loss and plugs them into the $\mu = 2K/\sqrt{V}$ of the symmetric CLT, which leaves two gaps. The pair is not symmetric, so Equation K.19 does not apply as stated, and the remainder of the expansion is never bounded. This section closes both gaps.

K.5.2. The idea

The skeleton is the one of Section K.4. The best test fires when the summed loss is small, its errors are distribution functions of the loss under P and under Q, and Berry–Esseen makes each one nearly normal. What changes is that the law under Q is no longer a mirror image, so its mean and variance have to be computed on their own. They come out as mirror images to leading order. Under P one step's loss has mean about $+\frac{q^2}{2}v$, under Q about $-\frac{q^2}{2}v$, and both variances are about q^2v, with errors of order q^3. Over k steps the means become $\pm\frac{kq^2}{2}v \to \pm\frac{c^2}{2}v$ and the variances $kq^2v \to c^2v$, while the errors add up to order $kq^3 \to 0$. So, in standard units, the two laws become normal curves $c\sqrt{v}$ apart, which is the Gaussian pair with $\mu = c\sqrt{v}$.

At $q = 0.01$ and $\sigma = 1$, $v = e - 1 = 1.7183$. Computed to high accuracy by numerical integration, one step's loss has mean 8.1890×10^{-5} and variance 1.6009×10^{-4} under P. Under Q they are -8.3812×10^{-5} and 1.7163×10^{-4}. The leading terms are $\pm\frac{q^2}{2}v = \pm 8.5914 \times 10^{-5}$ and $q^2v = 1.7183 \times 10^{-4}$.

K.5.3. Derivation

1. **The loss.** The ratio of the $\mathcal{N}(1,\sigma^2)$ density to the $\mathcal{N}(0,\sigma^2)$ density at y is $e^{(y^2-(y-1)^2)/(2\sigma^2)} = e^{(y-1/2)/\sigma^2}$. So the likelihood ratio is $Q(y)/P(y) = 1 + qW$ with $W = e^{(y-1/2)/\sigma^2} - 1$, and the privacy loss is
$$L = \ln\frac{P(y)}{Q(y)} = -\ln(1+qW). \tag{K.28}$$
Since $W > -1$, the number $x = qW$ is above $-q$. So $x \geq -\frac{1}{2}$ whenever $q \leq \frac{1}{2}$, which step 3 needs and which every small sampling rate meets. From here on, $q \leq \frac{1}{2}$.

2. **All moments of W are finite.** Under P, $y \sim \mathcal{N}(0,\sigma^2)$, and $(1+W)^n = e^{ny/\sigma^2}e^{-n/(2\sigma^2)}$. The moment generating function $\mathbb{E}[e^{\lambda y}] = e^{\lambda^2\sigma^2/2}$ at $\lambda = n/\sigma^2$ gives $e^{n^2/(2\sigma^2)}$ for the first factor, so
$$\mathbb{E}_P\big[(1+W)^n\big] = e^{n(n-1)/(2\sigma^2)}. \tag{K.29}$$
Here n is any whole number. The first two cases give the mean and the second moment of W: the mean is 0, and $\mathbb{E}_P[W^2] = e^{1/\sigma^2} - 2 + 1 = v$. The absolute moments are bounded too, because $|W|^n \leq (1+W)^n + 1$ when $W \geq -1$ (a negative W has $|W| \leq 1$). So $\mathbb{E}_P|W|^n \leq e^{n(n-1)/(2\sigma^2)} + 1$. The later steps use moments up to the sixth, and all of them are finite. At $\sigma = 1$ this bound is 21.09 for the third moment and 404.43 for the fourth, the values that the checks below use. Averages under Q are averages under P weighted by the likelihood ratio, $\mathbb{E}_Q[h(W)] = \mathbb{E}_P[(1+qW)h(W)]$ for any function h, so they are finite as well.

3. **The logarithm with a bounded remainder.** For $x \geq -\frac{1}{2}$,
$$\ln(1+x) = x - \frac{x^2}{2} + R(x), \qquad |R(x)| \leq \frac{2}{3}|x|^3. \tag{K.30}$$
The remainder R is what is left after the first two terms. It starts at $R(0) = 0$, and its slope is $R'(x) = \frac{1}{1+x} - 1 + x = \frac{x^2}{1+x}$. For $x \geq 0$ that slope lies between 0 and x^2, so integrating from 0 gives $0 \leq R(x) \leq x^3/3$. For $-\frac{1}{2} \leq x < 0$ the denominator $1+x$ is at least $\frac{1}{2}$, so the

slope is at most $2x^2$, and integrating gives $|R(x)| \le \frac{2}{3}|x|^3$. The logarithm itself has slope $1/(1+x) \le 2$ on the same range, so

$$|\ln(1+x)| \le 2|x| \quad \text{for } x \ge -\tfrac{1}{2}. \tag{K.31}$$

4. **The means.** Under P, by steps 2 and 3, $L = -qW + \frac{q^2W^2}{2} - R(qW)$ has

$$\Big|\mathbb{E}_P[L] - \frac{q^2}{2}v\Big| \le \frac{2}{3}q^3\,\mathbb{E}_P|W|^3. \tag{K.32}$$

Under Q, weighting by $1+qW$ gives $\mathbb{E}_Q[L] = -\frac{q^2}{2}v + \frac{q^3}{2}\mathbb{E}_P[W^3] - \mathbb{E}_P[(1+qW)R(qW)]$, because $\mathbb{E}_P[(1+qW)(-qW + \frac{q^2W^2}{2})] = -q^2v + \frac{q^2}{2}v + \frac{q^3}{2}\mathbb{E}_P[W^3]$. The middle term is at most $\frac{q^3}{2}\mathbb{E}_P|W|^3$ in size. The last is at most $\frac{2}{3}q^3\,\mathbb{E}_P|W|^3 + \frac{2}{3}q^4\,\mathbb{E}_P[W^4]$, by the bound on R and $|1+qW| \le 1+q|W|$. Adding the two gives

$$\Big|\mathbb{E}_Q[L] + \frac{q^2}{2}v\Big| \le q^3\Big(\frac{7}{6}\,\mathbb{E}_P|W|^3 + \frac{2}{3}\,q\,\mathbb{E}_P[W^4]\Big). \tag{K.33}$$

5. **The variances.** Write $L = -qW + r$, where $|r| \le \frac{q^2W^2}{2} + \frac{2}{3}q^3|W|^3$. Then $\mathbb{E}_P[L^2] = q^2v - 2q\,\mathbb{E}_P[Wr] + \mathbb{E}_P[r^2]$. The middle term is at most $q^3\,\mathbb{E}_P|W|^3 + \frac{4}{3}q^4\,\mathbb{E}_P[W^4]$ in size, and the last is of order q^4. The squared mean is of order q^4 by step 4. So $\mathrm{Var}_P(L) = q^2v + O(q^3)$, where $O(q^3)$ means at most a constant times q^3, the constant depending only on σ through the moments of step 2. Under Q, $\mathbb{E}_Q[L^2] = \mathbb{E}_P[L^2] + q\,\mathbb{E}_P[WL^2]$, and $|L| \le 2q|W|$ by step 3 makes the extra term at most $4q^3\,\mathbb{E}_P|W|^3$. So $\mathrm{Var}_Q(L) = q^2v + O(q^3)$ as well.

6. **The third moments.** By step 3, $|L| \le 2q|W|$, so $\mathbb{E}_P|L|^3 \le 8q^3\,\mathbb{E}_P|W|^3$, and under Q the extra weight adds at most $8q^4\,\mathbb{E}_P[W^4]$. As in step 7 of Section K.4, a third absolute central moment is at most 8 times the third absolute moment. So under both laws $\mathbb{E}|L - \mathbb{E}L|^3 = O(q^3)$.

7. **Add up k steps.** Under P the summed loss has mean $K_P = k\,\mathbb{E}_P[L]$ and variance $V_P = k\,\mathrm{Var}_P(L)$, and likewise K_Q and V_Q under Q. With $q\sqrt{k} \to c$, $kq^2 \to c^2$ and $kq^3 = kq^2 \cdot q \to 0$. So steps 4 and 5 give

$$K_P \to \frac{c^2v}{2}, \qquad K_Q \to -\frac{c^2v}{2}, \qquad V_P \to c^2v, \qquad V_Q \to c^2v. \tag{K.34}$$

By step 6 the summed third central moments are $O(kq^3)$, while $V^{3/2}$ tends to $(c^2v)^{3/2} > 0$. So the Berry–Esseen bounds w_P and w_Q under the two laws, each the summed third central moments over $V^{3/2}$, tend to 0. That this ratio tends to 0 is Lyapunov's condition for a triangular array. Lyapunov's CLT would give convergence to the normal without a rate, and Berry–Esseen gives the rate.

8. **The errors of a best test.** As in step 4 of Section K.4, a best test fires when the summed loss S is below a threshold τ, and at τ itself it fires with some probability. Write $x = (\tau - K_P)/\sqrt{V_P}$ for the threshold in standard units under P. Then step 7's Berry–Esseen bound under P gives $|\alpha - \Phi(x)| \le w_P$, as before.

Under Q the loss must be standardized with its own mean and variance. Since $\tau = K_P + x\sqrt{V_P}$, the event $S < \tau$ is the event

$$\frac{S - K_Q}{\sqrt{V_Q}} < \omega_k x + \mu_k, \qquad \omega_k = \sqrt{\frac{V_P}{V_Q}}, \qquad \mu_k = \frac{K_P - K_Q}{\sqrt{V_Q}}. \tag{K.35}$$

By step 7, the scale ratio ω_k tends to 1 and the shift μ_k tends to $c^2 v/(c\sqrt{v}) = c\sqrt{v} = \mu$. So the Berry–Esseen bound under Q puts the power within w_Q of $\Phi(\omega_k x + \mu_k)$.

It remains to show that $\Phi(\omega_k x + \mu_k)$ differs from $\Phi(x + \mu)$ by at most some ξ_k that tends to 0 and does not depend on x. Fix a large number A and split the values of x in two. For $|x| \le A$ the difference is at most $(|\omega_k - 1|A + |\mu_k - \mu|)/\sqrt{2\pi}$, because the normal density is at most $1/\sqrt{2\pi}$. For $|x| > A$, take k large enough that $\omega_k \ge \frac{1}{2}$ and $0 \le \mu_k \le \mu + 1$. Then both arguments are at least $A/2$ when $x > A$ and at most $\mu + 1 - A/2$ when $x < -A$, so both values lie within $\Phi(\mu + 1 - A/2)$ of the same end, 1 or 0. Choosing A large first makes the second part small, and then choosing k large makes the first part small. So $|\beta - \Phi(-x - \mu)| \le w_Q + \xi_k$.

9. **Conclude.** Steps 5 and 6 of Section K.4, with $w = \max(w_P, w_Q + \xi_k)$, put the curve of P^k against Q^k in a band around G_μ whose width tends to 0. Step 7 there turns this into uniform convergence. The remove direction swaps the roles of P and Q. Its loss is $-L$, and its type I error is measured under Q instead of P. Its means are $-K_Q \to \frac{c^2 v}{2}$ under Q and $-K_P \to -\frac{c^2 v}{2}$ under P, so the same argument gives the same limit. Finally, DP-SGD chooses each step after seeing the model so far. But clipping bounds each step's effect, so each step's curve is at least the curve of this pair, as the chapter shows in Section 32.8. By Section K.2 the whole run is then $T(P, Q)^{\otimes k}$-DP, and that curve tends to G_μ.

K.5.4. Checking it

Step 4 says that $(\mathbb{E}_P[L] - \frac{q^2}{2}v)/q^3$ stays bounded, by $\frac{2}{3}\mathbb{E}_P|W|^3 \le 14.06$ at $\sigma = 1$. Computed by numerical integration, it is -3.619, -4.024, -4.292 and -4.453 at $q = 0.02$, 0.01, 0.005 and 0.0025. It settles near a constant, so the remainder really is of order q^3, and the bound holds with room. The same ratios for the mean under Q settle near 2.26, and for the variance under P near -13.2. At the running example's $q = 0.01$, the remainder is about 5% of the leading term for the mean under P (8.1890×10^{-5} against 8.5914×10^{-5}) and about 7% for the variance (1.6009×10^{-4} against 1.7183×10^{-4}).

The Berry–Esseen bound under P is 0.3045, 0.0963 and 0.0304 at $k = 100$, 1000 and 10,000. It shrinks like $1/\sqrt{k}$. The summed third moments grow like kq^3, while $V^{3/2}$ grows like $(kq^2)^{3/2} = k^{3/2}q^3$, so their ratio is of order $1/\sqrt{k}$ whatever q is. The actual distance at $k = 100$, computed from a numerical PLD, is between 0.0312 and 0.0343, so the bound is about nine times too large. Figure K.7 shows the standardized laws. The shift between the two curves is μ, which grows with k: it is 0.1311, 0.4145 and 1.3108.

The theorem controls the bulk, not the tail, and Figure K.8 shows what that costs at $\delta = 10^{-5}$. It plots $\delta(\varepsilon)$ for the add and the remove direction against the Gaussian profile with the CLT's μ. Each direction is computed with a numerical PLD, which rounds each step's loss to a grid of spacing $h = 10^{-5}$. Table K.5 gives the values of ε at $\delta = 10^{-5}$ as brackets. Rounding every loss up gives the upper end of a bracket, which is a valid bound, and rounding down gives the lower

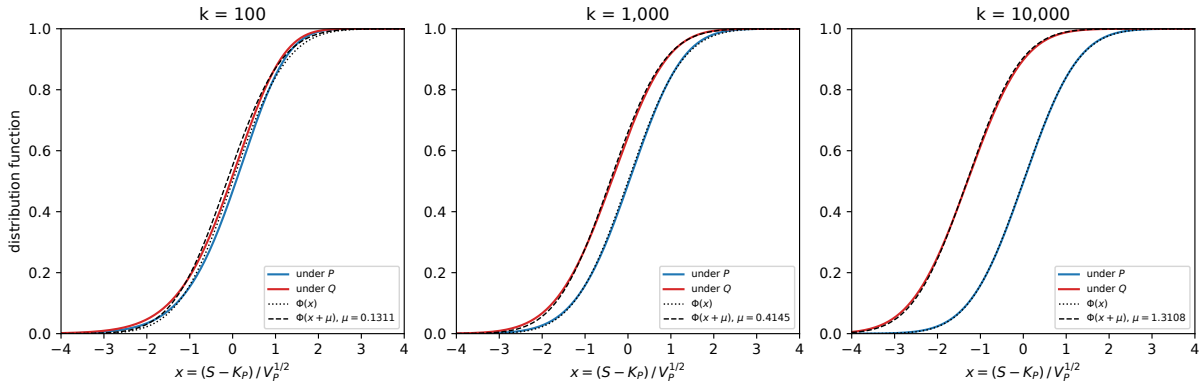

Figure K.7.: Distribution functions of the standardized summed loss $(S - K_P)/\sqrt{V_P}$ of k steps of the Poisson-subsampled Gaussian with $q = 0.01$ and $\sigma = 1$, under P (blue) and Q (red), computed from a numerical PLD, against $\Phi(x)$ and $\Phi(x + \mu)$ with $\mu = q\sqrt{k(e^{1/\sigma^2} - 1)}$. From left to right, $k = 100$, 1,000 and 10,000.

end. The two ends differ by at most kh, since each of the k steps contributes at most h, which is why the brackets widen to 0.1 at $k = 10{,}000$.

Table K.5.: ε at $\delta = 10^{-5}$ for the running DP-SGD example, from the CLT and from a numerical PLD in each direction of neighbours.

k	CLT ε	Add direction	Remove direction
100	0.4575	[0.3377, 0.3387]	[0.7175, 0.7185]
1,000	1.6177	[1.4117, 1.4217]	[1.8232, 1.8332]
10,000	6.0071	[5.5615, 5.6615]	[6.1377, 6.2377]

The two directions err in opposite ways (Table K.5). In the remove direction the loss is $\ln(1+qW)$ under the mixture. The rare outputs where the record was in the batch and the noise pushed y high make W large, so this loss has a long upper tail and δ lies above the Gaussian's. In the add direction the loss $-\ln(1+qW)$ can never exceed $-\ln(1-q)$ per step, so its upper tail is shorter than a Gaussian's. An accountant must take the worse direction, so the CLT under-reports ε at every k shown. Measured against ε itself, the gap shrinks as k grows, in line with the convergence the theorem proves, but at $\delta = 10^{-5}$ it is still 0.13 at $k = 10{,}000$.

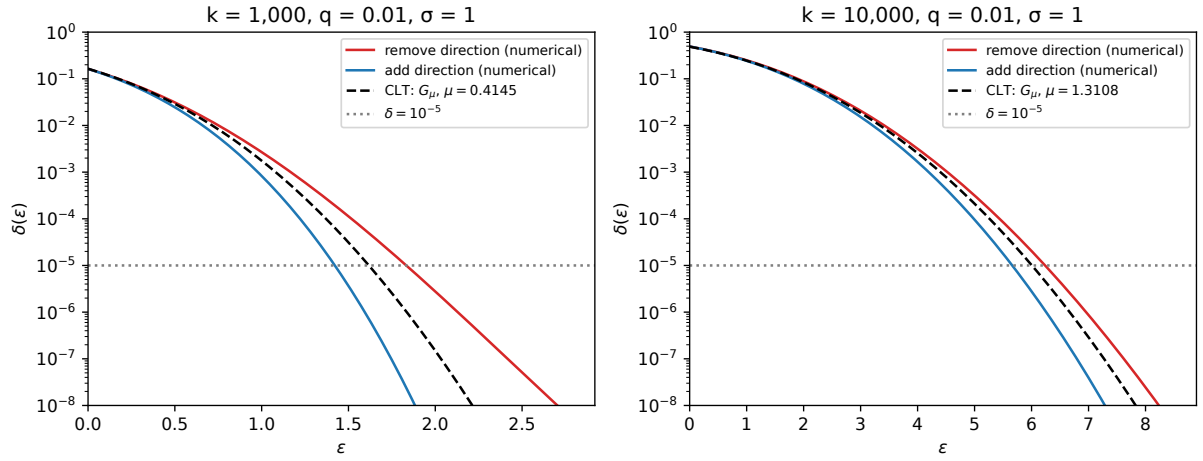

Figure K.8.: The privacy profile $\delta(\varepsilon)$ on a log scale for k steps of the Poisson-subsampled Gaussian with $q = 0.01$, $\sigma = 1$: the remove direction (red) and the add direction (blue) from a numerical PLD, rounded up, and the Gaussian profile of the CLT's μ (dashed). The dotted line is $\delta = 10^{-5}$. Left: $k = 1{,}000$. Right: $k = 10{,}000$.

K.5.5. What it does not cover

K.6. Code

The script code/appendix-derivations/apx_composition.py checks every derivation numerically. It builds the coarsened canonical pairs, computes exact trade-off curves of finite pairs by sorting likelihood ratios, and runs the test replacement on random tests. It computes hockey-stick divergences of the adaptive runs and their dominating products, the exact composed curves of randomized response against the Berry–Esseen band, and the moments and numerical PLDs of the subsampled Gaussian. It uses the standard library and NumPy only and runs in under a minute. From the repository root:

```
uv run python code/appendix-derivations/apx_composition.py
```

Output (seed 0):

Table K.6.: Results printed by the script with seed 0.

Check	Result
Canonical pair, 1000 cells: largest gap to f	G_1: 2.0×10^{-3}; $f_{1,0.1}$: 8.3×10^{-5}
Adaptive randomized response against $f \otimes f$	never below; largest gap 0.2812 at $\alpha = 0.0625$
Test replacement on 20,000 random tests	type I error unchanged (to 3.3×10^{-16}), type II never larger, mean drop 0.4013
Three-step run against the product, 502 values of γ	never above; $\delta(1)$ 0.3926 against 0.4190
100,000 random tests against the product's upper edge	none above; smallest margin 0.0726
CLT band, $k = 100$ randomized responses	$\mu = 1.0004$, $w = 0.0562$; curve inside, at most 0.0014 from G_μ
Subsampled Gaussian, mean remainder over q^3 at $q = 0.0025$	-4.453 under P, bound 14.06
DP-SGD, $k = 10{,}000$: ε at 10^{-5}	CLT 6.0071; remove direction $[6.1377, 6.2377]$

tests/test_appendix_composition.py checks that the output still matches Table K.6 and every other number on this page.

What to take from it. The replacement step never fails: on every random test the type I error is kept and the type II error does not grow, so composition is never worse than the product of the fixed pairs that bound each step. The adaptive examples show how loose that can be when the branches differ. The Berry–Esseen band always holds and is nearly sharp for the distribution functions, but the curve itself is far closer to G_μ. The subsampled-Gaussian expansions have remainders of order q^3, as proved. The CLT still under-reports ε at $\delta = 10^{-5}$, because the tail of the loss is longer than a Gaussian's in the direction that matters.

L. Subsampling, shuffling and iteration

Part 4 gets much of its privacy from the adversary's uncertainty. For example, a record that a training step samples only with some small probability may not have been used at all, and a report sent through a shuffler hides among the others. Likewise, a record used early in training is covered by the noise of every later step. The chapters state the results that turn this uncertainty into numbers, but several of the proofs are only cited or sketched. This appendix derives five of them in full. They sit together because they share one method: write what the adversary sees as an average, or as a post-processing, of something simpler, and then use two facts. The first is that averaging two runs with the same weights cannot make them easier to tell apart. The second is that processing the output cannot either.

Table L.1 lists the derivations and where the chapters state or use them.

Table L.1.: The derivations of this appendix and the chapter sections that state or use them.

L.1. The remove direction dominates in Rényi divergence

L.1.1. What the chapter uses

Stochastic gradient descent (SGD) run with differential privacy (DP) is called DP-SGD. Each of its steps uses each record with probability q, the **sampling rate**. It adds Gaussian noise to a sum whose sensitivity is 1, and the noise multiplier σ is the standard deviation of that noise. The chapter first reduces the step to one dimension, the direction in which your clipped gradient moves the sum, and takes the worst case, where it moves the sum by the full sensitivity 1. Then the output without your record is the normal distribution $P_0 = \mathcal{N}(0, \sigma^2)$. With your record, the step uses it with probability q and then shifts the mean by 1, so the output is the mixture

$$P_q = (1-q)P_0 + qP_1, \qquad P_1 = \mathcal{N}(1, \sigma^2). \tag{L.1}$$

The neighbouring relation is add/remove, so a guarantee must cover both orders of the pair. The **remove** direction puts the output with your record first, (P_q, P_0), and the **add** direction puts it second, (P_0, P_q). Rényi differential privacy (RDP) measures each direction by a Rényi divergence. For two distributions P and Q and a number $\alpha > 1$, called the order, it is the log-average of a power of the likelihood ratio,

$$D_\alpha(P\|Q) = \frac{1}{\alpha - 1} \ln \mathbb{E}_Q\Big[\Big(\frac{P}{Q}\Big)^\alpha\Big]. \tag{L.2}$$

Amplification by subsampling computes the RDP curve from the remove direction alone, because that direction has an exact binomial series. That is valid only if the remove direction is the larger one:

$$D_\alpha(P_q\|P_0) \;\geq\; D_\alpha(P_0\|P_q) \qquad \text{for every } \alpha > 1,\ q \in [0,1],\ \sigma > 0. \tag{L.3}$$

That chapter states this as part of Equation 33.9 in Section 33.5. Its step 8 cites Mironov, Talwar & Zhang (2019, Theorem 5) and checks the inequality numerically on a grid of orders. Concentrated DP (Section 31.8) says that the subsampling chapter derives both the reduction to one dimension and this inequality, but that chapter derives only the reduction. This section supplies the proof, for every real order, not only integer ones.

Both divergences can be written as averages under P_0. Write $r(y) = P_1(y)/P_0(y)$ for the likelihood ratio of the two Gaussians, so that $P_q/P_0 = 1 - q + q\,r$. The remove moment is the chapter's Equation 33.10. The add moment is an average under P_q of $(P_0/P_q)^\alpha$. Moving that average to P_0 multiplies the integrand by P_q/P_0, and $(P_0/P_q)^\alpha \cdot P_q/P_0 = (P_q/P_0)^{1-\alpha}$. So the two moments are

$$A_\alpha = \mathbb{E}_{P_0}\big[(1 - q + q\,r)^\alpha\big] = e^{(\alpha-1)D_\alpha(P_q\|P_0)}, \qquad B_\alpha = \mathbb{E}_{P_0}\big[(1 - q + q\,r)^{1-\alpha}\big] = e^{(\alpha-1)D_\alpha(P_0\|P_q)}. \tag{L.4}$$

Since $\alpha - 1 > 0$, Equation L.3 says exactly that $A_\alpha \geq B_\alpha$.

L.1.2. The idea

The proof cuts the Gaussian pair into many small pieces, each of which is a randomized response. The mirror $y \mapsto 1 - y$ swaps the two Gaussians, because P_0 is centred at 0 and P_1 at 1. So group the outputs in mirrored pairs $\{\frac{1}{2} - z, \frac{1}{2} + z\}$. Within one such pair, P_0 prefers the point $\frac{1}{2} - z$ by some factor and P_1 prefers the other point by the same factor. That is binary randomized response, a coin that reports one of two answers and favours the true one. All three distributions also put the same total mass on each mirrored pair, because the mirror swaps P_0 and P_1 and keeps the pair. So both moments A_α and B_α are averages, with shared weights, of the same moments for randomized-response pairs. It is enough to prove $A_\alpha \geq B_\alpha$ for randomized response of every strength.

For randomized response the two moments are sums over two outputs, and they have a closed form. Their gap turns out to be a difference of two averages of the function tanh over two intervals with the same centre, one wider than the other. The common centre turns out never to be negative. Since tanh rises steeply near 0 and flattens out far to the right, widening an interval with such a centre can only lower the average, so the gap is never negative.

Take a concrete pair, in which P_0 reports "+" with probability 0.7311 and "−" with probability 0.2689, and P_1 is the reverse. With $q = 0.1$, the mixture $P_q = 0.9P_0 + 0.1P_1$ reports "+" with probability 0.6848 (Table L.2). At $\alpha = 2$ the remove and add moments of this two-point pair, which we call A' and B' to keep them apart from the Gaussian A_α and B_α, are sums over the two outputs,

$$A' = \sum \frac{P_q^2}{P_0}, \qquad B' = \sum \frac{P_0^2}{P_q}. \tag{L.5}$$

The appendix's script (see Section L.6) gives $\ln A' = 0.010803$ and $\ln B' = 0.009846$, so here the remove direction is larger, as claimed.

Table L.2.: A randomized-response pair, with $P_0 = \pi_{0.5}$ in the notation of step 1, and its mixture at $q = 0.1$.

Output	P_0	P_1	$P_q = 0.9P_0 + 0.1P_1$
+	0.7311	0.2689	0.6848
−	0.2689	0.7311	0.3152

L.1.3. Derivation

1. **Name the two-point distributions.** For a real number u, let π_u put probability $e^u/(2\cosh u)$ on "+" and $e^{-u}/(2\cosh u)$ on "−". It is randomized response whose privacy loss is $\pm 2u$, since the two probabilities differ by the factor e^{2u}, and π_{-u} is the same coin reversed. The probability of "+" is $(1 + \tanh u)/2$, so $\tanh u$ is how strongly the coin leans to "+". In Table L.2, $P_0 = \pi_{0.5}$ and $P_1 = \pi_{-0.5}$.

2. **Split the Gaussian pair into mirrored pairs.** Fix $z > 0$ and compare the two points $\frac{1}{2} \mp z$. The Gaussian density is $e^{-y^2/(2\sigma^2)}$ up to a constant, so

$$\frac{P_0(\frac{1}{2} - z)}{P_0(\frac{1}{2} + z)} = \exp\Big(\frac{(\frac{1}{2} + z)^2 - (\frac{1}{2} - z)^2}{2\sigma^2}\Big) = e^{z/\sigma^2}. \tag{L.6}$$

   The mirror gives $P_1(y) = P_0(1 - y)$, so P_1 has the reverse ratio. Label the point $\frac{1}{2} - z$, on the side of P_0, as "+". Given that the output lies in the pair, P_0 is then π_a and P_1 is π_{-a}, with $a = z/(2\sigma^2)$.

3. **The pairs have the same weight under all three distributions.** Let $m(z) = P_0(\frac{1}{2} - z) + P_0(\frac{1}{2} + z)$ be the density of the pair under P_0. Under P_1 the two points swap, so the total is the same, and P_q is a mixture of the two. Write each density as $m(z)$ times a conditional probability on the pair. In $P_q(y)^\alpha P_0(y)^{1-\alpha}$ the powers of $m(z)$ add up to $\alpha + (1 - \alpha) = 1$, so

$$A_\alpha = \int_0^\infty m(z)\, A'(a)\, dz, \qquad B_\alpha = \int_0^\infty m(z)\, B'(a)\, dz, \qquad a = \frac{z}{2\sigma^2}, \tag{L.7}$$

   where $A'(a)$ and $B'(a)$ are the two moments of the randomized-response pair $(\pi_a, (1 - q)\pi_a + q\pi_{-a})$. If $A'(a) \geq B'(a)$ for every $a \geq 0$, then $A_\alpha \geq B_\alpha$.

4. **The mixture is again a randomized response.** Mixing averages the probabilities of "+", and so averages the leaning tanh. So $(1-q)\pi_a + q\pi_{-a} = \pi_b$, where

$$\tanh b = (1-q)\tanh a + q\tanh(-a) = (1-2q)\tanh a. \tag{L.8}$$

   Since $|1-2q| \le 1$ and tanh is increasing, $-a \le b \le a$. In the example, $a = 0.5$ and $b = 0.3881$.

5. **Compute the two moments.** On "+" the term $\pi_b^\alpha \pi_a^{1-\alpha}$ is $e^{\alpha b + (1-\alpha)a}$ divided by $(2\cosh b)^\alpha (2\cosh a)^{1-\alpha}$, and on "−" the exponent changes sign. So the two exponentials add up to a hyperbolic cosine. Writing $\ell(u)$ for $\ln\cosh u$, the logarithms of the two moments are

$$\ln A' = \ell(\alpha b + (1-\alpha)a) - \alpha\,\ell(b) - (1-\alpha)\,\ell(a), \qquad \ln B' = \ell(\alpha a + (1-\alpha)b) - \alpha\,\ell(a) - (1-\alpha)\,\ell(b). \tag{L.9}$$

6. **Turn the gap into two averages of tanh.** Let $d = a - b \ge 0$. Then $\alpha b + (1-\alpha)a = a - \alpha d$ and $\alpha a + (1-\alpha)b = a + (\alpha-1)d$. Subtracting the two lines of step 5 and collecting the terms in $\ell(a)$ and $\ell(b)$ gives

$$\ln A' - \ln B' = (2\alpha - 1)\big[\ell(a) - \ell(a-d)\big] - \big[\ell(a + (\alpha-1)d) - \ell(a - \alpha d)\big]. \tag{L.10}$$

   The derivative of ℓ is tanh, so each bracket is an integral of tanh over an interval. The first is over $I_1 = [b, a]$, of length d. The second is over $I_2 = [a - \alpha d,\ a + (\alpha-1)d]$, of length $(2\alpha-1)d$. Writing each integral as length times average,

$$\ln A' - \ln B' = (2\alpha - 1)\, d \left[\operatorname{avg}_{I_1} \tanh - \operatorname{avg}_{I_2} \tanh \right]. \tag{L.11}$$

   Both intervals have the same centre, $c = a - d/2 = (a+b)/2$. For $\alpha \ge 1$, I_2 is at least as wide as I_1 and contains it.

7. **A wider interval has a smaller average.** Let $G(h)$ be the average of tanh over $[c-h, c+h]$. Pairing each point $c + x$ with its mirror $c - x$,

$$G(h) = \int_0^1 \tfrac{1}{2}\big[\tanh(c + hs) + \tanh(c - hs)\big]\, ds. \tag{L.12}$$

   For $x \ge 0$ the bracket $\tanh(c+x) + \tanh(c-x)$ has derivative $\operatorname{sech}^2(c+x) - \operatorname{sech}^2(c-x)$. The function sech^2 is even and decreases as its argument moves away from 0. When $c \ge 0$ and $x \ge 0$, the point $c + x$ is at least as far from 0 as $c - x$, so the derivative is at most 0. So every bracket, and with it G, can only decrease as h grows.

8. **Conclude.** The centre satisfies $c = (a+b)/2 \ge 0$ because $b \ge -a$ (step 4). Step 7 then gives $\operatorname{avg}_{I_1} \tanh \ge \operatorname{avg}_{I_2} \tanh$, so Equation L.11 is at least 0. That proves $A'(a) \ge B'(a)$ for every a, and step 3 gives $A_\alpha \ge B_\alpha$, which is Equation L.3.

In the example, $c = 0.4440$. At $\alpha = 2$ the average of tanh is 0.416623 over I_1 and 0.413773 over the three-times-wider I_2. Multiplying their difference by $(2\alpha-1)d$ gives 0.000957, which is $\ln A' - \ln B' = 0.010803 - 0.009846$. Figure L.1 draws the two intervals for a larger example, where the difference is easy to see.

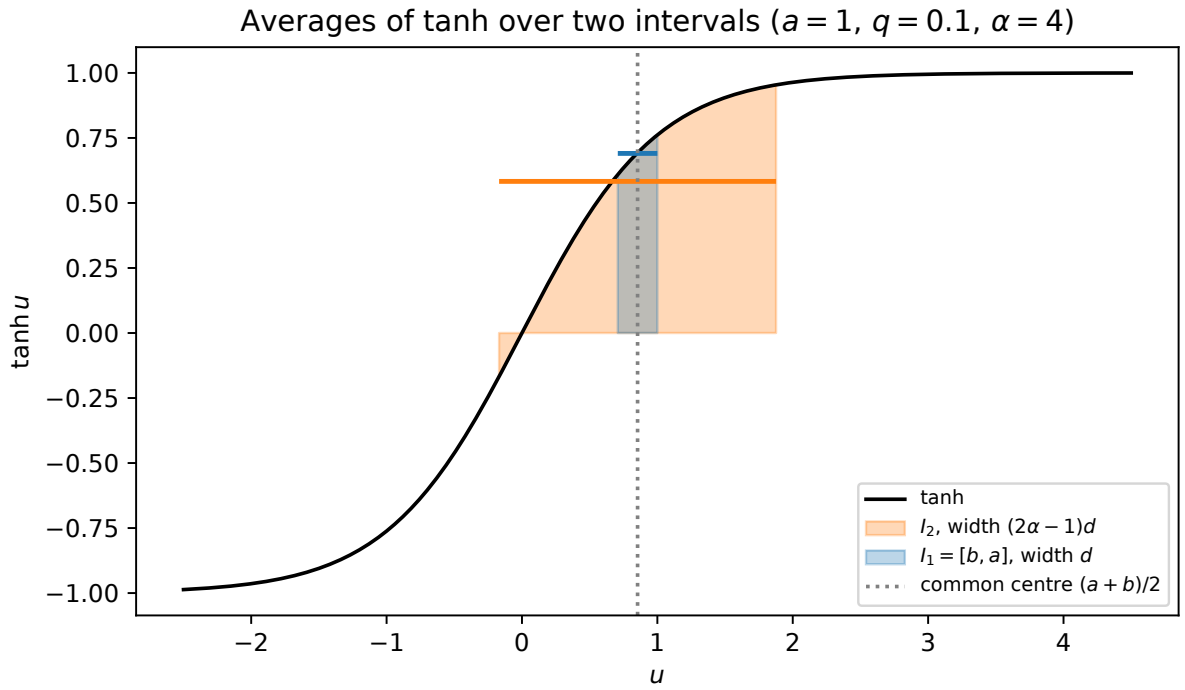

Figure L.1.: The function tanh with the two intervals of step 6 for $a = 1$, $q = 0.1$ and $\alpha = 4$. Both are centred at $(a + b)/2$. The horizontal bars are the averages of tanh over each interval. The wide interval reaches into the flat part on the right and the steep part on the left, so its average is lower.

L.1.4. Checking it

The script checks the pair inequality on a grid of 5,294,646 points. The grid has nine sampling rates from 0.001 to 0.9, 294 orders from 1.01 to 256, and 2,001 pair strengths a, up to likelihood ratios e^{2a} of 10^6. No point has a negative gap. The smallest value, -2.2×10^{-16}, is rounding at $a = 0$, where both moments equal 1 and their logarithms 0.

It also computes both directions for the Gaussian in two ways: by integrating over the output, as the chapter does, and by averaging the pair moments of step 3. Table L.3 shows that the two ways agree to every printed digit and that the remove direction is the larger.

Table L.3.: The two directions of the subsampled Gaussian with $q = 0.01$ and $\sigma = 1$. Integration over the output and the average over mirrored pairs give the same values.

α	$D_\alpha(P_q \Vert P_0)$	$D_\alpha(P_0 \Vert P_q)$
2	1.7181×10^{-4}	1.6022×10^{-4}
8	8.9364×10^{-4}	5.7239×10^{-4}
32	1.1246×10^{1}	1.6923×10^{-3}

Figure L.2 shows the decomposition and the gap for each mirrored pair. The gap is 0 only for the pair at $z = 0$, where the two points coincide, and it grows with the strength of the pair. Strong pairs sit far out in the tails of the Gaussians, and those are the outputs that high orders weight most. That is why the two directions differ by nearly four orders of magnitude at $\alpha = 32$.

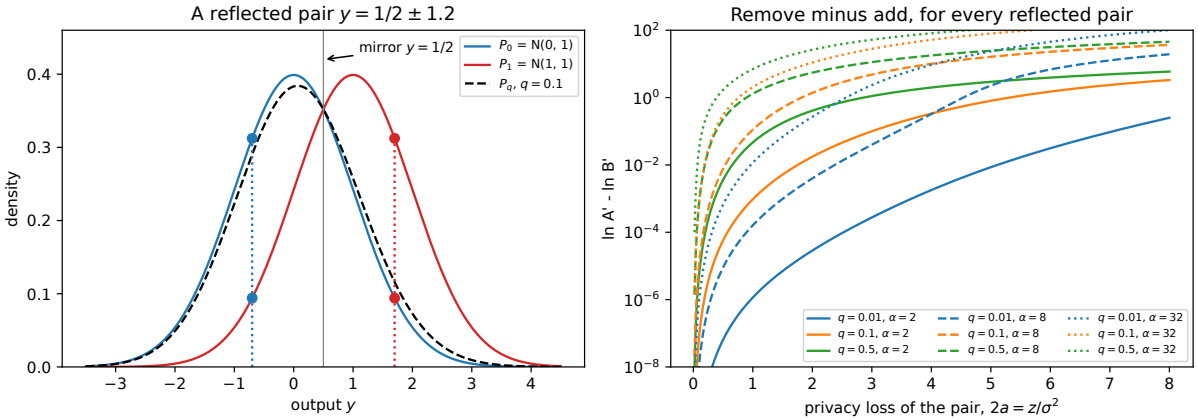

Figure L.2.: Left: P_0, P_1 and the mixture P_q for $q = 0.1$ and $\sigma = 1$, with one mirrored pair of outputs, $y = \frac{1}{2} \pm 1.2$. The density of P_0 at the left point equals that of P_1 at the right point, and the other way round. Right: the gap $\ln A' - \ln B'$ for each mirrored pair, against the pair's privacy loss $2a$, for three sampling rates and three orders. Every curve is positive.

L.1.5. What it does not cover

The proof uses only the mirror that swaps P_0 and P_1. So it covers every pair with such a mirror, for example the Laplace mechanism, but not a pair without one. It is also a statement about

Rényi divergences. For the hockey-stick divergence, which gives $\delta(\varepsilon)$, neither direction dominates in general, which is why Section 34.7 computes both. Mironov, Talwar & Zhang (2019, Theorem 5) state the same inequality, and the argument here is a self-contained route to it.

L.2. Dominating pairs for Poisson subsampling

L.2.1. What the chapter uses

Take add/remove neighbours, and write $D' = D \cup \{x\}$ for the dataset that holds your record x. A guarantee for a mechanism M must cover both orders of the pair, so there are two directions. The **remove** direction compares $M(D')$ against $M(D)$, with the dataset that holds the record first. The **add** direction compares $M(D)$ against $M(D')$.

One DP-SGD step draws a Poisson sample K of the data, keeping each record with probability q by its own coin. Write $g(u)$ for the clipped gradient of record u, divided by the clipping norm so that $\|g(u)\| \le 1$. The step outputs the noisy sum

$$M(D) = \sum_{u \in K} g(u) + \mathcal{N}(0, \sigma^2 I). \tag{L.13}$$

The gradients may depend on earlier steps, but they are fixed when the step runs.

The **hockey-stick divergence** at level γ is the largest amount by which P exceeds γ times Q on any event, $E_\gamma(P\|Q) = \max_A \left[P(A) - \gamma Q(A)\right]$. At $\gamma = e^\varepsilon$ it is the $\delta(\varepsilon)$ of the pair. The definition makes sense for every real γ, and for $\gamma \le 0$ the best event is the whole space, so $E_\gamma = 1 - \gamma$. A pair **dominates** one direction if its E_γ is at least the mechanism's E_γ in that direction, for every $\gamma \ge 0$ and all datasets. With $P_0 = \mathcal{N}(0, \sigma^2)$, $P_1 = \mathcal{N}(1, \sigma^2)$ and $P_q = (1-q)P_0 + qP_1$ as in Section L.1, the claim is that, for every $\gamma \ge 0$,

$$E_\gamma(M(D') \,\|\, M(D)) \le E_\gamma(P_q \| P_0), \qquad E_\gamma(M(D) \,\|\, M(D')) \le E_\gamma(P_0 \| P_q). \tag{L.14}$$

Numerical accounting states the two pairs in Section 34.7. It cites Zhu, Dong & Wang (2022, Theorem 11), and its step 7 says that they "prove each pair dominates its case". Choosing an accountant relies on both pairs in Section 37.2.

L.2.2. The idea

Two exact identities do the work, one for each order. Take a mixture $(1-q)Q + qP$ and one of its components, Q. On any event, the mixture's excess over γQ is q times the excess of P over $\gamma' Q$, at the stretched level $\gamma' = 1 + (\gamma - 1)/q$. The add direction, with the mixture second, has a similar identity. So the δ curve of the mixture against Q is the δ curve of P against Q, scaled by q and read at a different level. A larger base curve then gives a larger mixture curve, at every level.

The rest is bookkeeping. Fix everything except your record's coin, and the step is exactly such a mixture, with a Gaussian base pair whose shift is your clipped gradient. Of all such base pairs, the one with shift exactly 1 along one axis has the largest curve. Finally, averaging over the other records' coins cannot raise the curve.

For a feel of the stretch, take $q = 0.01$ and $\gamma = 1.5$. The remove identity reads the base pair at $\gamma' = 1 + 0.5/0.01 = 51$. For the subsampled step to make some event 1.5 times likelier, the base mechanism must make it 51 times likelier, which only happens far in its tail.

L.2.3. Derivation

1. **Fix the other records' coins.** Let K be the Poisson sample of D. Your record has its own coin, independent of K, so the sample of D' is K with probability $1-q$ and $K \cup \{x\}$ otherwise. Given K, $M(D)$ is $Q_K = \mathcal{N}(f_K, \sigma^2 I)$, with f_K the sum of the gradients in K. And $M(D')$ is $(1-q)Q_K + qP_K$, with $P_K = \mathcal{N}(f_K + v, \sigma^2 I)$ and $v = g(x)$, so $\|v\| \le 1$.

2. **Averaging over K cannot raise E_γ.** Both runs are averages over K with the same weights w_K. Write U_K and V_K for the two conditional outputs given K, in either order. For every event, $\sum_K w_K U_K(A) - \gamma \sum_K w_K V_K(A)$ is the weighted average of the excesses $U_K(A) - \gamma V_K(A)$, and an average is at most the largest term. So $E_\gamma(\sum_K w_K U_K \| \sum_K w_K V_K) \le \max_K E_\gamma(U_K \| V_K)$, for every real γ. This is Fact 1 of Amplification by subsampling. It reduces both claims to one fixed K.

3. **The remove identity.** For any event A, collect the terms in $Q(A)$: $(1-q)Q(A) + qP(A) - \gamma Q(A) = q[P(A) - \gamma' Q(A)]$, where $q\gamma' = \gamma - 1 + q$. Taking the maximum over A on both sides gives

$$E_\gamma((1-q)Q + qP \,\|\, Q) = q\, E_{\gamma'}(P \| Q), \qquad \gamma' = 1 + \frac{\gamma - 1}{q}. \tag{L.15}$$

   This holds for every γ. When $\gamma < 1 - q$, the level γ' is negative and both sides equal $1 - \gamma$, since $q(1 - \gamma') = 1 - \gamma$.

4. **The add identity.** Now the mixture is second. Collect the terms in $Q(A)$ again: $Q(A) - \gamma(1-q)Q(A) - \gamma q P(A) = c\, Q(A) - \gamma q\, P(A)$, with $c = 1 - \gamma(1-q)$. If $c > 0$, factor it out. If $c \le 0$, every event gives at most 0, because $\gamma \ge 0$ makes the last term non-positive, and the empty event gives exactly 0. So

$$E_\gamma(Q \,\|\, (1-q)Q + qP) = \begin{cases} c\, E_{\gamma q/c}(Q \| P), & c = 1 - \gamma(1-q) > 0, \\ 0, & c \le 0. \end{cases} \tag{L.16}$$

5. **The base pair with shift 1 is the worst.** Compare (P_K, Q_K) with (P_1, P_0) at every level and in both orders. Shifting both distributions by $-f_K$ and rotating v onto the first axis is an invertible map, the same for both, so it changes no E_γ. The other coordinates are then independent and identical in both, so dropping them and adding them back are both post-processing, and they change nothing either. What is left is $\mathcal{N}(\|v\|, \sigma^2)$ against $\mathcal{N}(0, \sigma^2)$. If $\|v\| < 1$, this pair is a post-processing of (P_1, P_0). The map $y \mapsto \|v\|\, y + \mathcal{N}(0, (1 - \|v\|^2)\sigma^2)$ turns P_1 into $\mathcal{N}(\|v\|, \sigma^2)$ and P_0 into P_0. **Data processing** says no such map raises E_γ. The reason is that a test on the output pulls back to a test on the input with acceptance probability between 0 and 1, and the best such test is an event. So $E_\gamma(P_K \| Q_K) \le E_\gamma(P_1 \| P_0)$ and $E_\gamma(Q_K \| P_K) \le E_\gamma(P_0 \| P_1)$.

6. **Put the pieces together.** Both identities are increasing in the base divergence, because $q > 0$ and $c > 0$ where it matters. For the remove direction, steps 2, 3 and 5 give

$$E_\gamma(M(D') \| M(D)) \le \max_K q\, E_{\gamma'}(P_K \| Q_K) \le q\, E_{\gamma'}(P_1 \| P_0) = E_\gamma(P_q \| P_0), \tag{L.17}$$

where the last equality is Equation L.15 read backwards for the Gaussian pair. The add direction is the same with Equation L.16, and both sides are 0 when $c \leq 0$. This is Equation L.14.

7. **One base curve for both directions.** The mirror $y \mapsto 1 - y$ swaps P_0 and P_1 and is invertible, so $E_\gamma(P_0 \| P_1) = E_\gamma(P_1 \| P_0)$ for every γ. Both identities therefore read the same curve, the Gaussian δ curve Equation 34.4 with $\mu = 1/\sigma$, at different levels.

A bonus: amplification for any mechanism. The identity in step 3 used nothing about Gaussians. Let M be any (ε, δ)-DP mechanism, and in step 1 let $Q_K = M(K)$ and $P_K = M(K \cup \{x\})$ be its outputs on two neighbouring samples. Set $e^{\varepsilon'} = 1 + q(e^\varepsilon - 1)$. Then the stretched level is $\gamma' = 1 + (e^{\varepsilon'} - 1)/q = e^\varepsilon$, and Equation L.15 gives $E_{e^{\varepsilon'}}((1-q)Q_K + qP_K \| Q_K) = q\, E_{e^\varepsilon}(P_K \| Q_K) \leq q\delta$. With step 2, that is the remove half of Equation 33.5 in one line.

L.2.4. Checking it

The script computes one step with $q = 0.01$ and $\sigma = 1$ in two ways. One uses the closed forms of step 6 of Section 34.7, which find the output threshold where the loss crosses ε. The other uses the two identities with the Gaussian curve. Over a grid of ε from -0.5 to 3, the largest relative gap between the two is 7.4×10^{-14} in the remove direction. In the add direction it is 3.0×10^{-12}. At $\varepsilon = 0.5$, for example, both give the remove value 2.214519×10^{-7}, the exact value of Table 34.6. The bonus checks out too. With base $\varepsilon = 1$ the amplified level is $\varepsilon' = 0.017037$. There, the subsampled $\delta(\varepsilon')$ equals q times the base $\delta(1)$, and both are 1.269367×10^{-3}.

The script also checks the domination on a small dataset that is not a worst case. In one dimension, the other records have gradients 0.3 and -0.5, your record has 0.8, $q = 0.3$ and $\sigma = 1$. The two other records give four possible samples, and adding yours gives eight, so the real outputs are mixtures of four and eight Gaussians. The script computes their E_γ at five levels from 0.8 to 5, in both directions. The real divergence is never above the pair's, and its largest ratio to the pair's is 0.9687: your gradient is shorter than 1, so the bound is not reached.

Figure L.3 shows the stretch and the result. In the add direction $\delta(\varepsilon)$ drops to 0 at $\varepsilon = -\ln(1-q) = 0.0101$, where c reaches 0.

L.2.5. What it does not cover

The pairs dominate one step, for add/remove neighbours. Composing them over many adaptively chosen steps needs the dominating-pair composition theorem, which Section 34.4 states and Appendix Section K.3 derives. Replace-one neighbours, or fixed-size batches, give different pairs, as Section 33.4 explains.

L.3. The clone reduction for shuffling

L.3.1. What the chapter uses

In the shuffle model, n users each send one report through a shuffler, which hides the order. The neighbouring relation is replace-one: you hold x^0 in D and x^1 in D', and everyone else holds the

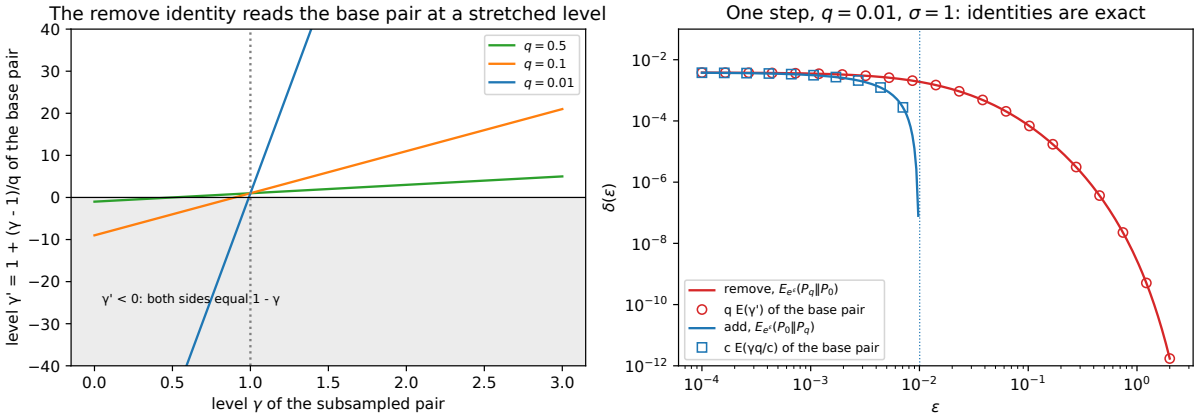

Figure L.3.: Left: the stretched level $\gamma' = 1 + (\gamma - 1)/q$ of the remove identity for three sampling rates. In the shaded region the level is negative and both sides equal $1 - \gamma$. Right: one step with $q = 0.01$ and $\sigma = 1$. The lines are $\delta(\varepsilon)$ of the remove pair (red) and of the add pair (blue), computed directly. The markers are the two identities applied to the Gaussian curve, and they fall on the lines. The dotted line marks $\varepsilon = -\ln(1-q)$.

same value in both. Every user applies the same local randomizer R, a randomized map from a value to a report, and $R(x)$ is the distribution of the report of a user who holds x. It is ε_0**-DP**: no report is more than e^{ε_0} times likelier under one input than under another.

The chapter's Theorem 3.2 (Feldman, McMillan & Talwar 2021) says that the shuffled output on D and on D' is the same post-processing of the two random pairs of counts of Equation 35.8,

$$\tilde{P} = (A + \Delta,\ C - A + 1 - \Delta), \qquad \tilde{Q} = (A + 1 - \Delta,\ C - A + \Delta). \tag{L.18}$$

The number of clones C is binomial, $\mathrm{Bin}(n-1, e^{-\varepsilon_0})$. A clone is another user's report that is distributed like one of your two possible reports, and the idea below makes this precise. Given C, the number A of clones of the first kind is $\mathrm{Bin}(C, \frac{1}{2})$. The bit Δ, independent of both, says whether your own report favours your true value, and it is 1 with probability

$$p = \frac{e^{\varepsilon_0}}{e^{\varepsilon_0} + 1}. \tag{L.19}$$

Section 35.4 proves a weaker reduction, in which your own report counts fully on one side, with counts $(A + 1, C - A)$ against $(A, C - A + 1)$. That pair ignores the noise in your own report. The chapter then replaces your exact contribution by the noisy bit Δ, citing Lemma 3.4 of the paper, but it does not show that the other users' clones can be rewritten in the same terms. It also cites, without the calculation, the Chernoff bounds that give the closed form Equation 35.7. This section proves the full reduction for one fixed randomizer and derives a closed-form bound with explicit constants.

L.3.2. The idea

Two facts about randomized response carry the proof. First, your own report can be produced in two stages. A biased coin picks one of two "pure" report distributions, Q_0 or Q_1, and then a

report is drawn from it. On D the coin picks Q_0 with probability p, and on D' it picks Q_1 with probability p. So your report is a randomized-response bit followed by processing that does not depend on your data.

Second, every other user's report contains, with probability $e^{-\varepsilon_0}$, a draw from the average $\frac{1}{2}(R(x^0) + R(x^1))$. That average equals $\frac{1}{2}(Q_0 + Q_1)$. So such a **clone** can be produced by a fair coin that picks Q_0 or Q_1. After shuffling, all that matters is how many reports came from Q_0 and how many from Q_1. Those two counts are $\tilde{P}$ on D and $\tilde{Q}$ on D'.

Take three-valued randomized response with $\varepsilon_0 = \ln 4$. It reports the true value with probability $\frac{2}{3}$ and each other value with probability $\frac{1}{6}$, so $p = \frac{4}{5}$. You hold 0 on D and 1 on D'. Table L.4 lists the pieces, and Figure L.4 draws them.

Table L.4.: The clone decomposition for three-valued randomized response with $\varepsilon_0 = \ln 4$. The clone part of another user's $R(2)$ is $e^{-\varepsilon_0} = \frac{1}{4}$ times $\frac{1}{2}(Q_0 + Q_1)$, and the leftover is the rest, rescaled by $\frac{4}{3}$ to a distribution.

Report	$R(0)$	$R(1)$	Q_0	Q_1	$\frac{1}{2}(Q_0 + Q_1)$	$R(2)$	clone part of $R(2)$	leftover $\mathrm{LO}(2)$
0	2/3	1/6	5/6	0	5/12	1/6	5/48	1/12
1	1/6	2/3	0	5/6	5/12	1/6	5/48	1/12
2	1/6	1/6	1/6	1/6	1/6	2/3	1/24	5/6

You can check two rows by hand. On report 0, $pQ_0 + (1-p)Q_1 = \frac{4}{5} \cdot \frac{5}{6} + 0 = \frac{2}{3}$, which is $R(0)$. And $\frac{1}{2}(R(0) + R(1))$ on report 0 is $\frac{1}{2}(\frac{2}{3} + \frac{1}{6}) = \frac{5}{12}$, the same as $\frac{1}{2}(Q_0 + Q_1)$.

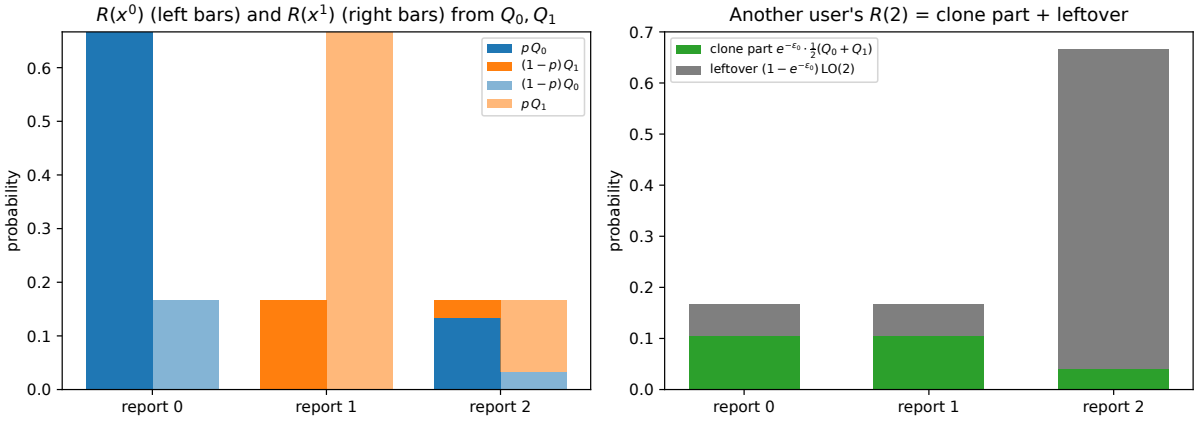

Figure L.4.: Left: the bars for $R(x^0)$ (solid) and $R(x^1)$ (pale) on the three reports, each split into its Q_0 part (blue) and its Q_1 part (orange), for three-valued randomized response with $\varepsilon_0 = \ln 4$. Right: another user's $R(2)$, split into the clone part $e^{-\varepsilon_0} \cdot \frac{1}{2}(Q_0 + Q_1)$ (green) and the leftover (grey).

L.3.3. Derivation

Steps 1 to 6 prove the reduction, and steps 7 to 13 bound the pair. Assume $\varepsilon_0 > 0$, since with $\varepsilon_0 = 0$ every report has the same distribution and there is nothing to prove.

1. **Define the two pure distributions.** Let

$$Q_0 = \frac{e^{\varepsilon_0} R(x^0) - R(x^1)}{e^{\varepsilon_0} - 1}, \qquad Q_1 = \frac{e^{\varepsilon_0} R(x^1) - R(x^0)}{e^{\varepsilon_0} - 1}. \tag{L.20}$$

   Each is non-negative on every report, because ε_0-DP gives $R(x^1)(y) \le e^{\varepsilon_0} R(x^0)(y)$, and the reverse. Each sums to $(e^{\varepsilon_0} - 1)/(e^{\varepsilon_0} - 1) = 1$. So both are distributions.

2. **Your report is randomized response followed by a draw.** Multiply out $pQ_0 + (1-p)Q_1$ over the common denominator $(e^{\varepsilon_0} + 1)(e^{\varepsilon_0} - 1)$. The terms in $R(x^1)$ are $-e^{\varepsilon_0} + e^{\varepsilon_0} = 0$, and the term in $R(x^0)$ is $e^{2\varepsilon_0} - 1$, so

$$R(x^0) = p\,Q_0 + (1-p)\,Q_1, \qquad R(x^1) = (1-p)\,Q_0 + p\,Q_1, \tag{L.21}$$

   where the second line is the same computation with x^0 and x^1 swapped.

3. **The average of your two report distributions is the average of the pure ones.** Adding the two definitions in step 1 gives $Q_0 + Q_1 = R(x^0) + R(x^1)$, because the factors $e^{\varepsilon_0} - 1$ cancel. So $\frac{1}{2}(R(x^0) + R(x^1)) = \frac{1}{2}(Q_0 + Q_1)$.

4. **Every other report contains a clone.** For another user holding x, ε_0-DP gives $R(x) \ge e^{-\varepsilon_0} R(x^0)$ and $R(x) \ge e^{-\varepsilon_0} R(x^1)$ on every report. Average the two and use step 3. The difference between $R(x)$ and $e^{-\varepsilon_0} \cdot \frac{1}{2}(Q_0 + Q_1)$ is non-negative with total mass $1 - e^{-\varepsilon_0}$, so it is that mass times a distribution $\mathrm{LO}(x)$, the leftover:

$$R(x) = \frac{e^{-\varepsilon_0}}{2}\,Q_0 + \frac{e^{-\varepsilon_0}}{2}\,Q_1 + (1 - e^{-\varepsilon_0})\,\mathrm{LO}(x). \tag{L.22}$$

   This is Equation 35.9 of the chapter, with the clones written in terms of Q_0 and Q_1.

5. **Count the faces.** Read each mixture as a coin with faces, followed by a draw from the face's distribution. Each other user's coin shows "Q_0" or "Q_1" with probability $e^{-\varepsilon_0}/2$ each, and "leftover" otherwise, independently. So the number of clones is $C \sim \mathrm{Bin}(n-1, e^{-\varepsilon_0})$, and $A \sim \mathrm{Bin}(C, \frac{1}{2})$ of them show Q_0. Your own coin (step 2) shows Q_0 with probability p on D and $1-p$ on D'. Let $\Delta = 1$ when your coin shows the face on your side, Q_0 on D and Q_1 on D'. Then the numbers of Q_0 and Q_1 faces among all users are $(A + \Delta,\ C - A + 1 - \Delta)$ on D and $(A + 1 - \Delta,\ C - A + \Delta)$ on D'. These are $\tilde{P}$ and $\tilde{Q}$.

6. **The shuffled output is a post-processing of the counts.** Here is the map, which makes Lemma 3.3 of the paper explicit. It receives counts (N_0, N_1) and knows every other user's value. It sets $c = N_0 + N_1 - 1$, since one of the $N_0 + N_1$ pure draws is your own report, and picks a uniformly random set of c other users as clones. It then draws N_0 reports from Q_0 and N_1 reports from Q_1. Every other user who was not picked gets one report from their own leftover distribution. Finally, the map outputs all n reports in a uniformly random order.

   Three facts show that this reproduces the shuffled output exactly. First, in the real process each other user is a clone independently and with the same probability. So, given that

there are c clones, which users they are is a uniformly random set of size c, independent of the faces. Second, given the faces, all reports are independent draws from Q_0, Q_1 or the leftovers. Third, the shuffler's random order removes every link between a report and its sender. The map uses only the counts, the other users' values and fresh randomness, which are the same on D and D'. So by data processing, every E_γ and D_α of the shuffled output is at most that of $(\tilde{P}, \tilde{Q})$.

7. **Condition on C.** Given $C = c$, the second count is $c + 1$ minus the first, so the first count a carries everything. The law of C is the same in both runs, so the pair is a shared-weight average over c of one-dimensional pairs.

8. **The likelihood ratio.** Write B_c for the probabilities of $\mathrm{Bin}(c, \frac{1}{2})$. Given c, $\tilde{P}(a) = p\,B_c(a-1) + (1-p)B_c(a)$ and $\tilde{Q}(a) = (1-p)B_c(a-1) + p\,B_c(a)$. Since $B_c(a-1)/B_c(a) = \binom{c}{a-1}/\binom{c}{a} = a/(c-a+1)$, dividing gives $\frac{pa+(1-p)(c-a+1)}{(1-p)a+p(c-a+1)}$. Measure a from the middle, $a = \frac{c+1}{2} + t$, and write $b = 2p - 1$. Then

$$\frac{\tilde{P}(a)}{\tilde{Q}(a)} = \frac{\frac{c+1}{2} + b\,t}{\frac{c+1}{2} - b\,t}, \qquad b = \frac{e^{\varepsilon_0} - 1}{e^{\varepsilon_0} + 1}. \tag{L.23}$$

   So the privacy loss, the logarithm of this ratio, grows with the distance t above the middle.

9. **δ is at most the chance of a large loss.** In $E_{e^\varepsilon}(\tilde{P}\|\tilde{Q})$, an outcome contributes $\tilde{P}(a) - e^\varepsilon \tilde{Q}(a)$ only if its loss exceeds ε, and then at most $\tilde{P}(a)$. So $\delta(\varepsilon)$ is at most the $\tilde{P}$-probability that the loss exceeds ε.

10. **Hoeffding on A.** Under $\tilde{P}$ the distance above the middle is $t = (A - \frac{c}{2}) + (\Delta - \frac{1}{2})$, which is at most $A - \frac{c}{2} + \frac{1}{2}$. Given $C = c$, the count A is a sum of c fair coins, so Hoeffding's inequality (Concentration) bounds the chance that it exceeds $c/2$ by more than s:

$$\Pr\left[A - \frac{c}{2} \geq s\right] \leq e^{-2s^2/c}. \tag{L.24}$$

    Choosing $s = \sqrt{c\ln(2/\delta)/2}$ makes this probability $\delta/2$.

11. **Chernoff on C.** The clone count has mean $\mu = (n-1)e^{-\varepsilon_0}$. The lower Chernoff bound of the same chapter says that it falls a fraction κ below its mean only rarely:

$$\Pr[C \leq (1-\kappa)\mu] \leq e^{-\kappa^2\mu/2}. \tag{L.25}$$

    Choosing $\kappa = \sqrt{2\ln(2/\delta)/\mu}$ makes this probability $\delta/2$, at the level $c_{\min} = (1-\kappa)\mu = \mu - \sqrt{2\mu\ln(2/\delta)}$.

12. **Combine the two tails.** By the union bound, the two failures of steps 10 and 11 together have $\tilde{P}$-probability at most δ. Outside them, $C > c_{\min}$ and, with c the value of C, $t \leq s + \frac{1}{2}$. Write the ratio Equation L.23 as $(1+u)/(1-u)$ with $u = b\,t/\frac{c+1}{2}$, which increases in u. The bound on t gives $u \leq h(c)$, where $h(c) = b(\sqrt{2c\ln(2/\delta)} + 1)/(c+1)$. Since the actual c is above $c_{\min}$, we want h to decrease, and it does for $c \geq 1$: its derivative has the sign of $\sqrt{2\ln(2/\delta)}\,\frac{1-c}{2\sqrt{c}} - 1$, which is negative there. So $u \leq h(c_{\min})$. The other direction, $E_{e^\varepsilon}(\tilde{Q}\|\tilde{P})$, is the same, because swapping the two counts and replacing A by $C - A$ turns $\tilde{P}$ into $\tilde{Q}$. So the pair, and with it the shuffled output, is (ε, δ)-DP with

$$\varepsilon = \ln\frac{1+x}{1-x}, \qquad x = b\,\frac{\sqrt{2c_{\min}\ln(2/\delta)} + 1}{c_{\min} + 1}, \qquad c_{\min} = \mu - \sqrt{2\mu\ln(2/\delta)}, \tag{L.26}$$

provided $c_{\min} \geq 1$ and $x < 1$.

13. **The shape of Equation 35.7.** Suppose the expected number of clones is at least $8\ln(2/\delta)$. Then the Chernoff margin $\sqrt{2\mu\ln(2/\delta)}$ is at most $\mu/2$, so $c_{\min}$ is at least $\mu/2$. Bounding $c+1$ below by c and putting $c = \mu/2$ into the decreasing $h(c)$ gives

$$x \leq \bar{x} = 2b\Big(\sqrt{\frac{\ln(2/\delta)}{\mu}} + \frac{1}{\mu}\Big). \tag{L.27}$$

If also $\bar{x} \leq \frac{1}{2}$, then $1-\bar{x} \geq \frac{1}{2}$, so $\frac{1+\bar{x}}{1-\bar{x}} = 1 + \frac{2\bar{x}}{1-\bar{x}}$ is at most $1+4\bar{x}$. Substituting $1/\mu = e^{\varepsilon_0}/(n-1)$ gives

$$\varepsilon \leq \ln\left(1 + \frac{e^{\varepsilon_0}-1}{e^{\varepsilon_0}+1}\left(\frac{8\sqrt{e^{\varepsilon_0}\ln(2/\delta)}}{\sqrt{n-1}} + \frac{8e^{\varepsilon_0}}{n-1}\right)\right). \tag{L.28}$$

This is Equation 35.7 with $\ln(2/\delta)$ in place of $\ln(4/\delta)$ and $n-1$ in place of n, under the two conditions just used. So the constant 8 of the paper is reproduced.

L.3.4. Checking it

The script checks steps 1 to 4 on 2,000 random randomizers that are 2-DP, each with four inputs and five reports. Q_0, Q_1 and every leftover are non-negative, and the identities of steps 2 and 3 hold to 1.1×10^{-16}. It then checks the whole reduction exactly on a small case: four users with three-valued randomized response at $\varepsilon_0 = \ln 4$, the other three holding 2, 2 and 0. The exact law of the shuffled reports and the law produced by the map of step 6 from $(\tilde{P}, \tilde{Q})$ agree to 8.3×10^{-17} on both D and D'.

Table L.5 compares the bounds at $\delta = 10^{-6}$. The numeric column is the exact ε of the clone pair, and it reproduces Table 35.4.

Table L.5.: Central ε at $\delta = 10^{-6}$ for n shuffled reports that are each ε_0-DP: the exact value for the clone pair, this section's closed form, its simplified form, and the closed form of Feldman, McMillan & Talwar. "n/a" marks where a condition fails.

n	ε_0	Clone pair, numeric	Equation L.26	Step 13, $\ln(1+4\bar{x})$	Equation 35.7
1,000	1	0.1824	0.3111	0.5565	0.5662
1,000	2	0.5455	1.0601	n/a	n/a
10,000	1	0.0530	0.0863	0.2096	0.2140
10,000	2	0.1550	0.2437	0.4919	0.5009
10,000	4	0.6009	1.0955	n/a	n/a
100,000	2	0.0450	0.0724	0.1823	0.1862
100,000	4	0.1698	0.2621	0.5251	0.5346

Equation L.26 is 1.54 to 1.94 times the numeric value, while the paper's closed form is 3.10 to 4.14 times it. The gain comes from keeping $\ln\frac{1+x}{1-x}$ and the exact $c_{\min}$ instead of simplifying them. The simplified form of step 13 is slightly below the paper's in every row, mainly because $\ln(2/\delta)$ is

smaller than $\ln(4/\delta)$. All the closed forms are loose in another way too. At the ε of Equation L.26, the pair's true δ is at most 3.84×10^{-11}, far below 10^{-6}, because each of steps 9 to 12 gives up some slack. Compute the numeric value to deploy.

Figure L.5 draws the two tails behind the bound for $n = 1000$ and $\varepsilon_0 = 2$. At the typical clone count, the loss stays below the closed-form ε across the whole Hoeffding window. The closed form must also cover clone counts as low as $c_{\min} = 72.6$, where the loss climbs faster, and that is where most of its slack comes from.

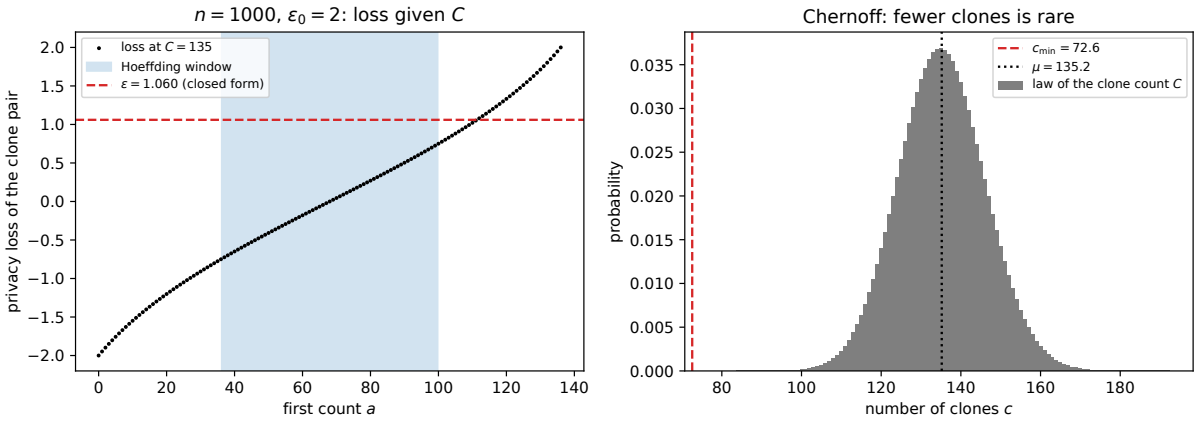

Figure L.5.: Left: the privacy loss of the clone pair against the first count a, given $C = 135$, the rounded mean, for $n = 1000$ and $\varepsilon_0 = 2$. The shaded band is the Hoeffding window of step 10 at $\delta = 10^{-6}$, and the dashed line is ε from Equation L.26. Right: the law of the clone count C, its mean μ and the Chernoff level $c_{\min}$ of step 11.

L.3.5. What it does not cover

The proof fixes one randomizer R that every user applies. Theorem 3.1 of the paper, as the chapter states it, also allows each randomizer to be chosen adaptively from the earlier outputs. Then step 4 has to compare a user's randomizer with yours, and the paper needs a more careful argument, which stays cited. The numeric clone bound is exact for the pair, not for the mechanism. For binary randomized response the exact shuffled ε of Section 35.3 is smaller still.

L.4. Shift reduction and contraction

L.4.1. What the chapter uses

Amplification by iteration tracks two runs of a noisy iteration that use different records. To compare where they end up, it moves one run a little before comparing. To **couple** two random variables is to build them on one draw, so that each value of one is paired with a value of the other. The **shifted Rényi divergence** allows the first distribution to be moved by at most z in this way:

$$D_\alpha^{(z)}(X\|X') = \inf\{D_\alpha(Y\|X') : \text{some coupling of } X \text{ and } Y \text{ has } \|X - Y\| \le z \text{ almost surely}\}. \tag{L.29}$$

With $z = 0$ it is the ordinary D_α.

The iteration adds Gaussian noise at every step. Write $Z \sim \mathcal{N}(0, \sigma^2 I)$ for one step's noise, independent of everything else. The price of hiding a shift of length at most a under it is

$$R_\alpha(a) = \sup_{\|w\| \le a} D_\alpha(Z + w \,\|\, Z) = \frac{\alpha a^2}{2\sigma^2}, \tag{L.30}$$

the Gaussian cost Equation 35.4, which is the same in both orders. The two lemmas are Lemmas 20 and 21 of Feldman, Mironov, Talwar & Thakurta (2018). The first lets the noise pay off a shift $a \ge 0$. The second handles the gradient steps, which differ between the runs because they use different records. It lets two maps ψ and ψ' act on the runs, where ψ' is a **contraction**, $\|\psi'(u) - \psi'(v)\| \le \|u - v\|$, and the two maps differ by at most s at every point. In symbols,

$$D_\alpha^{(z)}(X + Z \,\|\, X' + Z) \le D_\alpha^{(z+a)}(X \| X') + R_\alpha(a), \qquad D_\alpha^{(z+s)}(\psi(X) \,\|\, \psi'(X')) \le D_\alpha^{(z)}(X \| X'). \tag{L.31}$$

These are Equation 35.11 and Equation 35.12 in Section 35.5. The chapter shows the first only for point masses, and says that the general proof uses a coupling and bounds a joint pair. It states the second without proof. Theorems 22 and 23, and the plateau bound Equation 35.17 of Section 35.6, rest on both.

L.4.2. The idea

Contraction is the easy one. Move X to a nearby Y that is cheap to compare with X', and apply ψ' to Y. The maps can push the pair apart only by how much they differ, s. And applying the same map ψ' to Y and to X' cannot make them easier to tell apart.

For shift reduction, start from a coupling that moves each value of X by at most $z + a$. Split every move into two parts along the same direction. The **carried** part, of length at most z, is left for later, which is why the left side still allows a shift of z. The **paid** part, of length at most a, is absorbed into the noise. Absorbing it turns the noise Z into Z plus a random shift of length at most a. Such a noise is at most $R_\alpha(a)$ away from Z itself, and the chain rule adds that cost to the cost of Y.

Take X equal to 0 or 1 with probability $\frac{1}{2}$ each, and $X' = 1$. Moving every value of X to 1 makes it equal to X', so $D_\alpha^{(1)}(X \| X') = 0$. Now pay $a = 0.5$ of the shift with the noise. The value 0 needs a move of 1, split into 0.5 carried and 0.5 paid. The value 1 needs no move. The left panel of Figure L.6 draws this.

L.4.3. Derivation

Contraction.

1. **Pick a cheap nearby Y.** Fix $\xi > 0$. By the definition of the infimum, there is a Y and a coupling with $\|X - Y\| \le z$ and $D_\alpha(Y \| X') \le D_\alpha^{(z)}(X \| X') + \xi$.

2. **Carry the coupling through the maps.** Use the same coupling for $\psi(X)$ and $\psi'(Y)$. By the triangle inequality, $\|\psi(X) - \psi'(Y)\| \le \|\psi(X) - \psi'(X)\| + \|\psi'(X) - \psi'(Y)\| \le s + z$. The first term is at most s by the assumption on the two maps, and the second at most z because ψ' is a contraction.
3. **Apply the same map to both.** $D_\alpha(\psi'(Y)\|\psi'(X')) \le D_\alpha(Y\|X')$ by data processing: one map, applied to both, cannot raise a divergence.
4. **Conclude.** $\psi'(Y)$ is within $z + s$ of $\psi(X)$, so it is allowed in the infimum that defines $D_\alpha^{(z+s)}(\psi(X)\|\psi'(X'))$. That divergence is therefore at most $D_\alpha^{(z)}(X\|X') + \xi$, for every $\xi > 0$.

Only ψ' needs to be a contraction. The chapter assumes both maps are, which is more than enough.

Shift reduction.

1. **Pick a cheap nearby Y.** Fix $\xi > 0$ and take Y coupled to X with $\|X - Y\| \le z + a$ and $D_\alpha(Y\|X') \le D_\alpha^{(z+a)}(X\|X') + \xi$. Let the noise Z be independent of X, Y and X'.
2. **Split each move.** Let $W = X - Y$, and shorten it to length at most a:
$$W_2 = \min\Big(1, \frac{a}{\|W\|}\Big)W, \qquad W_1 = W - W_2, \tag{L.32}$$
with $W_2 = 0$ when $W = 0$. Both parts point along W. So $\|W_2\| \le a$ and $\|W_1\| = \max(\|W\| - a, 0) \le z$.
3. **Build the new nearby point.** Let $Y' = Y + W_2 + Z$. Then $(X+Z) - Y' = X - Y - W_2 = W_1$, so Y' is within z of $X + Z$, and
$$D_\alpha^{(z)}(X + Z \,\|\, X' + Z) \le D_\alpha(Y' \,\|\, X' + Z). \tag{L.33}$$
4. **Look at the pair before the sum.** Y' is the sum of Y and $W_2 + Z$, and $X' + Z$ is the sum of X' and Z. Adding the two coordinates is one map applied to both, so by data processing
$$D_\alpha(Y' \,\|\, X' + Z) \le D_\alpha((Y,\ W_2 + Z) \,\big\|\, (X',\ Z)). \tag{L.34}$$
5. **Use the chain rule.** The proof of Equation 29.10 in Rényi DP uses only one thing: each joint law is the law of a first coordinate times the law of the second given the first. It shows that the Rényi divergence of the joint pair is at most that of the first coordinates plus the largest divergence of the second coordinates given the first. Here the second coordinate of the right pair is Z, independent of X'. So
$$D_\alpha((Y,\ W_2 + Z) \,\big\|\, (X',\ Z)) \le D_\alpha(Y\|X') + \sup_y D_\alpha(\mathrm{Law}(W_2 + Z \mid Y = y) \,\big\|\, \mathcal{N}(0, \sigma^2 I)). \tag{L.35}$$
6. **Bound the noise with a random shift.** The noise is independent of Y and W_2. So given $Y = y$, the sum $W_2 + Z$ is a mixture of shifted Gaussians $\mathcal{N}(w, \sigma^2 I)$, one for each value w of the paid part, and each such w has length at most a. The moment of a Rényi divergence is an average of a convex function of the ratio,
$$e^{(\alpha-1)D_\alpha(P\|Q)} = \int Q\Big(\frac{P}{Q}\Big)^\alpha, \tag{L.36}$$
and $u \mapsto u^\alpha$ is convex for $\alpha > 1$, so the moment is convex in P for a fixed Q. The moment of a mixture is therefore at most the largest moment of its components. So the divergence in step 5 is at most the largest $D_\alpha(Z + w\|Z)$ over $\|w\| \le a$, which is $R_\alpha(a)$.
7. **Conclude.** Steps 3 to 6 give $D_\alpha^{(z)}(X + Z\|X' + Z) \le D_\alpha^{(z+a)}(X\|X') + \xi + R_\alpha(a)$, for every $\xi > 0$. This is Equation 35.11.

L.4.4. Checking it

In the example, $\sigma = 1$ and the total shift is 1, of which a is paid and $z = 1 - a$ carried. The cheap nearby point is $Y = 1$, with $D_\alpha(Y \| X') = 0$. The paid part is $W_2 = -a$ when $X = 0$ and 0 when $X = 1$, so the constructed $Y' = 1 + W_2 + Z$ is an equal mixture of $\mathcal{N}(1 - a, 1)$ and $\mathcal{N}(1, 1)$. It is compared with $X' + Z = \mathcal{N}(1, 1)$. Its order-2 divergence has a closed form. Write r for the likelihood ratio of $\mathcal{N}(1 - a, 1)$ to $\mathcal{N}(1, 1)$, which averages to 1 and has second moment e^{a^2} under $\mathcal{N}(1, 1)$. Then the second moment of the mixture's ratio is $\mathbb{E}[(\frac{1}{2} + \frac{1}{2}r)^2] = \frac{1}{4}(1 + 2 + e^{a^2})$, so

$$D_2(Y' \,\|\, X' + Z) = \ln\Big(1 + \tfrac{1}{4}(e^{a^2} - 1)\Big), \tag{L.37}$$

which is the subsampled Gaussian moment of Equation 33.11 at $\alpha = 2$, with $q = \frac{1}{2}$ and noise multiplier $1/a$. The lemma bounds it by $R_2(a) = a^2$. Table L.6 compares them, and the script confirms the closed form by numerical integration.

Table L.6.: The divergence of the constructed Y' in the example, against the price $R_2(a)$ that the shift-reduction lemma charges.

Paid shift a	Exact $D_2(Y' \| X' + Z)$	Bound $R_2(a)$
0.25	0.0160	0.0625
0.5	0.0686	0.2500
1	0.3574	1.0000

All the slack in this example comes from step 6. The paid shift is a only half the time, but the lemma charges the full $R_\alpha(a)$, as if it were paid every time. The lemma is tight when every value of X is moved by the full $z + a$, and then step 6 loses nothing. The script also checks the split of step 2 on 100,000 random moves in three dimensions, with $z = 0.6$ and $a = 0.4$. The largest carried part has length 0.6000 and the largest paid part 0.4000, as step 2 says.

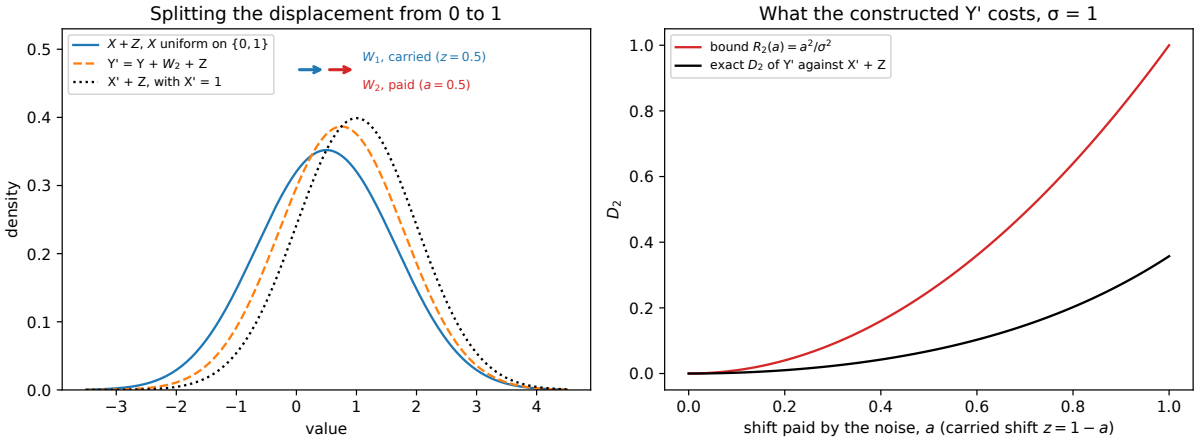

Figure L.6.: Left: the example with $\sigma = 1$ and $a = 0.5$. The densities of $X + Z$ (solid), of the constructed Y' (dashed) and of $X' + Z$ (dotted). The arrows split the move of the value 0 into the carried part W_1 and the paid part W_2. Right: the exact D_2 of Y' against $X' + Z$, and the lemma's price $R_2(a) = a^2$, as functions of the paid shift a.

L.5. The random stopping time

L.5.1. What the chapter uses

Projected noisy SGD makes one pass over n records, projecting each iterate back onto a convex set. The neighbouring relation is replace-one: the two datasets differ in the value of one record. Its losses are convex and β-smooth, the learning rate is at most $2/\beta$ so that each step is a contraction, and they are L-Lipschitz, which means each gradient has length at most L. It adds Gaussian noise of standard deviation σ to each gradient and releases only the last iterate. The chapter writes L_f for the Lipschitz constant, and this section writes L to keep formulas short. Theorem 23 in Section 35.5 gives the record used at step t of a run of T steps the curve

$$D_\alpha \le \frac{2\alpha L^2}{\sigma^2 (T - t + 1)}. \tag{L.38}$$

The last record is protected by only one step. A random stopping time fixes this. The chapter states Theorem 26 of Feldman, Mironov, Talwar & Thakurta (2018) without proof. Let the number of steps T be uniform on $\{1, \dots, n\}$ and independent of the data, and let the noise satisfy $\sigma \ge L\sqrt{2(\alpha - 1)\alpha}$. Then every record gets

$$\varepsilon(\alpha) = \frac{4\alpha L^2 \ln n}{n\sigma^2}. \tag{L.39}$$

This section derives a bound of this form. It reproduces the constant 4 for every $n \ge 37$.

L.5.2. The idea

The law of the output of the run that stops at a random time is an average over T of the laws of the runs that stop at T. Both datasets use the same weights $1/n$, because T does not depend on the data. Joint convexity then bounds the Rényi moment of the average by the average of the Rényi moments. A run that stops before your record is used leaks nothing. A run that stops k steps after your record is used leaks at most $2\alpha L^2/(\sigma^2 k)$, by Theorem 23. So for the first record the average leak is about $2\alpha L^2/\sigma^2$ times $\frac{1}{n}(1 + \frac{1}{2} + \cdots + \frac{1}{n})$, and that harmonic sum is about $\ln n$.

For $n = 1000$ and the first record, the average of $1/k$ over $k = 1, \dots, 1000$ is $H_{1000}/1000 = 0.0074855$, where $H_m = 1 + \frac{1}{2} + \cdots + \frac{1}{m}$ is the harmonic number. A run of fixed length gives the last record the full $1/1$.

L.5.3. Derivation

1. **The output is an average over the stopping time.** Fix the record at position t and the two datasets. Let P_T and Q_T be the laws of the iterate after T steps on D and on D'. The released output has law $P = \frac{1}{n}\sum_T P_T$ on D and $Q = \frac{1}{n}\sum_T Q_T$ on D'.

2. **Joint convexity of the moment.** For $\alpha > 1$ the moment of the Rényi divergence is an integral of $Q\, g(P/Q)$, with the convex function $g(u) = u^\alpha$. A function of the form $Q\, g(P/Q)$ is the **perspective** of g, and it is jointly convex in the pair (P, Q), as Appendix Section F.5 derives. The reason is Jensen's inequality. Take weights λ_i and pairs (P_i, Q_i), and let $\bar{P} = \sum_i \lambda_i P_i$ and $\bar{Q} = \sum_i \lambda_i Q_i$. Then $\sum_i \lambda_i Q_i\, g(P_i/Q_i)$ is $\bar{Q}$ times an average of the values $g(P_i/Q_i)$, with weights $\lambda_i Q_i/\bar{Q}$. That average is at least g of the averaged argument, which is $g(\bar{P}/\bar{Q})$. So
$$e^{(\alpha-1)D_\alpha(P\|Q)} \le \frac{1}{n}\sum_{T=1}^{n} e^{(\alpha-1)D_\alpha(P_T\|Q_T)}. \tag{L.40}$$

3. **The terms.** If $T < t$, your record has not been used, so $P_T = Q_T$ and the term is 1. If $T \ge t$, Theorem 23 for a run of T steps gives $D_\alpha(P_T\|Q_T) \le 2\alpha L^2/(\sigma^2 k)$, with $k = T - t + 1$. So the term is at most e^{x_k}, where
$$x_k = \frac{2\alpha(\alpha-1)L^2}{\sigma^2\, k}, \qquad k = 1, \dots, n-t+1. \tag{L.41}$$

4. **The noise condition keeps every exponent small.** The largest exponent is x_1, and $x_1 \le 1$ is exactly the condition $\sigma \ge L\sqrt{2(\alpha-1)\alpha}$.

5. **Replace each exponential by a line.** On $[0, 1]$ the convex function e^x lies below its chord from $(0, 1)$ to $(1, e)$, so $e^x \le 1 + (e-1)x$. Summing over k, the n terms add up to at most $n + (e-1)\frac{2\alpha(\alpha-1)L^2}{\sigma^2} H_{n-t+1}$. The harmonic number H_{n-t+1} is at most H_n, so the first record, $t = 1$, is the worst.

6. **Take logarithms.** Divide by n, use $\ln(1+u) \le u$, and divide by $\alpha - 1$:
$$D_\alpha(P\|Q) \le \frac{2(e-1)\,\alpha L^2\, H_n}{n\sigma^2}. \tag{L.42}$$

7. **Compare with the stated constant.** The stated bound is $4\alpha L^2 \ln n/(n\sigma^2)$. So it follows from Equation L.42 whenever the harmonic factor is small enough,
$$2(e-1)H_n \le 4\ln n. \tag{L.43}$$

   The script finds that this holds for every n from 37 to 10^6. Beyond 10^6 the bound $H_n \le 1 + \ln n$ is enough, because $2(e-1)(1+\ln n) \le 4\ln n$ once $n \ge 446$. For $n < 37$, though, the derivation gives $2(e-1)H_n$ in place of $4\ln n$. The chord matters here: with the cruder line $e^x \le 1 + 2x$, the constant would be $4H_n$, slightly above $4\ln n$.

L.5.4. Checking it

Take $n = 1000$, $\alpha = 2$, $L = 1$ and $\sigma = 2$, so $x_1 = 1.00$ and the noise condition holds with equality. At $\alpha = 2$, a run of fixed length n gives the first record the Rényi bound 0.0010 and the last record 1.0000. With the random stopping time, the average of step 2, before any approximation, gives at most 0.008527 to the first record and 0.001717 to the last. After the chord and the logarithm, Equation L.42 gives 0.012862 for every record, below the stated 0.013816. Figure L.7 shows the trade. A random stopping time gives up the excellent guarantee of the early records to protect the late ones.

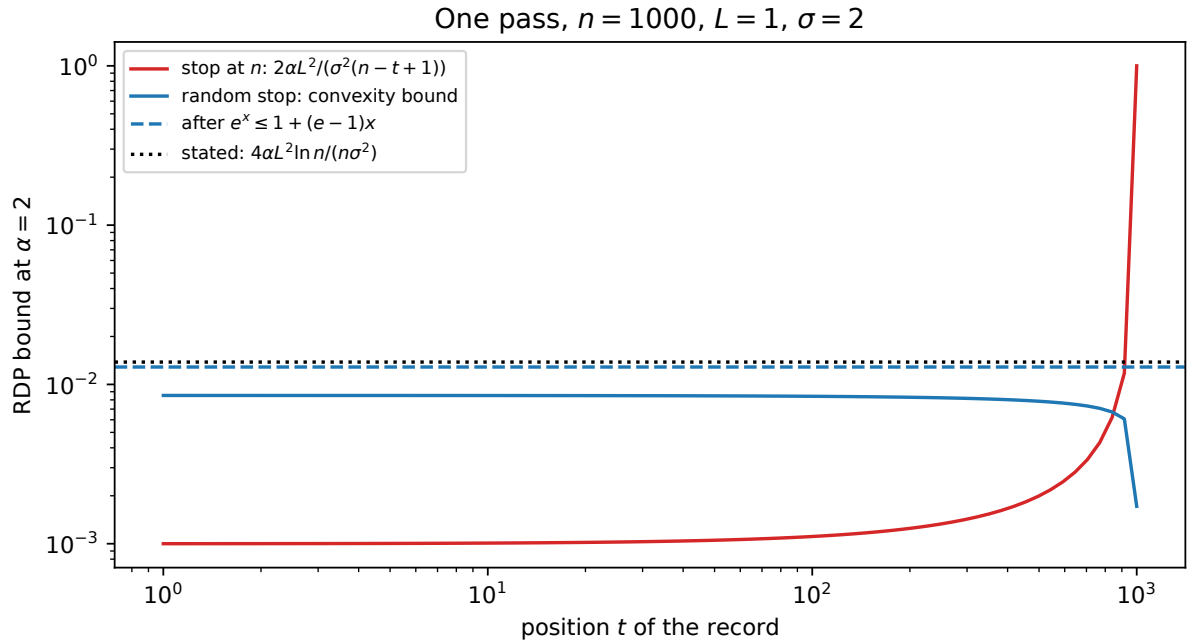

Figure L.7.: The RDP bound at $\alpha = 2$ for each record of a one-pass run with $n = 1000$, $L = 1$ and $\sigma = 2$, against the position t of the record. Red: the run always stops at n (Theorem 23). Blue: the random stopping time, from the convexity bound of step 2. Dashed: Equation L.42. Dotted: the stated bound $4\alpha L^2 \ln n/(n\sigma^2)$.

L.5.5. What it does not cover

The noise condition depends on the order: at $\alpha = 8$ it asks for $\sigma \ge L\sqrt{112}$. Larger orders need more noise, or a bound that does not use the chord. The result also needs one pass, a stopping time independent of the data, and the release of the final iterate only.

L.6. Code

The script `code/appendix-derivations/apx_amplification.py` computes every number on this page and draws its figures. It checks the randomized-response inequality on a grid and the Gaussian directions in two ways. It checks the two hockey-stick identities against closed forms, and domination on a small dataset. For the clones, it checks the decomposition on random randomizers, verifies the reduction exactly for four users, and computes the clone pair's exact ε next to the closed forms. It also evaluates the shift-reduction example and the random-stopping bounds. Run it with

```
uv run python code/appendix-derivations/apx_amplification.py
```

Table L.7 summarizes its output.

Table L.7.: The script's main results with the default seed.

Check	Result
Randomized-response gap on 5,294,646 grid points	no negative value
$D_\alpha(P_q\|P_0)$ and $D_\alpha(P_0\|P_q)$ at $\alpha = 32$, $q = 0.01$, $\sigma = 1$	11.246 and 1.6923×10^{-3}, two ways
Hockey-stick identities against closed forms, relative gap	7.4×10^{-14} (remove), 3.0×10^{-12} (add)
Three-record dataset, largest ratio of real to pair	0.9687
Clone decomposition on 2,000 random randomizers	no negative entry; identities to 1.1×10^{-16}
Exact reduction for four users	agreement to 8.3×10^{-17}
Clone closed form against numeric, $n = 10^4$, $\varepsilon_0 = 2$	0.2437 against 0.1550
Shift example at $a = 1$: exact D_2 against $R_2(a)$	0.3574 against 1.0000
Random stopping, $n = 1000$, $\alpha = 2$: Equation L.42 against the stated bound	0.012862 against 0.013816

Each derivation holds wherever the script can test it, and the closed forms are loose by the factors the sections report. For the clone bound, compute the pair numerically. For the stopping time, the stated constant is safe from $n = 37$ on.

M. Private learning and tuning

This appendix derives five results that the chapters on private machine learning state but do not prove in full. All five are about learning under differential privacy (DP). Each one takes a guarantee for a small building block and follows it through a learning procedure. The block is one noisy gradient step, one noisy vote, one training run, one record of a user, or one step's noise. The chapters cite papers for these proofs, sketch them, or check them only numerically. Here each is derived step by step from facts the book has already met, and each is checked by a script. Table M.1 lists them.

Table M.1.: The derivations of this appendix and the chapter sections that state or use them.

Derivation	Where the chapter states or uses it
The best excess risk of private convex empirical risk minimization, from above and below, and exact bounds for output and objective perturbation	Section 38.7, Section 38.6, Section 38.3 and Section 38.4
The data-dependent Rényi bound for a noisy vote of teachers	Section 42.7
The Rényi bound for the best of a random number of training runs	Section 40.6
The worst case for a user with k records in private gradient descent with record-level sampling	Section 44.4
How one step of private gradient descent changes the loss of one group	Section 45.5

The page keeps one notation throughout, even where a source paper uses other letters. The model's parameters are θ, the Rényi order is always α, the learning rate is η and the sampling rate is q. The letter λ is a ridge coefficient in the first section and a curvature in the last, and μ is a ratio of sensitivity to noise. Each section names its letters again where they first appear.

M.1. The optimal rates of private convex learning

M.1.1. What the chapter uses

Private empirical risk minimization trains a model by **empirical risk minimization (ERM)**: it minimizes the average loss on n training records, plus a ridge penalty. For a dataset D the

objective is

$$\mathcal{L}(\theta; D) = \frac{1}{n} \sum_{i=1}^{n} \ell(\theta; z_i) + \frac{\lambda}{2} \|\theta\|^2. \tag{M.1}$$

Here θ is the vector of model parameters in d dimensions, z_i is the i-th record, and we write $\mathcal{L}(\theta)$ when the dataset is fixed. The loss ℓ is convex, and its gradient has length at most a constant L. The ridge coefficient is λ, and the minimizer of the objective $\mathcal{L}$ is θ^*.

A private algorithm releases parameters $\tilde{\theta}$, and its **excess risk** is $\mathcal{L}(\tilde{\theta}) - \mathcal{L}(\theta^*)$, how much worse they fit than the minimizer. Neighbouring datasets differ by replacing one record, and the guarantee is DP with privacy parameters ε and δ.

Section 38.7 states in Equation 38.23 that the best expected excess risk any (ε, δ)-DP algorithm can reach is of order

$$\frac{L^2 d}{\lambda n^2 \varepsilon^2}, \tag{M.2}$$

up to logarithms. Section 38.6 states the matching lower bound of order $RL\sqrt{d}/(n\varepsilon)$ for losses without a ridge, with weights in a ball of radius R. The chapter says that "the proofs of the optimal rate and of the lower bound are long" and cites Bassily, Smith & Thakurta (2014) for both. It also gives the excess risk of output perturbation, Equation 38.10, and of objective perturbation, Equation 38.14, only to second order in the noise.

This section proves three things. The first is an upper bound of the right order, with explicit constants, for noisy projected gradient descent. The second is a lower bound for every private algorithm, again with explicit constants, which proves the rate up to those constants. The third is a pair of exact two-sided bounds that replace the chapter's second-order formulas.

The upper bound uses the exact Gaussian calibration of the chapter. There, $\mu(\varepsilon, \delta)$ is the largest ratio of sensitivity to noise at which one Gaussian release is (ε, δ)-DP, given by Equation 38.2. The algorithm is noisy projected gradient descent, started from $\theta_1 = 0$ and kept in the ball of radius $R = L/\lambda$. It runs for T steps, and the learning rate at step t is $\eta_t = 2/(\lambda(t+1))$. Each gradient gets Gaussian noise of standard deviation $\sigma = (2L/n)\sqrt{T}/\mu(\varepsilon, \delta)$ per coordinate. The release $\tilde{\theta}$ is the average of the iterates in which iterate t has weight proportional to t. If the number of steps is $T \geq n^2\mu^2/d$, then

$$\mathbb{E}[\mathcal{L}(\tilde{\theta})] - \mathcal{L}(\theta^*) \leq \frac{16 L^2 d}{\lambda n^2 \mu(\varepsilon, \delta)^2} \leq \frac{32 L^2 d \ln(1.25/\delta)}{\lambda n^2 \varepsilon^2}. \tag{M.3}$$

The second form holds for $\varepsilon < 1$.

The lower bound uses a number K that measures how many records a private mean needs. The fingerprinting bound of Lower bounds says that estimating d means of ± 1 attributes privately to a constant accuracy needs a number of records proportional to

$$K = \frac{\sqrt{d}}{(e^{\varepsilon} - 1) + 4\delta\sqrt{d}}. \tag{M.4}$$

The denominator is how much one record can influence a correlation score under DP, and the numerator is the spread of that score. The proof below builds hard datasets with m real records

out of n, for an integer m that it is free to choose. For every (ε, δ)-DP algorithm there is a dataset of n records, with linear losses whose gradients have length at most L, on which

$$\mathbb{E}[\mathcal{L}(\tilde{\theta})] - \mathcal{L}(\theta^*) \geq \frac{L^2}{2\lambda} \max_{1 \leq m \leq n} \left[\frac{m}{n}\left(\frac{1}{3} - \frac{m}{2K}\right)\right]^2 \geq \frac{L^2 K^2}{2592\,\lambda n^2} \quad \text{when } 3 \leq K \leq 3n. \tag{M.5}$$

The range for K makes the best choice of m, about $K/3$, a whole number between 1 and n. When δ is small enough that $4\delta\sqrt{d} \leq e^\varepsilon - 1$, the number K is at least $\sqrt{d}/(2(e^\varepsilon - 1))$. Then, still for $3 \leq K \leq 3n$, the bound is at least $L^2 d/(10368\,\lambda n^2 (e^\varepsilon - 1)^2)$. For $\varepsilon \leq 1$, $e^\varepsilon - 1$ is between ε and 1.72ε, so this is of the order of Equation 38.23. Without a ridge, over the ball of radius R and with the same K, every private algorithm has excess risk at least

$$\max_{1 \leq m \leq n} \frac{mLR}{16n}\left(\frac{2}{3} - \frac{m}{K}\right)^2 \geq \frac{LRK}{729\,n} \quad \text{when } \tfrac{9}{2} \leq K \leq \tfrac{9}{2}n, \tag{M.6}$$

which is of order $RL\sqrt{d}/(n\varepsilon)$.

The exact bounds sandwich the excess risk between two multiples of the noise's average squared length. Write β_s for the largest curvature of $\mathcal{L}$, for example $\beta_s = \frac{1}{4} + \lambda$ for the chapter's logistic regression with features of length at most 1. Output perturbation adds noise Z to θ^*, and objective perturbation adds $\frac{1}{n}\langle b, \theta\rangle$ to the objective. Then

$$\frac{\lambda}{2}\mathbb{E}\|Z\|^2 \leq \mathbb{E}[\mathcal{L}(\theta^* + Z) - \mathcal{L}(\theta^*)] \leq \frac{\beta_s}{2}\mathbb{E}\|Z\|^2, \qquad \frac{\lambda\,\mathbb{E}\|b\|^2}{2\beta_s^2 n^2} \leq \mathbb{E}[\mathcal{L}(\tilde{\theta}) - \mathcal{L}(\theta^*)] \leq \frac{\mathbb{E}\|b\|^2}{2\lambda n^2}. \tag{M.7}$$

M.1.2. The idea

The upper bound treats privacy noise as one more source of gradient noise. Stochastic gradient descent (SGD) on a strongly convex objective converges at a rate that depends on the noise only through the average squared length G^2 of the noisy gradient. Privacy adds $d\sigma^2$ to G^2, one σ^2 per coordinate. The noise per step must grow like $\sqrt{T}$ to keep the total privacy fixed, so $d\sigma^2$ grows like T. But the convergence bound divides G^2 by T, so the number of steps cancels from the noise term. What is left is d times the noise of one full-budget release, which is the rate.

The lower bound turns a private trainer into a private mean estimator, which the fingerprinting argument says cannot be accurate with few records. Take the loss $-\langle\theta, x\rangle$ on records x, plus the ridge. Then the objective is a bowl centred on the mean of the records divided by λ, and the excess risk of any θ is $\frac{\lambda}{2}$ times its squared distance from that centre. A trainer with small excess risk therefore outputs a good estimate of the mean of the records.

The rate in n comes from padding with records equal to zero. Figure M.1 shows the move in two dimensions. Four real records sit at corners of a square, and four zero records sit at the origin. The mean of all eight is half the mean of the four real ones, so multiplying the trainer's output by $n/m = 2$ estimates the real mean. That multiplication also doubles the trainer's error. So a trainer whose error is e on n records gives an estimator whose error is $(n/m)e$ on m records. Fingerprinting says the estimator's error is at least a constant when m is about K or less, so the trainer's error is at least that constant times m/n, about K/n. Squaring a distance of order K/n gives an excess risk of order K^2/n^2.

The exact bounds hold because a strongly convex, smooth function lies between two parabolas around its minimizer. The excess risk of any point is at least $\frac{\lambda}{2}$ and at most $\frac{\beta_s}{2}$ times its squared distance from θ^*. The chapter's second-order formula sits between the two, with the true curvature in place of λ or β_s.

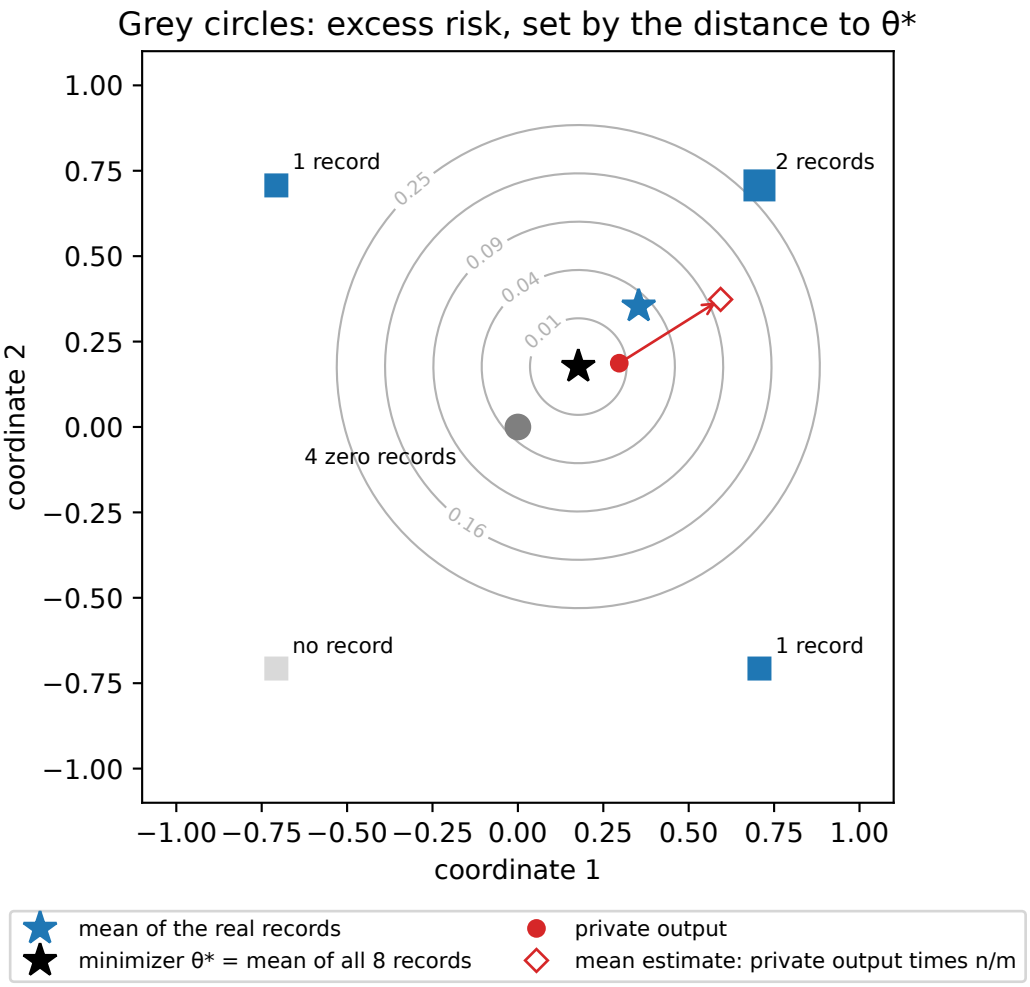

Figure M.1.: The reduction in two dimensions, with $L = \lambda = 1$. Four real records sit at corners of the square (one corner holds two), and four zero records at the origin. The minimizer θ^* of the objective is the mean of all eight, and the grey circles are levels of the excess risk. Multiplying a private output by $n/m = 2$ estimates the mean of the four real records, with twice the output's error.

M.1.3. Derivation

The upper bound. Three facts from earlier chapters do the work, and each is restated where it is used.

1. **Privacy.** Each step releases the noisy gradient $\nabla\mathcal{L}(\theta_t) + \xi_t$, where the noise ξ_t is fresh, normal, with mean zero and variance σ^2 in each coordinate. Replacing one record changes the average of the loss gradients by at most $2L/n$, because one gradient of length at most L leaves and another arrives. The ridge term $\lambda\theta_t$ is the same on both datasets. So each step is a Gaussian mechanism with ratio $2L/(n\sigma)$. By Fact 5 of Private empirical risk minimization, T adaptive Gaussian steps are exactly as private as one Gaussian release with ratio $\sqrt{T} \cdot 2L/(n\sigma)$, and the choice of σ makes this $\mu(\varepsilon, \delta)$. The projection and the average use only released values, so they are post-processing.
2. **The ball contains the minimizer.** The gradient of $\mathcal{L}$ is zero at θ^*, so $\lambda\theta^* = -\frac{1}{n}\sum_i \nabla\ell(\theta^*; z_i)$. The right side is an average of vectors of length at most L, so $\|\theta^*\| \le L/\lambda = R$. The minimizer over the ball is therefore the overall minimizer.
3. **The noisy gradient's second moment.** On the ball, $\|\nabla\mathcal{L}(\theta)\| \le L + \lambda\|\theta\| \le 2L$. The noise has mean zero and is independent of θ_t, so the cross term vanishes when the square is expanded:
$$\mathbb{E}\|\nabla\mathcal{L}(\theta_t) + \xi_t\|^2 = \|\nabla\mathcal{L}(\theta_t)\|^2 + \mathbb{E}\|\xi_t\|^2 \le 4L^2 + d\sigma^2 = G^2. \tag{M.8}$$
4. **The bound for SGD on a strongly convex objective.** Optimization proves Equation 6.13. It is about a function F that is λ-strongly convex on a closed convex set containing its minimizer. The random step directions must be right on average, with average squared length at most G^2. Then projected steps with learning rates $2/(\lambda(t+1))$ and the average weighted by t satisfy
$$\mathbb{E}[F(\tilde{\theta}_T)] - F^* \le \frac{2G^2}{\lambda(T+1)}. \tag{M.9}$$
The proof follows the squared distance to the minimizer, and the noise enters only through G^2. The ridge makes $\mathcal{L}$ λ-strongly convex, and step 2 puts the minimizer in the ball, so the bound applies to $\mathcal{L}$.
5. **Substitute the noise.** The calibration gives $\sigma^2 = 4L^2T/(n^2\mu^2)$. So
$$\frac{2G^2}{\lambda(T+1)} = \frac{8L^2}{\lambda(T+1)} + \frac{8L^2d}{\lambda n^2\mu^2} \cdot \frac{T}{T+1} \le \frac{8L^2}{\lambda(T+1)} + \frac{8L^2d}{\lambda n^2\mu^2}. \tag{M.10}$$
The noise term no longer depends on T.
6. **Choose T.** When $T \ge n^2\mu^2/d$, the first term is at most the second, so the sum is at most $16L^2d/(\lambda n^2\mu^2)$. This is the first form of Equation M.3.
7. **In terms of ε.** For $\varepsilon < 1$ the classic Gaussian calibration is (ε, δ)-DP. It adds noise $\Delta\sqrt{2\ln(1.25/\delta)}/\varepsilon$ to a function whose sensitivity is Δ. The exact calibration uses the least noise that works, so its ratio is at least the classic one, and
$$\frac{1}{\mu^2} \le \frac{2\ln(1.25/\delta)}{\varepsilon^2}. \tag{M.11}$$
Substituting this doubles the constant to 32.

The other schedule of that section, learning rates $1/(\lambda t)$ with the uniform average, has the bound $G^2(1+\ln T)/(2\lambda T)$. The same substitution gives at most $4L^2d(1+\ln T)/(\lambda n^2\mu^2)$ for $T \ge n^2\mu^2/d$.

Since T grows like n^2, the factor $1 + \ln T$ grows like $\ln n$. This is the logarithm the chapter mentions, and the weighted average removes it.

The strongly convex lower bound. The plan is to build a family of hard datasets and an estimator, and then to apply the fingerprinting bound.

1. **A loss whose excess risk is a distance.** Take the linear loss $\ell(\theta; x) = -\langle \theta, x \rangle$ on records with $\|x\| \le L$, so every loss gradient, $-x$, has length at most L. With the ridge, completing the square gives
$$\mathcal{L}(\theta) = \frac{\lambda}{2}\|\theta\|^2 - \langle \theta, \bar{x} \rangle = \frac{\lambda}{2}\Big\|\theta - \frac{\bar{x}}{\lambda}\Big\|^2 - \frac{\|\bar{x}\|^2}{2\lambda}, \tag{M.12}$$
where $\bar{x}$ is the mean of the records. So $\theta^* = \bar{x}/\lambda$, and the excess risk of any θ is exactly $\frac{\lambda}{2}\|\theta - \theta^*\|^2$.
2. **Hard datasets.** The fingerprinting bound uses random records $y_i \in \{-1, +1\}^d$ with random attribute means, as in Section 27.3, so the hard datasets are built from them. Fix an integer m between 1 and n. The dataset has m real records $x_i = (L/\sqrt{d})\, y_i$, each of length L, and $n - m$ records equal to zero. The zeros add nothing to the sum, so the mean of all n records is $\bar{x} = (m/n)(L/\sqrt{d})\, \bar{y}$, where $\bar{y}$ is the mean of the y_i.
3. **From a trainer to a mean estimator.** Given the m records y_i, build the dataset of step 2 and run the private trainer to get $\tilde{\theta}$. The estimator M rescales $\tilde{\theta}$ so that θ^* maps to $\bar{y}$, then clips each coordinate to $[-1, 1]$:
$$M = \mathrm{clip}_{[-1,1]^d}\Big(\frac{n\lambda\sqrt{d}}{mL}\,\tilde{\theta}\Big). \tag{M.13}$$
Replacing one y_i replaces one record of the padded dataset, so M is (ε, δ)-DP by post-processing. Clipping never moves a coordinate away from $\bar{y}$, because $\bar{y}$ lies in $[-1, 1]^d$. And by the Cauchy–Schwarz inequality the ℓ_1 norm is at most $\sqrt{d}$ times the Euclidean norm. So
$$\|M - \bar{y}\|_1 \le \sqrt{d} \cdot \frac{n\lambda\sqrt{d}}{mL}\|\tilde{\theta} - \theta^*\| = \frac{dn\lambda}{mL}\|\tilde{\theta} - \theta^*\|. \tag{M.14}$$
4. **Average error.** Write E for the trainer's expected excess risk on these datasets. By step 1, $\mathbb{E}\|\tilde{\theta} - \theta^*\|^2 = 2E/\lambda$, and the average of a length is at most the square root of the average squared length. So the average error per attribute, $a = \mathbb{E}\|M - \bar{y}\|_1/d$, satisfies
$$a \le \frac{n}{m} \cdot \frac{\sqrt{2\lambda E}}{L}. \tag{M.15}$$
5. **The fingerprinting bound.** Equation 27.30 says that an (ε, δ)-DP estimator of d attribute means from m records, with outputs in $[-1, 1]^d$ and average error a per attribute, needs
$$m \ge \Big(\frac{2}{3} - 2a\Big)K. \tag{M.16}$$
Its proof plays two facts against each other. An accurate estimate must correlate with the records by a total of order d. DP lets each record carry only about $(e^\varepsilon - 1)\sqrt{d} + 4\delta d$ of that total. Rearranging the inequality gives $a \ge \frac{1}{3} - \frac{m}{2K}$, and step 4 turns it into
$$\frac{\sqrt{2\lambda E}}{L} \ge \frac{m}{n}\Big(\frac{1}{3} - \frac{m}{2K}\Big). \tag{M.17}$$

6. **Choose m.** This holds for every m, so it holds for the best one. When the right side is negative it says nothing, so only values of m below $2K/3$ matter, where both sides are non-negative. Squaring and multiplying by $L^2/(2\lambda)$ gives the first form of Equation M.5. The bracket is largest near $m = K/3$. If $K \geq 3$, the integer $m = \lfloor K/3 \rfloor$ lies between $K/6$ and $K/3$, so $\frac{m}{n}(\frac{1}{3} - \frac{m}{2K}) \geq \frac{K}{6n} \cdot \frac{1}{6} = \frac{K}{36n}$. Squaring and multiplying by $L^2/(2\lambda)$ gives $L^2K^2/(2592\lambda n^2)$. The condition $K \leq 3n$ keeps this m at most n. The trainer's expected excess risk on the random datasets is at least this, so some dataset has at least this much.

The convex lower bound. Without a ridge in the objective, the same idea works if the ridge is moved into the loss and its size is chosen from m.

1. **The loss.** On the ball of radius R, take $\ell(\theta; x) = \frac{\lambda}{2}\|\theta\|^2 - \langle \theta, x \rangle$ with $\|x\| \leq L/2$ and $\lambda = mL/(2nR)$. Its gradient $\lambda\theta - x$ has length at most $\lambda R + L/2 \leq L$, because $m \leq n$. So it is a convex loss with gradients of length at most L on the ball.
2. **The datasets.** Use m real records $x_i = (L/(2\sqrt{d}))\, y_i$ and $n - m$ zero records. As before, $\mathcal{L}(\theta) = \frac{\lambda}{2}\|\theta - \bar{x}/\lambda\|^2$ plus a constant, and now $\bar{x}/\lambda = (R/\sqrt{d})\, \bar{y}$. That point has length at most R, so it is the minimizer over the ball, and the excess risk is again $\frac{\lambda}{2}\|\theta - \theta^*\|^2$.
3. **The estimator.** Output $M = \mathrm{clip}_{[-1,1]^d}((\sqrt{d}/R)\, \tilde{\theta})$. As in steps 3 and 4 above, $a \leq \sqrt{2E/\lambda}/R = \sqrt{4nE/(mLR)}$.
4. **Fingerprinting.** The condition $m \geq (\frac{2}{3} - 2a)K$ rearranges to $2a \geq \frac{2}{3} - \frac{m}{K}$, so

$$E \geq \frac{mLR}{16n}\Big(\frac{2}{3} - \frac{m}{K}\Big)^2, \tag{M.18}$$

   which is Equation M.6 before the choice of m.
5. **Choose m.** The right side is largest at $m = 2K/9$. If $K \geq 9/2$, the integer $m = \lfloor 2K/9 \rfloor$ lies between $K/9$ and $2K/9$, so $\frac{2}{3} - \frac{m}{K} \geq \frac{4}{9}$ and the bound is at least $\frac{LR}{16n} \cdot \frac{K}{9} \cdot \frac{16}{81} = \frac{LRK}{729n}$. The condition $K \leq \frac{9}{2}n$ keeps $m \leq n$.

The exact bounds. Two inequalities from Optimization give all four bounds. A β_s-smooth function lies below its tangent plus $\frac{\beta_s}{2}$ times the squared distance, by the descent lemma Equation 6.6. A λ-strongly convex function lies above its tangent plus $\frac{\lambda}{2}$ times the squared distance. Here β_s must bound the curvature of $\mathcal{L}$ everywhere, not only at θ^*. For the loss $g(y\langle \theta, x \rangle)$ with $0 \leq g'' \leq c$ and $\|x\| \leq 1$, the Hessian is at most $(c + \lambda)I$.

1. **Output perturbation.** At θ^* the gradient is zero, so the tangent is flat. The two inequalities give $\frac{\lambda}{2}\|Z\|^2 \leq \mathcal{L}(\theta^* + Z) - \mathcal{L}(\theta^*) \leq \frac{\beta_s}{2}\|Z\|^2$ for every noise vector Z. Averaging gives the first pair of Equation M.7. For Gaussian noise, $\mathbb{E}\|Z\|^2 = d\sigma^2$.
2. **Objective perturbation, from above.** The perturbed objective $\mathcal{L}_b(\theta) = \mathcal{L}(\theta) + \frac{1}{n}\langle b, \theta \rangle$ is λ-strongly convex and minimized at $\tilde{\theta}$. Strong convexity at its minimizer, where the gradient is zero, gives $\mathcal{L}_b(\theta^*) \geq \mathcal{L}_b(\tilde{\theta}) + \frac{\lambda}{2}\|\theta^* - \tilde{\theta}\|^2$. Writing out $\mathcal{L}_b$ and moving terms,

$$\mathcal{L}(\tilde{\theta}) - \mathcal{L}(\theta^*) \leq \frac{1}{n}\langle b, \theta^* - \tilde{\theta} \rangle - \frac{\lambda}{2}\|\tilde{\theta} - \theta^*\|^2 \leq \frac{\|b\|}{n}t - \frac{\lambda}{2}t^2, \qquad t = \|\tilde{\theta} - \theta^*\|, \tag{M.19}$$

   by the Cauchy–Schwarz inequality. The right side is a downward parabola in t whose largest value is $\|b\|^2/(2\lambda n^2)$. This holds for every draw of b, so averaging over b gives the upper bound of Equation M.7.

3. **Objective perturbation, from below.** The gradient of $\mathcal{L}_b$ is zero at its minimizer $\tilde{\theta}$, so the gradient of $\mathcal{L}$ is $-b/n$ there, and it is zero at θ^*. A β_s-smooth function's gradient changes by at most β_s per unit of distance, so $\|b\|/n \le \beta_s t$. Strong convexity of $\mathcal{L}$ at θ^* gives $\mathcal{L}(\tilde{\theta}) - \mathcal{L}(\theta^*) \ge \frac{\lambda}{2}t^2 \ge \frac{\lambda\|b\|^2}{2\beta_s^2 n^2}$. Averaging over b gives the lower bound.
4. **Compare with the chapter.** The second-order formulas average $\frac{1}{2}Z^\top HZ$ and $\frac{1}{2n^2}b^\top H^{-1}b$, where H is the Hessian at θ^*. Every eigenvalue of H lies between λ and β_s. So the exact upper bounds are the chapter's formulas with H replaced by its worst case, $\beta_s I$ for output perturbation and λI for objective perturbation.

Step 1 also shows what output perturbation achieves. The minimizer moves by at most $2L/(\lambda n)$ when one record is replaced (Fact 2 of the chapter), so the Gaussian noise has standard deviation $2L/(\lambda n\mu)$, and the upper bound is $2\beta_s dL^2/(\lambda^2 n^2\mu^2)$. This is the rate of Equation M.3 times the condition number β_s/λ, so output perturbation reaches the optimal rate only when β_s/λ is bounded by a constant. Objective perturbation with the chapter's pure-DP noise, whose density is proportional to $e^{-\varepsilon'\|b\|/2}$ with ε' the part of the budget left for the noise, has $\mathbb{E}\|b\|^2 = d(d+1)(2/\varepsilon')^2$, which grows like d^2, the price of $\delta = 0$.

M.1.4. Checking it

The script computes the bounds on the chapter's running example. It is logistic regression in $d = 10$ dimensions with ridge $\lambda = 0.01$ and $L = 1$. The budget is $\varepsilon = 1$ and $\delta = 10^{-5}$, so $\mu = 0.2681$. At $n = 10{,}000$ the rule $T = \lceil n^2\mu^2/d \rceil$ asks for 718,515 steps, with noise $\sigma = 0.6325$ on the mean gradient. The upper bound Equation M.3 is 2.2268×10^{-3}. The uniform average's bound is 8.0638×10^{-3}, larger by about $(1 + \ln T)/4$, the ratio of the two closed forms. That many full-batch steps are too slow for the script, so it runs the algorithm at smaller n, on two freshly drawn datasets each. With 300 records the measured excess risk is 2.2640×10^{-1}, and the bound is 10.9 times larger. The ratio grows to 16.5 at 1,000 records, where the measured value is 1.3489×10^{-2}, and to 23.0 at 3,000 records, where it is 1.0754×10^{-3}. It is loose for the reason the chapter gives: the logistic loss has more curvature than λ near its minimizer, which the bound does not use.

The lower bound is far below. The running example has $K = 1.8402$, which is below 3, so only the first form of Equation M.5 applies, at $m = 1$. At $n = 10{,}000$ it gives 1.8991×10^{-9}, a factor 1.17×10^6 below the upper bound. In high dimension the factor settles near 4.3×10^5: at $n = 10{,}000$ it is 4.27×10^5 for $d = 1{,}000$ and 4.28×10^5 for $d = 10{,}000$. The convex bound Equation M.6, with $R = 5$, is 8.6×10^3 times below the chapter's upper bound Equation 38.21 at both dimensions. These constants are as poor as those of the fingerprinting bound itself, which the lower-bounds chapter already calls loose. What the proof establishes is the shape: both bounds fall like $1/n^2$ and grow like d, as Figure M.2 shows.

The exact bounds bracket the measurements. At $n = 10{,}000$, output perturbation with Gaussian noise has the bounds 2.7835×10^{-4} and 7.2372×10^{-3} from Equation M.7. The chapter's second-order value is 8.7070×10^{-4}, and 20 releases average 9.6417×10^{-4}. Objective perturbation has the bounds 3.2872×10^{-7} and 2.2221×10^{-4}, the second-order value 7.1266×10^{-5}, and the measured 7.1178×10^{-5}. On 50 draws of the noise, every single release also obeys the per-draw inequalities of steps 2 and 3. The upper bounds are 7.5 and 3.1 times the measurements. The lower bounds are much weaker, because $\lambda = 0.01$ is far below the data's curvature. Figure M.3 shows why:

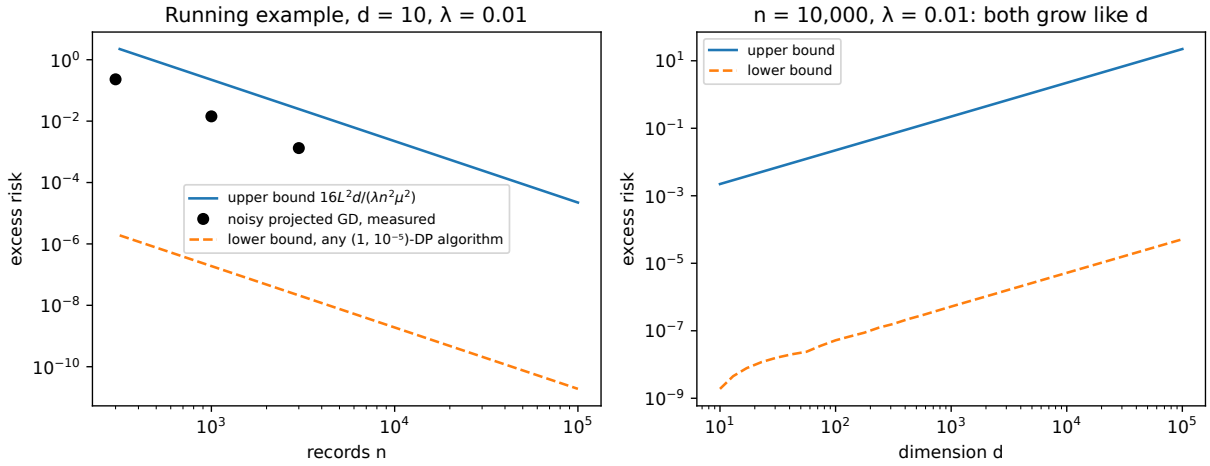

Figure M.2.: Left: excess risk against the number of records on the running example ($d = 10$, $\lambda = 0.01$, $(1, 10^{-5})$-DP), log–log. The upper bound Equation M.3 (solid), noisy projected gradient descent measured on two datasets per point (circles), and the lower bound Equation M.5 for every private algorithm (dashed). Right: the two bounds against the dimension at $n = 10{,}000$. Both fall like $1/n^2$ and grow like d; the constants are far apart.

along any direction, the objective lies between the two parabolas, and close to its second-order approximation.

M.1.5. What it does not cover

The lower bound loses large constants in three places: the fingerprinting bound itself, the factor $\sqrt{d}$ between the ℓ_1 and Euclidean errors, and the choice of m. It also loses a factor $\sqrt{\ln(1/\delta)}$, which Steinke & Ullman (2016) recover with a sharper distribution of the attribute means. It needs δ small compared with $1/\sqrt{d}$, so that K is of order $\sqrt{d}/(e^{\varepsilon} - 1)$, and it holds for replace neighbours. The upper bound uses full gradients, so it costs about $n^3\mu^2/d$ gradient evaluations. Bassily, Smith & Thakurta (2014) use one random record per step and subsampling, which is much cheaper and adds logarithmic factors; that analysis stays cited.

M.2. The data-dependent bound for a noisy vote

M.2.1. What the chapter uses

Private prediction answers a query with GNMax: each of many teachers votes for a label, Gaussian noise of standard deviation σ is added to each label's count, and the label with the highest noisy count is released. This is the vote of **private aggregation of teacher ensembles (PATE)**. GNMax satisfies **Rényi differential privacy (RDP)** with cost α/σ^2 at every order α. When the teachers agree, the answer is almost certain, and Section 42.7 charges it less with the bound Equation 42.9 of Papernot et al. (2018, Theorem 6).

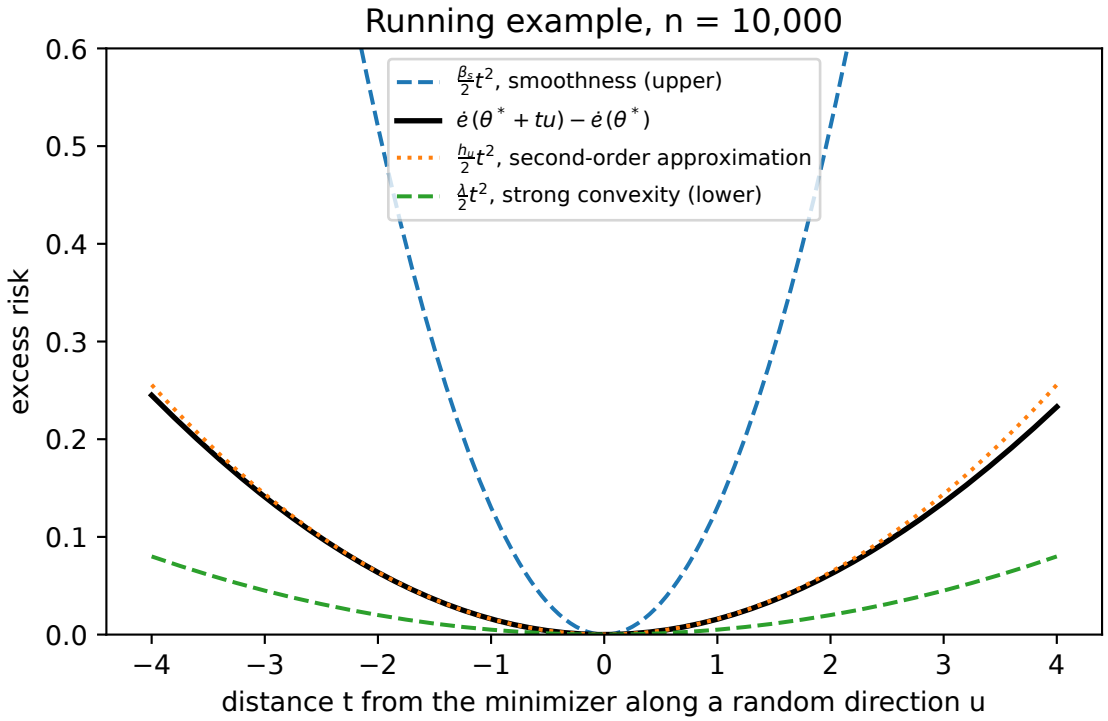

Figure M.3.: The running example's objective at $n = 10{,}000$ along a random direction u through its minimizer (black), between the parabolas of strong convexity, $\frac{\lambda}{2}t^2$, and smoothness, $\frac{\beta_s}{2}t^2$ (dashed). The second-order approximation $\frac{h_u}{2}t^2$, with h_u the curvature along u, is dotted.

Write $P = M(D)$ and $P' = M(D')$ for the distributions of the answer on the dataset and on a neighbour. Let i^* be the likely answer, and let $\tilde{\beta}$ be a known bound on the probability $\beta = P(\text{not } i^*)$ that the answer is something else, a failure probability (Papernot et al. write it q). The bound uses two auxiliary orders, $\alpha_2 = \sigma\sqrt{\ln(1/\tilde{\beta})}$ and $\alpha_1 = \alpha_2 + 1$, with the RDP costs of GNMax at those orders, $\varepsilon_1 = \alpha_1/\sigma^2$ and $\varepsilon_2 = \alpha_2/\sigma^2$. Theorem 6 requires $\alpha \le \alpha_1$, $\alpha_2 > 1$, and the condition

$$\tilde{\beta} \le \frac{e^{(\alpha_2-1)\varepsilon_2}}{\left(\frac{\alpha_1}{\alpha_1-1}\cdot\frac{\alpha_2}{\alpha_2-1}\right)^{\alpha_2}}. \tag{M.20}$$

Under these, the order-α divergence of the answer on the dataset from the answer on any neighbour satisfies

$$D_\alpha(P\|P') \le \frac{1}{\alpha-1}\ln\Big[(1-\tilde{\beta})A^{\alpha-1} + \tilde{\beta}B^{\alpha-1}\Big], \quad A = \frac{1-\tilde{\beta}}{1-(\tilde{\beta}e^{\varepsilon_2})^{(\alpha_2-1)/\alpha_2}}, \quad B = \frac{e^{\varepsilon_1}}{\tilde{\beta}^{1/(\alpha_1-1)}}. \tag{M.21}$$

Here D_α is the Rényi divergence of order α, defined in Equation 42.1 by

$$e^{(\alpha-1)D_\alpha(P\|P')} = \sum_y P(y)^\alpha P'(y)^{1-\alpha}. \tag{M.22}$$

The chapter derives the simpler pure-DP form Equation 42.8 and says of the Gaussian form that "its proof is in Papernot et al. (2018, Appendix A)". In step 4 of its derivation, it also uses that the pure-DP bound increases in β, which step 7 below proves.

This section proves the Gaussian bound with the true β in place of $\tilde{\beta}$. It then shows that the largest value over all $\beta \le \tilde{\beta}$ is a valid bound with no condition at all, and checks that this largest value is the value at $\tilde{\beta}$ in the chapter's setting. It also proves that the pure-DP bound always increases in β, which closes the gap in step 4.

M.2.2. The idea

Split the Rényi sum into the likely answer and all the others. On the likely answer, the two distributions are both close to 1, so the term is close to 1. It can only be large if the neighbour puts much more probability off i^* than P does. A Rényi guarantee at a high order α_2, applied to the single event "not i^*", forbids that. On the other answers, P has total mass only β. Their likelihood ratios could be large, but a Rényi guarantee at order $\alpha_1 \ge \alpha$ controls their average, and the average of a smaller power is controlled by the average of a larger one.

A small example shows the split. Take three answers with $P = (0.99, 0.008, 0.002)$ and $P' = (0.985, 0.01, 0.005)$, and order $\alpha = 2$. The Rényi sum is $0.99^2/0.985 + 0.008^2/0.01 + 0.002^2/0.005 = 0.99503 + 0.0064 + 0.0008 = 1.00223$. The first term is near $1 - \beta = 0.99$, inflated a little because P' has slightly less mass on i^*. The other two are $\beta = 0.01$ times an average ratio below 1. The bound treats the two parts separately and replaces each by its worst case.

M.2.3. Derivation

The orders α_1 and α_2 are fixed numbers in steps 1 to 4, chosen before β enters. The bound holds for any order $\alpha > 1$ and any orders with $\alpha \le \alpha_1$, $\alpha_2 > 1$ and $\beta e^{\varepsilon_2} < 1$. The last one keeps the denominator of A positive.

1. **Split the sum.** Write $\beta' = P'(\text{not } i^*)$. Then

$$e^{(\alpha-1)D_\alpha(P\|P')} = (1-\beta)^\alpha(1-\beta')^{1-\alpha} + \sum_{y\neq i^*} P(y)^\alpha P'(y)^{1-\alpha}. \tag{M.23}$$

2. **The neighbour cannot move much mass off i^*.** GNMax is $(\alpha_2, \varepsilon_2)$-RDP for every pair of neighbours, in either order, because the neighbour relation is symmetric. So $D_{\alpha_2}(P'\|P) \le \varepsilon_2$. Post-processing never increases a Rényi divergence, and reducing an answer to "is it i^*?" is post-processing. The reduced distributions are $(1-\beta', \beta')$ and $(1-\beta, \beta)$, and their Rényi sum is at least its "not i^*" term:

$$\beta'^{\alpha_2}\beta^{1-\alpha_2} \le e^{(\alpha_2-1)\varepsilon_2}, \qquad \text{so} \qquad \beta' \le (\beta e^{\varepsilon_2})^{(\alpha_2-1)/\alpha_2}. \tag{M.24}$$

3. **The likely answer's term.** The exponent $1-\alpha$ is negative, so a smaller base gives a larger power. Step 2 bounds $1-\beta'$ from below, so

$$(1-\beta)^\alpha(1-\beta')^{1-\alpha} \le (1-\beta)^\alpha\big(1-(\beta e^{\varepsilon_2})^{(\alpha_2-1)/\alpha_2}\big)^{1-\alpha} = (1-\beta)A^{\alpha-1}, \tag{M.25}$$

   with A as in the statement, β in place of $\tilde\beta$.

4. **The other answers.** Write their sum as β times an average under P given "not i^*". With the likelihood ratio $r(y) = P(y)/P'(y)$,

$$\sum_{y\neq i^*} P(y)^\alpha P'(y)^{1-\alpha} = \beta \sum_{y\neq i^*} \frac{P(y)}{\beta}\, r(y)^{\alpha-1}. \tag{M.26}$$

   Now set $s = (\alpha-1)/(\alpha_1-1)$, which lies in $(0,1]$ because $\alpha \le \alpha_1$. Then $r^{\alpha-1} = (r^{\alpha_1-1})^s$. The function $t \mapsto t^s$ is concave, so by Jensen's inequality the average of X^s is at most (average of $X)^s$. For example, with $s = \frac{1}{2}$, the average of $\sqrt{1}$ and $\sqrt{9}$ is 2, below $\sqrt{5}$. The average of r^{α_1-1} given "not i^*" is $\frac{1}{\beta}\sum_{y\neq i^*} P(y)^{\alpha_1}P'(y)^{1-\alpha_1}$. That sum is part of the full Rényi sum of order α_1, which RDP bounds by $e^{(\alpha_1-1)\varepsilon_1}$. So

$$\sum_{y\neq i^*} P(y)^\alpha P'(y)^{1-\alpha} \le \beta\Big(\frac{e^{(\alpha_1-1)\varepsilon_1}}{\beta}\Big)^s = \beta\Big(\frac{e^{\varepsilon_1}}{\beta^{1/(\alpha_1-1)}}\Big)^{\alpha-1} = \beta B^{\alpha-1}. \tag{M.27}$$

5. **Collect.** Adding steps 3 and 4 and taking $\frac{1}{\alpha-1}\ln$ gives the bound with the true β:

$$D_\alpha(P\|P') \le V(\beta) = \frac{1}{\alpha-1}\ln\Big[(1-\beta)A(\beta)^{\alpha-1} + \beta B(\beta)^{\alpha-1}\Big]. \tag{M.28}$$

6. **From β to $\tilde\beta$.** Only the bound $\tilde\beta \ge \beta$ is known, so take the largest value of V over all β in $(0, \tilde\beta]$. That is a valid bound, with no condition beyond those listed before step 1. When V increases in β, the largest value is $V(\tilde\beta)$, which is Equation 42.9. The condition of Theorem 6 is what Papernot et al. use to prove that V increases. The script checks it directly instead: at the chapter's $\sigma = 40$ and $\alpha = 8$, V increases on $(0, \tilde\beta]$ at every vote gap (the difference between the top two counts) where the condition holds.

7. **The pure-DP form increases in β.** For a mechanism that is pure DP with parameter ε_0, write $\kappa = e^{\varepsilon_0}$ for its largest ratio of probabilities. The same split gives the bracket of Equation 42.8,

$$f(\beta) = (1-\beta)^{\alpha}(1-\kappa\beta)^{1-\alpha} + \beta\,\kappa^{\alpha-1}, \tag{M.29}$$

on $0 \le \beta < 1/\kappa$. Its first term has the form $y\,\psi(x/y)$, with the power function $\psi(t) = t^{\alpha}$, $x = 1-\beta$ and $y = 1-\kappa\beta$. That is the **perspective** of the convex function ψ, and a perspective is jointly convex in (x, y) (Section F.5).

The reason is short. A convex function is the largest of its tangent lines, so $\psi(t) = \max(at+c)$ over the slopes a and intercepts c of its tangents. Then $y\psi(x/y)$ is the largest of the linear functions $ax + cy$, and a maximum of linear functions is convex. Here x and y are linear in β, so the first term is convex in β, and the second term is linear. So f is convex, and its slope only grows. At $\beta = 0$ the slope is

$$f'(0) = \kappa^{\alpha-1} + (\alpha-1)\kappa - \alpha, \tag{M.30}$$

which is 0 at $\kappa = 1$ and grows with κ. So $f' \ge 0$ on the whole range, and the bound is largest at $\beta = \tilde{\beta}$, in every case.

8. **Why $\alpha_2 = \sigma\sqrt{\ln(1/\tilde{\beta})}$.** The bound is small when A is close to 1, that is when step 2's bound on β' is close to $\tilde{\beta}$. With $\varepsilon_2 = \alpha_2/\sigma^2$, the logarithm of that bound is

$$\Big(1 - \frac{1}{\alpha_2}\Big)\Big(\ln\tilde{\beta} + \frac{\alpha_2}{\sigma^2}\Big) = \ln\tilde{\beta} + \frac{\alpha_2}{\sigma^2} + \frac{\ln(1/\tilde{\beta})}{\alpha_2} - \frac{1}{\sigma^2}. \tag{M.31}$$

The middle two terms trade a larger order against a larger cost, and their sum is smallest at $\alpha_2 = \sigma\sqrt{\ln(1/\tilde{\beta})}$, where it equals $2\sqrt{\ln(1/\tilde{\beta})}/\sigma$. So this choice makes the neighbour's failure probability as close to $\tilde{\beta}$ as the argument allows: at most $\tilde{\beta}\,e^{2\sqrt{\ln(1/\tilde{\beta})}/\sigma - 1/\sigma^2}$. The choice $\alpha_1 = \alpha_2 + 1$ is Papernot et al.'s, and any $\alpha_1 \ge \alpha$ gives a valid bound.

M.2.4. Checking it

Take the chapter's example: two labels, $\sigma = 40$, order $\alpha = 8$ and a gap of 150 votes. On two labels the difference of the two noises is normal with variance $2\sigma^2$, so the answer is wrong with probability $\tilde{\beta} = \beta = \frac{1}{2}\operatorname{erfc}(150/80) = 4.0050 \times 10^{-3}$. The orders are $\alpha_2 = 93.981$ and $\alpha_1 = 94.981$. Their costs are $\varepsilon_2 = 0.05874$ and $\varepsilon_1 = 0.05936$. Step 2 allows the neighbour a failure probability of at most 4.5014×10^{-3}. That is 1.1240 times $\tilde{\beta}$, which is the factor $e^{2\sqrt{\ln(1/\tilde{\beta})}/\sigma - 1/\sigma^2}$ of step 8. The likely answer's term is 0.999477 and the other answers' term is 9.1545×10^{-3}. The bound is 1.2278×10^{-3}, the value the chapter quotes, and the largest value over $\beta \le \tilde{\beta}$ is the same. One teacher that changes its vote moves the gap by 2, so the neighbours have gaps of 148 and 152. Against the worse of the two, the exact divergence in this direction is 2.2362×10^{-4}, 5.49 times smaller.

Over gaps from 0 to 300 in steps of 5, the condition holds from a gap of 20 on, and at all 57 such gaps V increases on $(0, \tilde{\beta}]$ and the exact two-label divergence lies below the bound. At $\sigma = 40$ the condition allows any $\tilde{\beta}$ up to 0.36321. With three labels and votes $(200, 40, 10)$, the union bound of Equation 42.6 gives $\tilde{\beta} = 2.7303 \times 10^{-3}$ and the bound 8.7544×10^{-4}. The exact worst divergence over the six ways one teacher can move its vote is 1.5188×10^{-4}, and the data-independent cost

is 5.0000×10^{-3}. The script also checks step 7 numerically: on a grid of orders and values of ε_0, the pure-DP bracket is convex and increasing in β.

Figure M.4 splits the bound into its two parts. Below a gap of 116 the bound exceeds α/σ^2 and is not used. Above it, the other answers' term is the larger one: the cost of an answer is mostly the chance that the noise overturns the vote, weighted by how much an overturned vote reveals. Figure M.5 shows the two facts behind step 6. With the orders fixed, V rises steadily up to $\tilde{\beta}$. And the largest value over $\beta \le \tilde{\beta}$, as a function of $\tilde{\beta}$, falls far below the data-independent cost as the vote becomes certain.

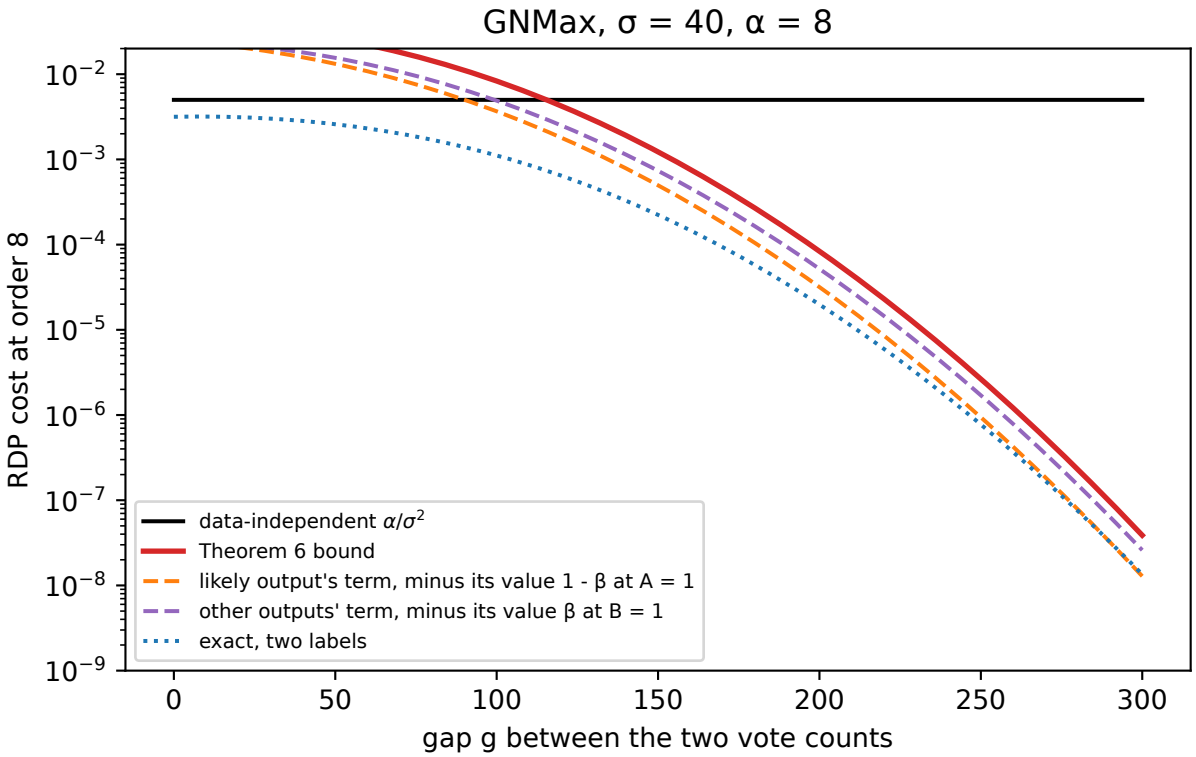

Figure M.4.: The data-dependent cost of one GNMax answer at order 8 with $\sigma = 40$, against the gap between the two vote counts, log scale. The bound (red) is the logarithm of 1 plus the two dashed parts, divided by $\alpha - 1$: the likely answer's term minus $1 - \tilde{\beta}$, and the other answers' term minus $\tilde{\beta}$. Black: the data-independent cost α/σ^2. Dotted: the exact cost on two labels.

M.2.5. What it does not cover

The proof that the condition of Theorem 6 makes V increasing stays cited to Papernot et al. (2018, Appendix A). Taking the largest value over $\beta \le \tilde{\beta}$ is a valid replacement that needs no condition, and it costs only a one-dimensional search. The union bound $\tilde{\beta}$ of Equation 42.6 for many labels is the paper's Proposition 7 and is not derived here. The bound is for one direction, $D_\alpha(M(D)\|M(D'))$ with D the actual dataset, which is the direction the chapter's accounting uses.

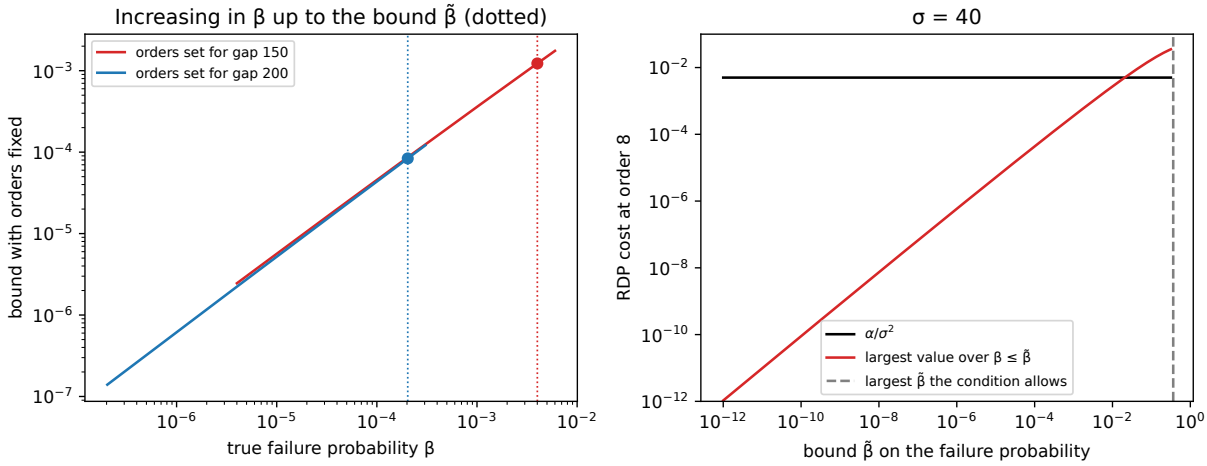

Figure M.5.: Left: the bound Equation M.28 as a function of the true failure probability β, with the orders set for gaps of 150 and 200 votes; it increases up to $\tilde{\beta}$ (dotted). Right: the largest value over $\beta \le \tilde{\beta}$ against $\tilde{\beta}$, at order 8 and $\sigma = 40$, with the data-independent cost and the largest $\tilde{\beta}$ the condition of Theorem 6 allows.

M.3. The best of a random number of runs

M.3.1. What the chapter uses

Hyperparameter tuning releases the best of K independent training runs, with K drawn at random before the search. Each run is an algorithm Q with RDP curve $\varepsilon(\alpha)$ at order α. The number of runs K follows a **truncated negative binomial** distribution with parameters $\nu > -1$ and $\omega \in (0, 1)$ (Papernot & Steinke write η for ν, γ for ω and λ for the order), whose generating function is $f(x) = \mathbb{E}[x^K]$. Its mean is $\mathbb{E}[K]$, and the case $\nu = 0$ is the logarithmic distribution. Section 40.6 states Papernot & Steinke's (2022) Theorem 2 as Equation 40.12: for every $\hat{\alpha} \ge 1$, the best-of release M satisfies

$$\varepsilon_M(\alpha) \le \varepsilon(\alpha) + (1+\nu)\Big(1 - \frac{1}{\hat{\alpha}}\Big)\varepsilon(\hat{\alpha}) + \frac{(1+\nu)\ln(1/\omega)}{\hat{\alpha}} + \frac{\ln \mathbb{E}[K]}{\alpha - 1}. \tag{M.32}$$

The chapter derives the generic bound Equation 40.10. For neighbours with run distributions Q, Q',

$$D_\alpha(M(D)\|M(D')) \le D_\alpha(Q\|Q') + \frac{1}{\alpha - 1}\ln\Big[f'(p)^\alpha f'(p')^{1-\alpha}\Big], \tag{M.33}$$

where p and p' are the probabilities that one and the same randomized test accepts a run's output, on D and on D'. The chapter takes outputs to be finite and $\Pr[K = 0] = 0$. Its step 9 then says that the truncated negative binomial case follows by bounding the rejection probabilities through the run's RDP at a second order $\hat{\alpha}$, and that "Papernot & Steinke (2022, Appendix B.2) carry out the algebra". The chapter also quotes their Corollary 3, $(2+\nu)\varepsilon$-DP for an ε-DP run, and Corollary 4 for zero-concentrated DP runs. This section carries out that algebra and derives both corollaries.

M.3.2. The idea

For this distribution, $f'(x)$ is a power of one simple quantity, $a = \omega + (1-\omega)(1-x)$. Here $1-x$ is the probability that the test rejects, and ω is a floor that comes from the distribution of K, not from the data. So the worst-case term of the generic bound is a power of $\omega a'^{\alpha-1}/a^{\alpha}$, with a' the same quantity on D'. That ratio is large only if a' is much larger than a.

Two facts stop that. The run's RDP guarantee says that the neighbour cannot reject much more often than D does: in Rényi terms the rejection probability on D' is at most a power of that on D. And a is never below ω, so dividing by it costs at most a power of $1/\omega$. The floor ω is the "few runs" explanation of the chapter: it caps how much the event "every run was rejected" can say about the data.

M.3.3. Derivation

The steps continue the chapter's derivation, whose steps 1 to 5 give Equation 40.10. Write $r = 1-p$ and $r' = 1-p'$ for the probabilities that the test rejects a run's output, on D and D'.

1. **The generating function.** The weights of the distribution are $\Pr[K=k] = (1-\omega)^k\binom{k+\nu-1}{k}/(\omega^{-\nu}-1)$ for $k \geq 1$, because $\prod_{j=0}^{k-1}\frac{j+\nu}{j+1} = \binom{k+\nu-1}{k}$. The negative binomial series $\sum_{k\geq 0}\binom{k+\nu-1}{k}z^k = (1-z)^{-\nu}$, with the $k=0$ term removed, gives

$$f(x) = \frac{(1-(1-\omega)x)^{-\nu}-1}{\omega^{-\nu}-1}, \qquad f'(x) = \mathbb{E}[K]\,\omega^{\nu+1}\,a(x)^{-(\nu+1)}, \quad a(x) = 1-(1-\omega)x. \tag{M.34}$$

   The mean is the slope at 1, as in the chapter:

$$\mathbb{E}[K] = f'(1) = \frac{\nu(1-\omega)}{\omega(1-\omega^{\nu})}. \tag{M.35}$$

   Since $a(1) = \omega$, the formula for f' is consistent at $x = 1$. For $\nu = 0$ the same formulas hold in the limit, where f becomes $\ln(1-(1-\omega)x)/\ln\omega$.
2. **The worst-case term.** Write $a = a(p) = \omega + (1-\omega)r$ and $a' = a(p') = \omega + (1-\omega)r'$. The constant $\mathbb{E}[K]\omega^{\nu+1}$ appears with total power $\alpha + (1-\alpha) = 1$, so

$$f'(p)^{\alpha} f'(p')^{1-\alpha} = \mathbb{E}[K]\omega^{\nu+1}(a^{-\alpha}a'^{\alpha-1})^{\nu+1} = \mathbb{E}[K]\Big(\frac{\omega\, a'^{\alpha-1}}{a^{\alpha}}\Big)^{1+\nu}. \tag{M.36}$$

3. **The neighbour cannot reject much more often.** The run is $(\hat\alpha, \hat\varepsilon)$-RDP with $\hat\varepsilon = \varepsilon(\hat\alpha)$, for both orders of every pair of neighbours. The test's verdict, reject or accept, is post-processing of a run's output (Fact 2 of the chapter), so $D_{\hat\alpha}$ between the verdict's distributions on D' and on D is at most $\hat\varepsilon$. Their Rényi sum is at least its "reject" term, so

$$r'^{\hat\alpha} r^{1-\hat\alpha} \leq e^{(\hat\alpha-1)\hat\varepsilon}, \qquad \text{so} \qquad r' \leq e^{s\hat\varepsilon} r^{s}, \quad s = 1-\frac{1}{\hat\alpha}. \tag{M.37}$$

4. **Carry it to a'.** Since $e^{s\hat\varepsilon} \geq 1$, step 3 gives

$$a' \leq \omega + (1-\omega)e^{s\hat\varepsilon} r^{s} \leq e^{s\hat\varepsilon}\big(\omega\cdot 1^{s} + (1-\omega)r^{s}\big) \leq e^{s\hat\varepsilon}\big(\omega + (1-\omega)r\big)^{s} = e^{s\hat\varepsilon}a^{s}. \tag{M.38}$$

   The last inequality is Jensen's inequality for the concave function $t \mapsto t^{s}$, with weights ω and $1-\omega$ at the points 1 and r. For example, with $s = \frac{1}{2}$, $\omega = \frac{1}{2}$ and $r = 0$, the middle bracket is $\frac{1}{2}$ and the right side is $\sqrt{1/2} = 0.71$.

5. **Bound the ratio.** Substituting step 4,

$$\frac{\omega\, a'^{\alpha-1}}{a^{\alpha}} \le e^{(\alpha-1)s\hat{\varepsilon}}\, \omega\, a^{s(\alpha-1)-\alpha}. \tag{M.39}$$

   The exponent of a is $s(\alpha-1)-\alpha = -1-(\alpha-1)/\hat{\alpha}$, which is negative. So the power is largest where a is smallest, and $a \ge \omega$. Replacing a by ω gives

$$\frac{\omega\, a'^{\alpha-1}}{a^{\alpha}} \le e^{(\alpha-1)(1-1/\hat{\alpha})\hat{\varepsilon}}\, \omega^{-(\alpha-1)/\hat{\alpha}}. \tag{M.40}$$

6. **Assemble.** Raise step 5 to the power $1+\nu > 0$, which keeps the inequality, and multiply by $\mathbb{E}[K]$ as in step 2. Taking $\frac{1}{\alpha-1}\ln$ gives

$$\frac{1}{\alpha-1}\ln\Big[f'(p)^{\alpha} f'(p')^{1-\alpha}\Big] \le (1+\nu)\Big(1-\frac{1}{\hat{\alpha}}\Big)\varepsilon(\hat{\alpha}) + \frac{(1+\nu)\ln(1/\omega)}{\hat{\alpha}} + \frac{\ln \mathbb{E}[K]}{\alpha-1}. \tag{M.41}$$

   Adding $D_{\alpha}(Q\|Q') \le \varepsilon(\alpha)$ in Equation 40.10 gives Equation 40.12. At $\hat{\alpha}=1$ step 3 says nothing, but then $s=0$ and the trivial bound $a' \le 1 = a^0$ gives the same formula, with the term $(1+\nu)\ln(1/\omega)$.
7. **Corollary 3, pure DP.** An ε-DP run has $\varepsilon(\alpha) \le \varepsilon$ at every order, so the first term is at most ε. Let $\hat{\alpha} \to \infty$: the second term tends to $(1+\nu)\varepsilon$ and the third to 0. Then let $\alpha \to \infty$: the last term tends to 0, and the order-∞ divergence is the largest log ratio of probabilities. So the release is $(2+\nu)\varepsilon$-DP.
8. **Corollary 4, zero-concentrated DP.** A run that satisfies zero-concentrated DP with parameter ρ, a number that measures its privacy loss, has the RDP curve $\varepsilon(\alpha) = \rho\alpha$. Then $(1-1/\hat{\alpha})\varepsilon(\hat{\alpha}) = \rho(\hat{\alpha}-1)$, and the terms with $\hat{\alpha}$ are $(1+\nu)(\rho\hat{\alpha} + \ln(1/\omega)/\hat{\alpha}) - (1+\nu)\rho$. For positive numbers u and v, the sum $u\hat{\alpha} + v/\hat{\alpha}$ is smallest at $\hat{\alpha} = \sqrt{v/u}$, where it equals $2\sqrt{uv}$. Here the best second order is

$$\hat{\alpha} = \sqrt{\frac{\ln(1/\omega)}{\rho}}, \tag{M.42}$$

   which is at least 1 when $\rho \le \ln(1/\omega)$. So

$$\varepsilon_{M}(\alpha) \le \rho\alpha + \frac{\ln \mathbb{E}[K]}{\alpha-1} + 2(1+\nu)\sqrt{\rho\ln(1/\omega)} - (1+\nu)\rho. \tag{M.43}$$

   By the same rule, applied to $\rho(\alpha-1) + \ln \mathbb{E}[K]/(\alpha-1)$, the first two terms are smallest at the order

$$\alpha^{*} = 1 + \sqrt{\frac{\ln \mathbb{E}[K]}{\rho}}, \tag{M.44}$$

   where they equal $\rho + 2\sqrt{\rho \ln \mathbb{E}[K]}$. Adding up gives the chapter's closed form, $2\sqrt{\rho \ln \mathbb{E}[K]} + 2(1+\nu)\sqrt{\rho\ln(1/\omega)} - \nu\rho$, at α^{*}. The Rényi divergence grows with the order, so the bound at α^{*} also holds at every order $\alpha \le \alpha^{*}$.

M.3.4. Checking it

The chapter checks Equation 40.12 on randomized response with $\varepsilon = 0.5$ and a logarithmic number of runs with mean 10, for which $\omega = 0.02692$. At order $\alpha = 5$ its terms are 0.3842 for one run,

0.5756 for $\ln \mathbb{E}[K]/(\alpha-1)$, and, at $\hat{\alpha} = 100.95$, 0.4904 and 0.0358 for the two middle terms. Their sum is 1.4860, against an exact divergence of 0.3912. Figure M.6 draws the four terms against $\hat{\alpha}$.

The figure shows why $\hat{\alpha} = 100.95$ is not the best choice. Randomized response is pure DP, so as $\hat{\alpha}$ grows the second term rises to $(1+\nu)\varepsilon = 0.5$ and the third falls to 0. The sum keeps falling, to its limit 1.4599, and that limit is the value in the chapter's table. A grid of orders that stops at $\hat{\alpha} = 100.95$ still gives a valid bound, just slightly above the best one. The same happens at the table's other orders: the limits, which the table gives, are 3.0299 at order 2 and 1.0962 at order 20, against 3.0561 and 1.1224 at the end of the grid.

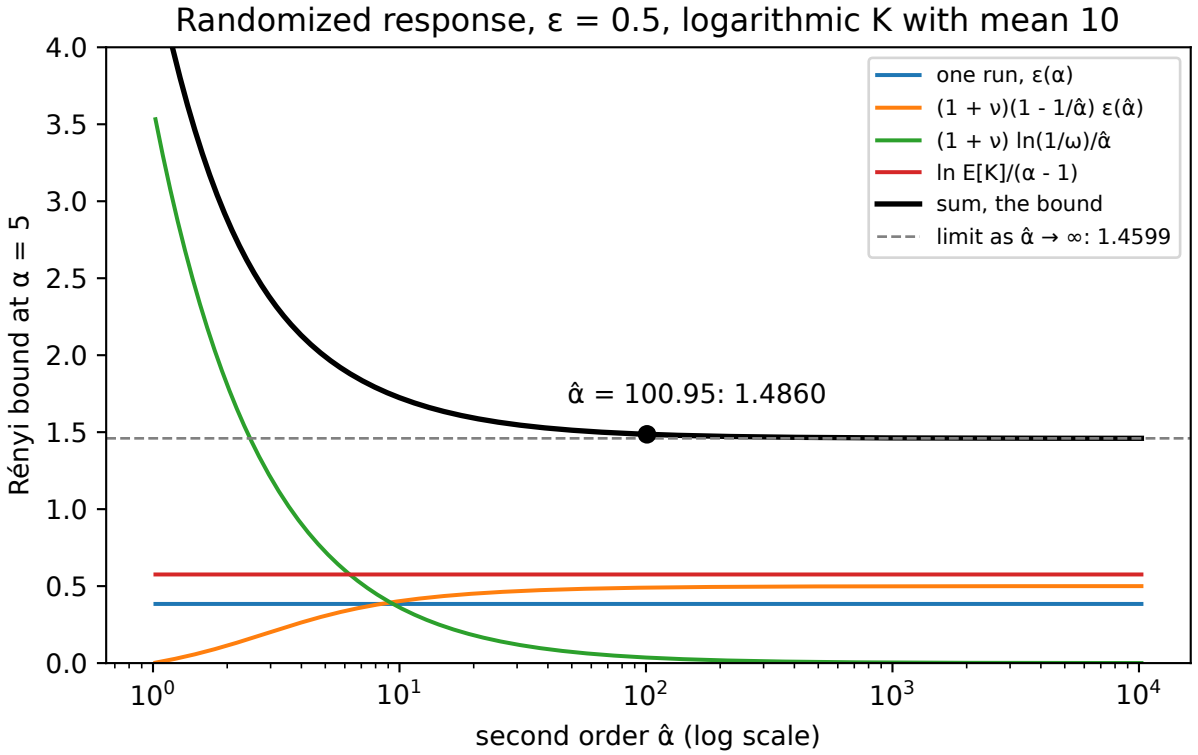

Figure M.6.: The four terms of Equation 40.12 at order $\alpha = 5$ against the second order $\hat{\alpha}$, for randomized response with $\varepsilon = 0.5$ and a logarithmic number of runs with mean 10. The sum (black) keeps falling toward its limit (dashed); the dot marks the end of the chapter's grid of orders.

The script also checks every step of the chain on 20,000 random cases of ω, α, $\hat{\alpha}$, $\hat{\varepsilon}$ and rejection probabilities that obey step 3, and none fails. For Corollary 4 with $\rho = 0.1$ and a geometric number of runs ($\nu = 1$) with mean 10, so $\omega = 0.1$, the closed form gives 2.7791. Minimizing the theorem over $\hat{\alpha}$ numerically at $\alpha^* = 5.7985$ gives the same, with the best $\hat{\alpha} = 4.7985$.

Figure M.7 shows where the slack is. The shaded region is every pair of rejection probabilities that order-4 RDP allows, and the red curve is the looser constraint that step 3 keeps. On the shaded region the ratio $\omega a'^{\alpha-1}/a^{\alpha}$ is at most 7.67, while step 5 bounds it by 89.63. Most of the gap comes from replacing a by ω, which is exact only when the test rejects nothing on D.

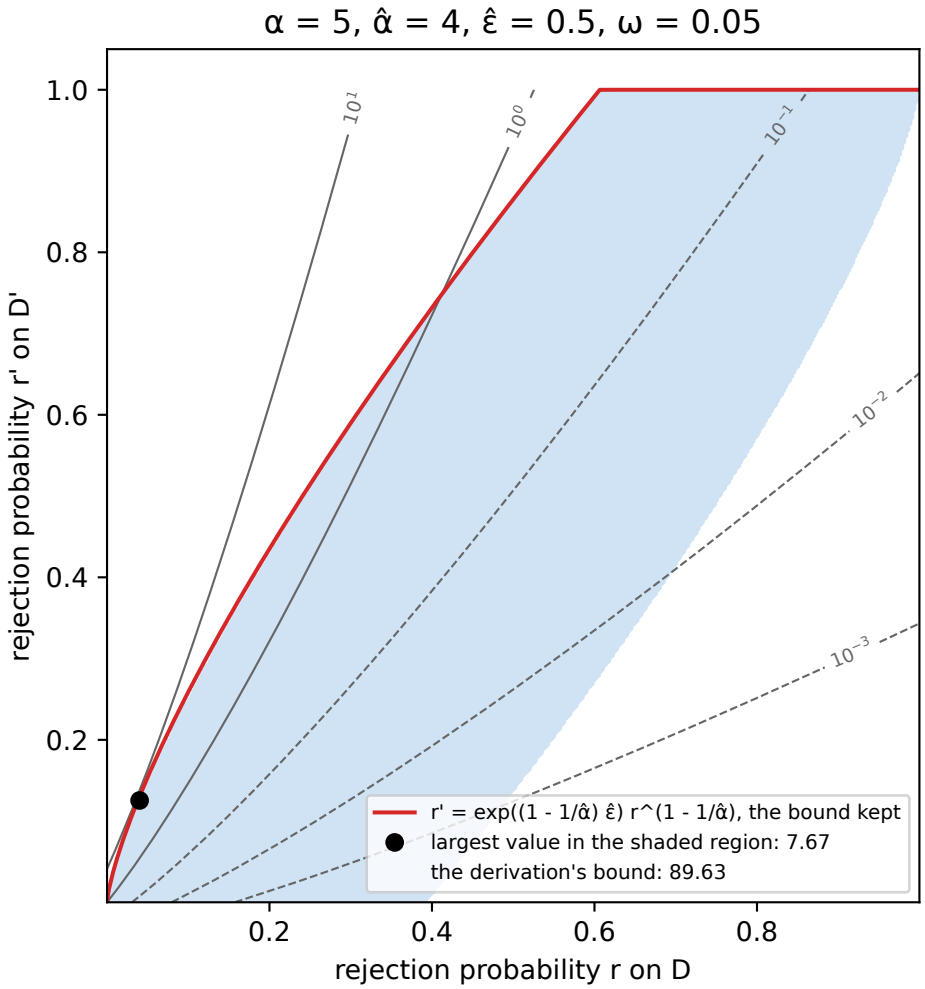

Figure M.7.: The unit square of rejection probabilities (r, r') on D and D'. Shaded: the pairs that order-$\hat{\alpha}$ RDP with $\hat{\alpha} = 4$ and $\hat{\varepsilon} = 0.5$ allows. Red: the bound $r' \leq e^{(1-1/\hat{\alpha})\hat{\varepsilon}} r^{1-1/\hat{\alpha}}$ of step 3. Grey: levels of $\omega a'^{\alpha-1}/a^{\alpha}$ at $\alpha = 5$, $\omega = 0.05$, with its largest value on the shaded region marked.

M.3.5. What it does not cover

The derivation keeps the chapter's simplification to finite outputs and $\Pr[K = 0] = 0$. Papernot & Steinke (2022) handle the general case, where an empty search releases a fixed output, and that stays cited.

M.4. A user with many records in record-level DP-SGD

M.4.1. What the chapter uses

User-level differential privacy asks what DP-SGD, the private SGD of the earlier chapters, guarantees to a user who owns k records. DP-SGD samples each record into a batch independently with probability q, clips each record's gradient to length at most C, and adds Gaussian noise of standard deviation σC to the sum. In units of C, Section 44.4 compares the output without the user, $P_0 = \mathcal{N}(0, \sigma^2)$, with the output with the user, the mixture Equation 44.6:

$$P_{(k)} = \sum_{m=0}^{k} b_m \, \mathcal{N}(m, \sigma^2), \qquad b_m = \binom{k}{m} q^m (1-q)^{k-m}. \tag{M.45}$$

Its **Rényi moment** at integer order α is the average $A_\alpha = \mathbb{E}_{y \sim P_0}[(P_{(k)}(y)/P_0(y))^\alpha]$, so that $D_\alpha(P_{(k)} \| P_0) = \ln A_\alpha/(\alpha - 1)$. The chapter computes it as Equation 44.7:

$$A_\alpha = \mathbb{E}\Big[\exp\Big(\frac{1}{\sigma^2} \sum_{1 \le i < j \le \alpha} N_i N_j \Big) \Big], \tag{M.46}$$

where $N_1, \dots, N_\alpha$ are independent copies of the number $N \sim \mathrm{Bin}(k, q)$ of the user's records in a batch. The chapter derives A_α for this pair, in which every drawn record pushes the sum by the full C in the same direction. But it takes from Charles et al. (2024, Theorem 3) that this aligned case is the worst over all configurations of the user's gradients, and gives only the intuition.

This section proves that claim for the divergence $D_\alpha(P \| P_0)$ of the output with the user from the output without, at integer orders. The user's gradients may point in any directions in any number of dimensions. The Rényi moment is never larger than Equation 44.7, and it equals it when the gradients are aligned.

M.4.2. The idea

The Rényi moment of order α is an average over α independent draws of the user's subset of records. Each draw shifts the output by the sum v of the drawn gradients. The moment turns out to be the average of the exponential of the sum of inner products $\langle v_i, v_j \rangle$ between different draws. An inner product is at most the product of the lengths, and a sum of m gradients of length at most 1 has length at most m. So each inner product is at most the product of the two counts, which is exactly what Equation 44.7 has. Gradients that point the same way reach that maximum.

A user with two records and orthogonal gradients e_1 and e_2 shows the difference. Table M.2 lists the inner product of two independent draws for each pair of subsets, against the aligned case where both gradients are e_1.

Table M.2.: The inner product $\langle v_1, v_2 \rangle$ of the summed gradients of two independent draws of a two-record user's subset, for orthogonal and for aligned unit gradients. Draws that include no record give 0 in both cases.

Draw 1	Draw 2	Orthogonal gradients	Aligned gradients
$\{1\}$	$\{1\}$	1	1
$\{1\}$	$\{2\}$	0	1
$\{1\}$	$\{1,2\}$	1	2
$\{1,2\}$	$\{1,2\}$	2	4

Every entry of the orthogonal column is at most the aligned one, and the exponential of a larger number is larger. So the aligned moment is larger.

M.4.3. Derivation

1. **One step, with the past fixed.** By adaptive composition, it is enough to bound one step for every possible history. Given the history, the model is fixed, so the user's clipped gradients $g_1, \dots, g_k$ are fixed vectors in $\mathbb{R}^d$ with $\|g_a\| \le 1$ in units of C. The user's drawn subset S contains each record independently with probability q, and the user adds $v_S = \sum_{a \in S} g_a$ to the sum.
2. **The other records do not matter.** The other records' contribution U is random but has the same distribution with and without the user, and it is independent of S. So both outputs are mixtures over U of a pair shifted by U. The quantity $e^{(\alpha-1)D_\alpha(P\|Q)} = \sum_y Q(y)\big(P(y)/Q(y)\big)^\alpha$ is a perspective of $t \mapsto t^\alpha$, so it is jointly convex in the pair (Section F.5). Its value at a mixture of pairs is therefore at most the average of its values at the pairs. A shift by U changes nothing, so it suffices to take $U = 0$: compare $P_0 = \mathcal{N}(0, \sigma^2 I)$ with $P = \sum_S \pi(S)\,\mathcal{N}(v_S, \sigma^2 I)$, where $\pi(S) = q^{|S|}(1-q)^{k-|S|}$.
3. **The likelihood ratio.** Two normal densities with the same covariance $\sigma^2 I$ differ by $\|y\|^2 - \|y - v\|^2 = 2\langle v, y\rangle - \|v\|^2$ in the exponent, so

$$\frac{P(y)}{P_0(y)} = \sum_S \pi(S) \exp\Big(\frac{2\langle v_S, y\rangle - \|v_S\|^2}{2\sigma^2}\Big). \tag{M.47}$$

   This is the chapter's Equation 44.4, with vectors in place of numbers.
4. **The α-th power is an average over independent copies.** As in step 4 of the chapter, multiplying out α copies of the sum gives one term for every choice $(S_1, \dots, S_\alpha)$, with weight $\pi(S_1)\cdots\pi(S_\alpha)$. That is an average over independent subsets. With $u = v_{S_1} + \cdots + v_{S_\alpha}$,

$$\Big(\frac{P(y)}{P_0(y)}\Big)^\alpha = \mathbb{E}\Big[\exp\Big(\frac{2\langle u, y\rangle - \sum_i \|v_{S_i}\|^2}{2\sigma^2}\Big)\Big]. \tag{M.48}$$

5. **Average over y with the Gaussian moment generating function.** Fact 3 of the chapter gives the **moment generating function (MGF)** of a normal variable Y with mean 0 and variance σ^2. For every real s,

$$\mathbb{E}[e^{sY}] = e^{s^2\sigma^2/2}. \tag{M.49}$$

Under P_0 the coordinates of y are independent normal variables of this kind. So $\mathbb{E}[e^{\langle u,y\rangle/\sigma^2}]$ is a product of one-dimensional MGFs, one per coordinate j, with $s = u_j/\sigma^2$:

$$\mathbb{E}_{y\sim P_0}\big[e^{\langle u,y\rangle/\sigma^2}\big] = \prod_j e^{u_j^2/(2\sigma^2)} = e^{\|u\|^2/(2\sigma^2)}. \tag{M.50}$$

Everything is positive, so the two averages can be exchanged, and

$$A_\alpha = \mathbb{E}\Big[\exp\Big(\frac{\|u\|^2 - \sum_i \|v_{S_i}\|^2}{2\sigma^2}\Big)\Big] = \mathbb{E}\Big[\exp\Big(\frac{1}{\sigma^2}\sum_{i<j}\langle v_{S_i}, v_{S_j}\rangle\Big)\Big], \tag{M.51}$$

because $\|u\|^2 = \sum_i \|v_{S_i}\|^2 + 2\sum_{i<j}\langle v_{S_i}, v_{S_j}\rangle$ and the squares cancel.

6. **Bound each inner product.** By the Cauchy–Schwarz inequality, $\langle v_{S_i}, v_{S_j}\rangle \le \|v_{S_i}\|\,\|v_{S_j}\|$. By the triangle inequality, $\|v_S\| \le \sum_{a\in S}\|g_a\| \le |S|$. So $\langle v_{S_i}, v_{S_j}\rangle \le |S_i|\,|S_j|$.
7. **The aligned value.** The exponential is increasing and every weight is positive, so step 6 can be applied inside the average of Equation M.51. The counts $|S_1|, \dots, |S_\alpha|$ are independent $\mathrm{Bin}(k, q)$ variables, so the bound is Equation 44.7. Equality holds when every g_a is the same unit vector e, because then $v_S = |S|e$ and both inequalities of step 6 are equalities.
8. **Compose.** RDP curves add over steps, even when each step depends on the earlier outputs. So after T steps the user's divergence of this direction is at most $\frac{T}{\alpha-1}\ln A_\alpha$, with A_α from Equation 44.7.

M.4.4. Checking it

The script computes Equation M.51 exactly, by summing over all subsets, for $k = 5$, $q = 0.05$ and $\sigma = 1$. When the five gradients are aligned, $A_2 = 1.232011$, so the order-2 divergence is 0.208648, the value of Equation 44.7. When every pair of gradients meets at 60 degrees, $A_2 = 1.066665$, and at 90 degrees $A_2 = 1.021664$. Figure M.8 draws the divergence against the common angle, at orders 2 and 3. It is largest at angle 0, where it equals the aligned value. On 200 random configurations of four gradients of random length in three dimensions, no Rényi moment of order 2 or 3 exceeds the aligned one.

The identity of step 5 is checked against a direct integral. For three unit gradients in the plane at angles 0, 60 and 150 degrees, with $q = 0.3$ and $\sigma = 1$, a two-dimensional quadrature of $\mathbb{E}_{P_0}[(P/P_0)^2]$ gives 1.516754, and Equation M.51 gives 1.516754.

Figure M.9 shows which pairs of counts carry Equation 44.7. Pairs in which either copy draws no record contribute 0.948825 in total, their probability, because their weight $e^{N_1N_2/\sigma^2}$ is 1. The pair $(1, 1)$ adds 0.112710, the two mixed pairs $(1, 2)$ and $(2, 1)$ add 0.064501 together, and $(2, 2)$ adds 0.025084. Even the pair $(5, 5)$ contributes 7.032×10^{-3}. Its probability is only q^{10}, below 10^{-13}, but its weight is e^{25}. This is why the user's cost grows faster than linearly in k once the higher terms wake up, as the right panel shows.

M.4.5. What it does not cover

The argument needs an integer order, because step 4 multiplies out the α-th power. For non-integer orders, for the other direction $D_\alpha(P_0\|P)$, and for the privacy loss distribution (PLD) form that the tightest accountants use, the claim that the aligned pair is the worst case stays cited to Charles

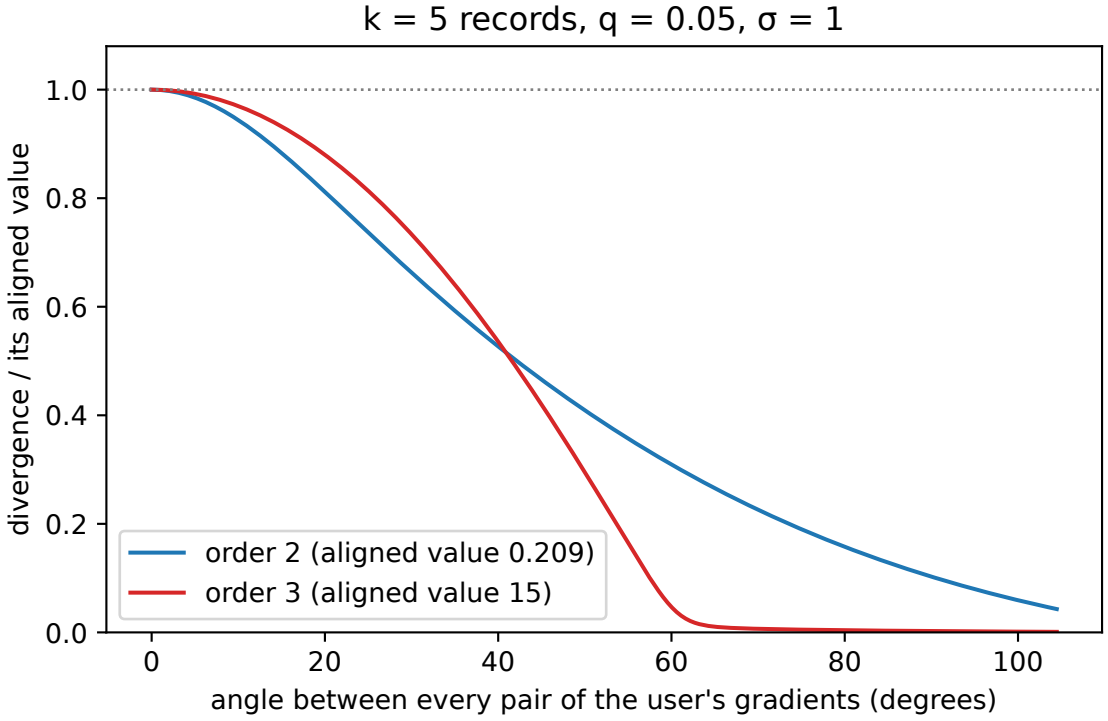

Figure M.8.: The Rényi divergence of the output with a user of five records from the output without, as a fraction of its aligned value, when every pair of the user's gradients meets at the same angle ($q = 0.05$, $\sigma = 1$). Orders 2 and 3. Both are largest when the gradients are aligned.

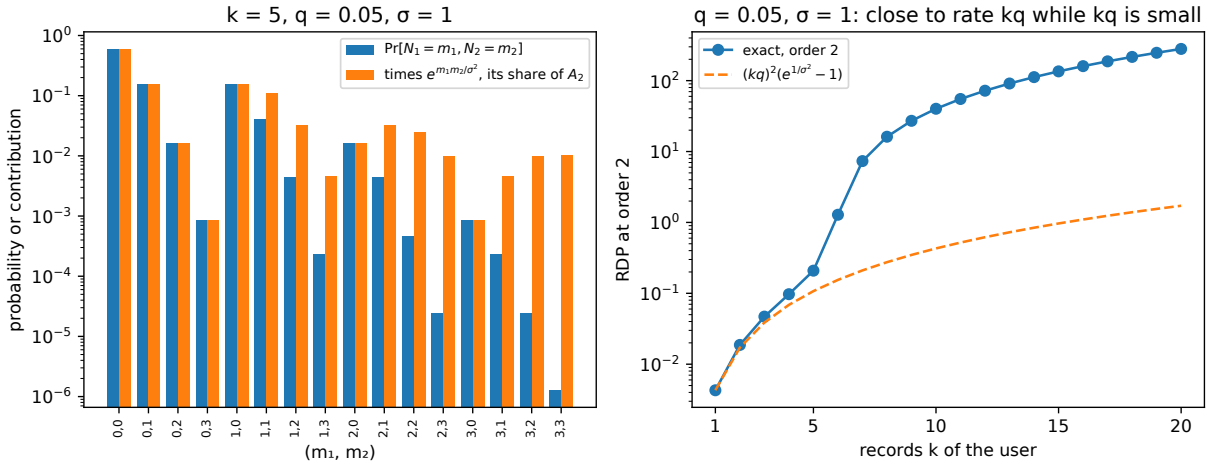

Figure M.9.: Left: the probability of each pair of counts (m_1, m_2) of a user's records in two independent batches ($k = 5$, $q = 0.05$), and its contribution to A_2 after weighting by $e^{m_1 m_2/\sigma^2}$ with $\sigma = 1$, log scale. Right: the exact order-2 RDP of one step against the number of records k, with the small-kq approximation $(kq)^2(e^{1/\sigma^2} - 1)$.

et al. (2024, Theorem 3). In the other direction the ratio is raised to the negative power $1-\alpha$, so the expansion of step 4 does not exist.

M.5. How one step of DP-SGD changes a group's loss

M.5.1. What the chapter uses

Disparate impact splits the records into groups g with shares s_g, and asks why DP-SGD hurts small groups more. In Section 45.5 it describes in words a result of Tran, Dinh & Fioretto (2021). The expected change in a group's loss in one step has a clipping term, driven by the group's gradient norms, and a noise term proportional to $\eta^2\sigma^2C^2$ times the trace of the group's loss Hessian. Here η is the learning rate, σ the noise multiplier and C the clipping norm. The chapter gives no formula. This section derives the decomposition and shows that it is exact for quadratic losses. It also shows that it contains the chapter's noise floor Equation 45.8.

Write $\mathcal{L}_g$ for group g's average loss, $\nabla\mathcal{L}_g$ for its gradient (the group's average gradient $\bar{g}_g$ of the chapter), and H_g for its Hessian. The unclipped training gradient is $\nabla\mathcal{L} = \sum_h s_h \nabla\mathcal{L}_h$, the share-weighted average of the groups' gradients.

One step moves the weights by $-\eta u$, with update $u = G_t/B + \tau\xi$. Here G_t is the sum of the batch's clipped gradients, B the expected batch size, ξ standard normal noise and $\tau = \sigma C/B$ the noise per coordinate. By Equation 45.5, the update's mean is $m = \sum_h s_h m_h$, with m_h the group's average clipped gradient. Write Σ_B for the covariance of G_t/B, which comes from sampling the batch, and $\Delta\mathcal{L}_g$ for the change in $\mathcal{L}_g$ over the step. Then, to second order in η,

$$\mathbb{E}[\Delta\mathcal{L}_g] \approx \underbrace{-\eta\langle\nabla\mathcal{L}_g, \nabla\mathcal{L}\rangle}_{\text{descent}} \underbrace{-\eta\langle\nabla\mathcal{L}_g, m-\nabla\mathcal{L}\rangle}_{\text{clipping}} + \frac{\eta^2}{2}\Big(\underbrace{m^\top H_g m}_{\text{curvature}} + \underbrace{\operatorname{tr}(H_g\Sigma_B)}_{\text{sampling}} + \underbrace{\tau^2 \operatorname{tr} H_g}_{\text{noise}}\Big), \quad \text{(M.52)}$$

and the approximation is exact when $\mathcal{L}_g$ is quadratic. The noise term is $\eta^2\sigma^2C^2 \operatorname{tr} H_g/(2B^2)$, the form the chapter describes.

M.5.2. The idea

One step moves the weights by a random vector. A group's loss responds to the average move through its gradient, to first order, and to the spread of the move through its curvature, to second order. Clipping changes the average move. It shortens the gradients of groups with long gradients, so their share of the average falls and their loss falls more slowly. The noise does not change the average, but it adds spread. That spread is the same in every direction, so it raises a group's loss in proportion to the group's total curvature, the trace of its Hessian.

One dimension shows both effects. Take $\mathcal{L}(\theta) = \frac{h}{2}\theta^2$ and a step $\theta - \eta(m + \tau\xi)$, with ξ standard normal. The new loss averages to $\frac{h}{2}((\theta-\eta m)^2 + \eta^2\tau^2)$, because a squared normal variable has mean equal to its variance. Expanded, that is $\mathcal{L}(\theta) - \eta h\theta m + \frac{\eta^2}{2}(hm^2 + h\tau^2)$. Here $h\theta$ is the gradient, so the first-order term is the gradient times the average move, and the noise adds $\frac{\eta^2}{2}h\tau^2$ whatever the average move is.

M.5.3. Derivation

1. **The update's mean and spread.** By Equation 45.5, $\mathbb{E}[G_t/B] = m$. The noise $\tau\xi$ has mean zero, covariance $\tau^2 I$, and is independent of the batch. So u has mean m and covariance $\Sigma_B + \tau^2 I$.
2. **Expand the group's loss.** A second-order Taylor expansion around the current weights θ gives
$$\mathcal{L}_g(\theta - \eta u) = \mathcal{L}_g(\theta) - \eta\langle\nabla\mathcal{L}_g(\theta), u\rangle + \frac{\eta^2}{2}u^\top H_g u + R, \tag{M.53}$$
where the remainder R involves third derivatives. If $\mathcal{L}_g$ is quadratic, $R = 0$ and H_g is constant.
3. **Average.** The first-order term averages to $-\eta\langle\nabla\mathcal{L}_g, m\rangle$. For the second-order term, write $u = m + e$ with $\mathbb{E}[e] = 0$. Then $u^\top H_g u = m^\top H_g m + 2m^\top H_g e + e^\top H_g e$, and the middle term averages to zero. The last term averages to $\operatorname{tr}(H_g \operatorname{Cov}(u))$, because $\mathbb{E}[e^\top H_g e] = \sum_{jk}(H_g)_{jk}\mathbb{E}[e_j e_k]$. With step 1, that is $\operatorname{tr}(H_g\Sigma_B) + \tau^2 \operatorname{tr} H_g$.
4. **Split off clipping.** Write $m = \nabla\mathcal{L} + (m - \nabla\mathcal{L})$. The first part is what the step would do without clipping. The second, $m - \nabla\mathcal{L} = \sum_h s_h(m_h - \nabla\mathcal{L}_h)$, is the bias that clipping adds. A group whose records are all shorter than C has $m_h = \nabla\mathcal{L}_h$ and adds nothing to it. This gives the descent and clipping terms of Equation M.52.
5. **The sampling term.** Under Poisson sampling, each record i enters the batch independently with probability q, so $G_t = \sum_i b_i c_i$ with c_i the clipped gradient and b_i a coin with variance $q(1-q)$. With $B = qn$,
$$\Sigma_B = \frac{q(1-q)}{B^2}\sum_i c_i c_i^\top = \frac{1-q}{qn^2}\sum_i c_i c_i^\top. \tag{M.54}$$
It vanishes for full batches, $q = 1$.
6. **The noise term.** Substituting $\tau = \sigma C/B$ gives $\frac{\eta^2}{2}\tau^2 \operatorname{tr} H_g = \eta^2\sigma^2 C^2 \operatorname{tr} H_g/(2B^2)$. It does not depend on the group's share, its gradients or the clipping weights, only on its curvature.
7. **The chapter's noise floor.** Take the chapter's quadratic model: group g owns d_g weights θ_g, $\mathcal{L}_g = \frac{\lambda}{2}\|v\|^2$ with $v = \theta_g - \theta_g^*$, full batches and no clipping. On group g's weights the mean update is $s_g\lambda v$ and the group's gradient is λv, while $H_g = \lambda I$ on its d_g weights. With $a = \eta s_g\lambda$, Equation M.52 is exact and reads
$$\mathbb{E}[\Delta\mathcal{L}_g] = -\eta s_g\lambda^2\|v\|^2 + \frac{\eta^2}{2}(s_g^2\lambda^3\|v\|^2 + \tau^2 d_g\lambda) = -a(2-a)\mathcal{L}_g + \frac{\eta^2\tau^2 d_g\lambda}{2}. \tag{M.55}$$
The loss stops changing on average when the two terms balance, at
$$\mathbb{E}[\mathcal{L}_g] = \frac{\eta^2\tau^2 d_g\lambda}{2a(2-a)} = \frac{d_g\eta\tau^2}{2s_g(2-\eta s_g\lambda)}, \tag{M.56}$$
which is Equation 45.8. The descent term shrinks as the loss falls, and the noise term does not, which is why the loss settles at a floor rather than at zero. The same balance, direction by direction with share 1, gives the per-direction cost $\eta s^2/(2(2-\eta h_j))$ of Equation 43.2, where s is the noise per coordinate and h_j a curvature.

M.5.4. Checking it

The script uses the chapter's clipping example (Figure 45.2): 95 majority records with gradient $(0.2, 0)$ and 5 minority records with gradient $(0, 4)$. It gives each group the quadratic loss $\frac{1}{2}\|\theta - \theta_g^*\|^2$, whose Hessian is the identity, placed so that its gradient at the current weights is the group's gradient. All 100 records are in every batch, so the sampling term is zero. The noise is the running example's at $\varepsilon = 4$, $\sigma = 1.36$, with $B = 100$ and $\eta = 0.5$.

At $C = 0.5$ the majority is not clipped, so its clipping term is 0. Its descent term is -0.01900, its curvature term 0.00459 and its noise term 1.156×10^{-5}, for a total of -0.01440. The minority's descent term is -0.40000, but clipping adds back 0.35000. With the same curvature and noise terms, its total is -0.04540. So clipping has cancelled seven eighths of the minority's progress in this step.

The formula is exact here because the losses are quadratic. To check it, the script raises the noise multiplier to $\sigma = 100$, so that the noise term matters, and averages the minority's loss change over 2,000,000 noise draws. The average is 0.01707, against 0.01709 from Equation M.52. Step 7 is checked on the chapter's model with 51 weights per group, $\lambda = 1$, $\eta = 0.5$ and $\tau = 0.0068$. For a group with share 0.05 the floor is 5.9702×10^{-3}, and the expected change there is 0.

Figure M.10 shows the four terms against the clipping norm. For the minority, the clipping term is almost as large as the descent term until C approaches the minority's gradient length 4. The noise term grows like C^2 and is tiny per step at this budget. It matters over many steps because it does not shrink when the gradients do, which is the noise floor of step 7.

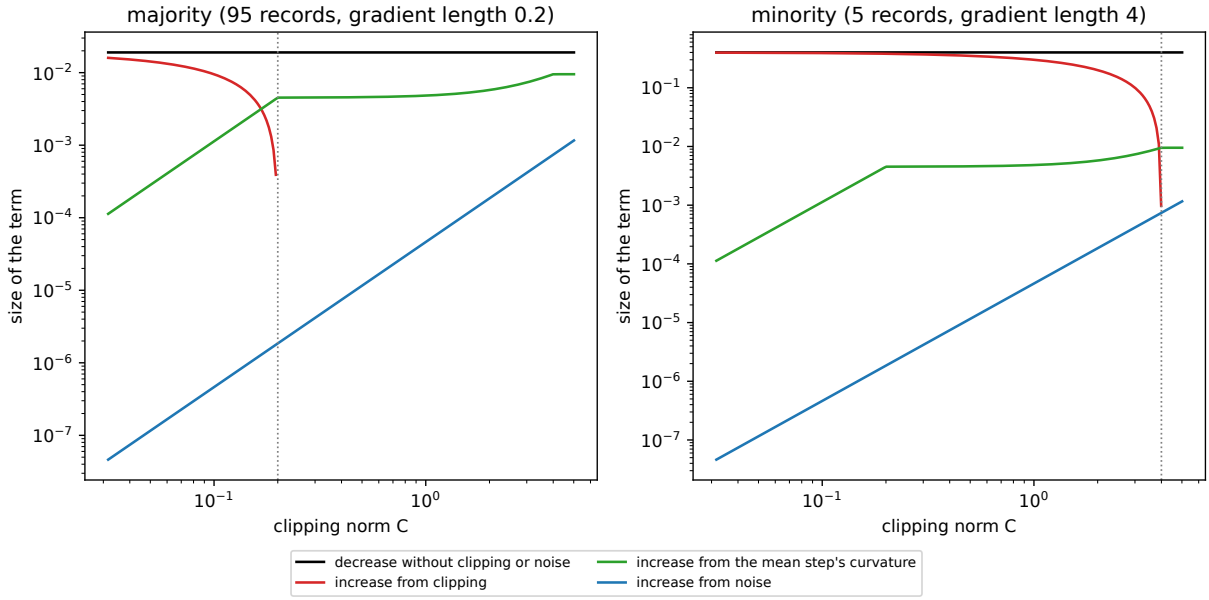

Figure M.10.: The terms of Equation M.52 for one full-batch step of the chapter's two-group example, against the clipping norm C, log–log: the loss decrease without clipping or noise, and the increases from clipping, from the curvature of the mean step and from the noise ($\sigma = 1.36$, $B = 100$, $\eta = 0.5$). The dotted line marks each group's gradient length.

M.5.5. What it does not cover

For a loss that is not quadratic, the remainder of step 2 is of order η^3 times the third derivatives, so Equation M.52 is accurate only for small steps. The decomposition is for one step at the current weights. It does not say how the terms evolve over training, which the chapter's feedback loop and noise floor address. Tran, Dinh & Fioretto (2021) also relate the trace of a group's Hessian to its distance from the decision boundary and its input norms, and that relation stays cited.

M.6. Code

The script apx_learning.py computes every number on this page and draws every figure. It runs noisy projected gradient descent and output and objective perturbation on the running example. It evaluates the data-dependent PATE bound against exact divergences on two and three labels. It sums the Rényi moment of a user's subsets exactly, and checks the identity against a quadrature. For the tuning and fairness sections, it checks every inequality on random cases and by Monte Carlo. From the repository root:

```
uv run python code/appendix-derivations/apx_learning.py
```

Table M.3 collects the main results.

Table M.3.: The main numbers the script prints, each against the value it is compared with.

Check	Value	Compared with
Upper bound Equation M.3, $n = 3{,}000$	2.4742×10^{-2}	measured 1.0754×10^{-3}
Lower bound Equation M.5, $n = 10{,}000$	1.8991×10^{-9}	upper bound 2.2268×10^{-3}
Output perturbation, $n = 10{,}000$	$[2.7835 \times 10^{-4},\ 7.2372 \times 10^{-3}]$	measured 9.6417×10^{-4}
Objective perturbation, $n = 10{,}000$	$[3.2872 \times 10^{-7},\ 2.2221 \times 10^{-4}]$	measured 7.1178×10^{-5}
PATE bound, gap 150	1.2278×10^{-3}	exact 2.2362×10^{-4}
PATE bound, votes $(200, 40, 10)$	8.7544×10^{-4}	exact 1.5188×10^{-4}
Tuning bound at order 5, limit in $\hat{\alpha}$	1.4599	exact 0.3912
Corollary 4, closed form	2.7791	numerical minimum 2.7791
User moment A_2, aligned	1.232011	60 degrees: 1.066665
Moment identity, quadrature	1.516754	formula 1.516754
Minority's step, formula	0.01709	Monte Carlo 0.01707

What to take from it. Every bound holds on every check. The upper bounds are 3.1 to 23.0 times the measured values. The lower bounds prove the rates but not useful constants. The two

places where the chapters relied on numerical evidence now have proofs, or a rigorous replacement. The pure-DP PATE bound always increases in β, and the Gaussian one can always be replaced by its largest value over $\beta \leq \tilde{\beta}$. The tuning bound for a pure-DP run is best in the limit of large $\hat{\alpha}$, slightly below its value at the end of any finite grid of orders, and the chapter's table now reports that limit.

N. Auditing, reconstruction and adaptive analysis

This appendix proves four results that the last chapters of Part 5 state and use but do not prove in full. Each one starts from a limit on how much an output can reveal and turns it into a limit on what someone can learn from it. Three of them start from a differential privacy (DP) guarantee, and the fourth, the Ladder, from the small number of different outputs it can produce.

A one-run audit plants test records, called canaries, in one training run and guesses which were used, and the first result limits how many of those guesses can be right. The transfer theorem is about an analyst who asks a dataset many questions, each chosen after seeing earlier answers, and it limits how far private answers can drift from the truth about the population. The Ladder is a rule for releasing a competition leaderboard, and its bound limits how far repeated submissions can push the leaderboard away from the truth. Finally, the reconstruction bound limits how close any unbiased estimate of a training record can get. The proofs share one habit, which is to bound something the attacker or the analyst chooses by a quantity that holds for every choice at once. For example, a sum of guesses is compared with a binomial count, and a classifier the analyst chose is compared with every classifier it could have submitted.

The four results sit together because they use the same few tools. Each proof conditions on what was observed, changes from one distribution to another through a likelihood ratio, or counts the possible outputs and applies a union bound. Table N.1 lists each derivation and the chapter section that uses it.

Table N.1.: The derivations of this appendix and the chapter sections that use them.

Derivation	What it proves	Where the chapter states or uses it
Section N.1	Correct guesses in a one-run audit are dominated by a binomial	Section 47.6, step 4 of the derivation
Section N.2	Private answers that are accurate on the sample are accurate on the population with high probability	Section 48.6, the first of the three cited results
Section N.3	The Ladder leaderboard's error is of order $(\ln k/n)^{1/3}$ against any analyst	Section 48.8, rule 5
Section N.4	An unbiased reconstruction has mean squared error at least $w^2/(4(e^{\varepsilon}-1))$	Section 46.6, the paragraph on Guo et al.

N.1. One-run auditing: correct guesses are dominated by a binomial

N.1.1. What the chapter uses

A one-run audit plants m canaries in the training set, each included by its own fair coin, and trains a model once. Write $S_i = +1$ if canary i is in the training set and $S_i = -1$ if it is not. The auditor then scores every canary, and it guesses "in", written $\hat{S}_i = +1$, for some canaries and "out", written $\hat{S}_i = -1$, for others. On the rest it abstains, written $\hat{S}_i = 0$. Each score is a number computed from the trained model, such as the canary's loss, and a high score suggests the canary was in. In the chapter the number of guesses r is fixed in advance: the auditor guesses "in" on the $r/2$ highest scores and "out" on the $r/2$ lowest. Let W be the number of correct guesses.

The privacy level ε of the training run is the number being tested. The chapter states that an ε-DP training run limits the count of correct guesses. That count reaches any level v no more often than a binomial count does:

$$\Pr[W \geq v] \leq \Pr\left[\mathrm{Bin}(r, p_\varepsilon) \geq v\right], \qquad p_\varepsilon = \frac{e^\varepsilon}{1 + e^\varepsilon}, \tag{N.1}$$

where $\mathrm{Bin}(r, p)$ is a binomial count of r independent trials that each succeed with probability p. This is Equation 47.10 in Section 47.6. The chapter derives it for pure DP, in which the slack δ of (ε, δ)-DP is zero, in four steps. Its step 4 writes whether each guess is right as an indicator that is 1 when a uniform random number falls below a threshold. The threshold depends on the earlier guesses, and the step compares the sum of the indicators with a binomial. It does not prove that this comparison is allowed. That missing piece is the **domination lemma** below. The version with δ, Equation 47.11, is cited to Steinke, Nasr & Jagielski (2023), and it stays cited here.

N.1.2. The idea

Each guess, on its own, is a guess about one fair coin, made from an output that is ε-DP in that coin. So no guess can be right more often than p_ε. The reason is that DP lets the output make one value of the coin at most e^ε times as likely as the other, and Bayes' rule turns odds of e^ε to 1 into the probability $e^\varepsilon/(1 + e^\varepsilon)$. The difficulty is that the guesses are not independent. The auditor ranks all the canaries together, so whether one guess is right can change the odds of the next. What saves the argument is that, once the guesses are put in some fixed order, the bound p_ε holds *given whether every earlier guess was right*, so the past can make a guess less likely to be right, but never more likely than p_ε. A count of successes in which every success has conditional probability at most p is never more likely to be large than a binomial count with success probability p.

A small case shows the last claim. Take $r = 2$ guesses and $p = 3/4$. The first guess is right with probability $3/4$. The second is right with probability $3/4$ after a correct first guess and only $1/2$ after a wrong one, so the past changes its odds, but never above $3/4$. Table N.2 compares the count with a $\mathrm{Bin}(2, 3/4)$ count.

Table N.2.: Two guesses whose second success probability depends on the first, against a binomial with the same largest success probability. Every tail of the adaptive count is at most the binomial's.

Correct guesses	0	1	2
Adaptive guesser	$\frac{1}{4} \cdot \frac{1}{2} = \frac{2}{16}$	$\frac{3}{4} \cdot \frac{1}{4} + \frac{1}{4} \cdot \frac{1}{2} = \frac{5}{16}$	$\frac{3}{4} \cdot \frac{3}{4} = \frac{9}{16}$
$\mathrm{Bin}(2, \frac{3}{4})$	$\frac{1}{16}$	$\frac{6}{16}$	$\frac{9}{16}$
Adaptive $\Pr[W \geq v]$, for $v = 1, 2$		$\frac{14}{16}$	$\frac{9}{16}$
Binomial $\Pr[\mathrm{Bin} \geq v]$, for $v = 1, 2$		$\frac{15}{16}$	$\frac{9}{16}$

Every tail of the adaptive count is at most the binomial's tail. The derivation shows why by building both counts from the same uniform random numbers, so that the adaptive count is never larger, outcome by outcome.

N.1.3. Derivation

The setting is the chapter's. The inclusion bits $S_1, \ldots, S_m$ are independent fair coins. Training produces an output from the dataset with the included canaries. The guesses $\hat{S}$ are computed from that output alone, possibly with extra randomness that is independent of the bits, and exactly r of them are non-zero. The first three steps are the chapter's, restated so that each says what it conditions on.

1. **Each inclusion bit is protected.** Fix every bit except S_i. Changing S_i adds or removes one record, so the training output is ε-DP as a function of S_i. The guesses are computed from the output without looking at the data, so they are ε-DP too, because post-processing cannot weaken privacy. So for every vector of guesses s,

$$\Pr[\hat{S} = s \mid S_i = +1, S_{-i}] \leq e^{\varepsilon} \Pr[\hat{S} = s \mid S_i = -1, S_{-i}], \tag{N.2}$$

   where S_{-i} stands for all the bits except S_i.

2. **Average over the later bits.** Write $S_{<i}$ for the bits $S_1, \ldots, S_{i-1}$, and $S_{>i}$ for the bits after i. Keep $S_{<i}$ fixed and average both sides of step 1 over $S_{>i}$. The later bits are independent of S_i, so the same weights appear on both sides, and the inequality survives:

$$\Pr[\hat{S} = s \mid S_i = +1, S_{<i}] \leq e^{\varepsilon} \Pr[\hat{S} = s \mid S_i = -1, S_{<i}]. \tag{N.3}$$

3. **No guess is right more than p_ε of the time, given the guesses and the earlier bits.** Write x and y for the two sides of step 2 without the factor e^{ε}, so that $x \leq e^{\varepsilon} y$. The bit S_i has prior probability $\frac{1}{2}$ of each value, and it is independent of $S_{<i}$. So Bayes' rule gives

$$\Pr[S_i = +1 \mid \hat{S} = s, S_{<i}] = \frac{\frac{1}{2}x}{\frac{1}{2}x + \frac{1}{2}y} = \frac{x}{x+y} \leq \frac{e^{\varepsilon} y}{e^{\varepsilon} y + y} = p_\varepsilon. \tag{N.4}$$

The inequality holds because $x/(x+y)$ grows with x. Swapping the roles of $+1$ and -1 gives the same bound for $\Pr[S_i = -1 \mid \hat{S} = s, S_{<i}]$. So whichever way canary i is guessed, the guess is right with probability at most p_ε, given the guesses and the earlier bits.

4. **Fix the guesses and put the guessed canaries in order.** Condition on the event $\hat{S} = s$ for one guess vector s. That fixes which r canaries are guessed. List them in index order, $i_1 < i_2 < \cdots < i_r$, and write $X_j = \mathbf{1}[S_{i_j} = s_{i_j}]$ for the indicator that the j-th guess is right. So $W = X_1 + \cdots + X_r$. The earlier indicators $X_1, \ldots, X_{j-1}$ are functions of the earlier bits $S_{<i_j}$ alone, because s is fixed. Step 3, applied to canary $i = i_j$, says that $X_j = 1$ has chance at most p_ε given $\hat{S} = s$ and the earlier bits $S_{<i_j}$. Knowing only the earlier indicators is knowing less than the earlier bits. So the chance of $X_j = 1$ given $\hat{S} = s$ and the earlier indicators is an average of those step-3 chances, taken over the values of $S_{<i_j}$ that produce the observed indicators. An average of numbers that are each at most p_ε is at most p_ε, so

$$\Pr[X_j = 1 \mid \hat{S} = s,\ X_1, \ldots, X_{j-1}] \le p_\varepsilon \qquad \text{for every } j \text{ and every past.} \tag{N.5}$$

Index order is the simplest choice. Any other order of the canaries works too, as long as it is chosen before the bits are drawn, because steps 1 to 3 can be redone with "earlier" meaning earlier in that order.

5. **The domination lemma.** Steps 1 to 4 leave a sequence of 0/1 variables in which each has conditional probability at most p of being 1, whatever happened before. The lemma says that their sum is never more likely to reach v than a binomial count.

> **Domination lemma.** Let $X_1, \ldots, X_r$ take values in $\{0, 1\}$, and suppose $\Pr[X_j = 1 \mid X_1, \ldots, X_{j-1}] \le p$ for every j and every value of the past. Then for every v,
>
> $$\Pr[X_1 + \cdots + X_r \ge v] \le \Pr\left[\mathrm{Bin}(r, p) \ge v\right]. \tag{N.6}$$

The proof builds both counts from the same random numbers. Write $g_j(x_1, \ldots, x_{j-1})$ for the conditional probability that $X_j = 1$ after the past $x_1, \ldots, x_{j-1}$, which is at most p by assumption. Draw independent numbers $U_1, \ldots, U_r$, each uniform on $[0, 1]$, and build two sequences from them.

- **A copy of the X's.** Set $Y_1 = \mathbf{1}[U_1 \le g_1]$ and, one step at a time, $Y_j = \mathbf{1}[U_j \le g_j(Y_1, \ldots, Y_{j-1})]$.
- **A binomial.** Set $B_j = \mathbf{1}[U_j \le p]$. The B_j are independent, each 1 with probability p, so their sum is $\mathrm{Bin}(r, p)$.

The sequence Y has the same distribution as X. The reason is that U_j is independent of the earlier U's, and so of $Y_1, \ldots, Y_{j-1}$. So given the past, Y_j is 1 with probability exactly g_j of that past, which is the conditional law of X_j. Multiplying these conditional probabilities along any 0/1 string gives the same probability for Y as for X, by the chain rule of probability. Next, compare the two sequences outcome by outcome. Since $g_j \le p$, whenever $U_j \le g_j$ also $U_j \le p$, so $Y_j \le B_j$ for every j and every outcome. Summing, $Y_1 + \cdots + Y_r \le B_1 + \cdots + B_r$ on every outcome. So whenever the Y count reaches v, so does the binomial count, and

$$\Pr\Big[\sum_j X_j \ge v\Big] = \Pr\Big[\sum_j Y_j \ge v\Big] \le \Pr\Big[\sum_j B_j \ge v\Big] = \Pr\left[\mathrm{Bin}(r, p) \ge v\right]. \tag{N.7}$$

This is the chapter's step 4 made precise. The uniform numbers U_j exist only inside the proof, and the copy Y is what lets the threshold g_j depend on the past.

6. **Average over the guesses.** Given $\hat{S} = s$, step 4 puts the correctness indicators in the lemma's setting with $p = p_\varepsilon$, so

$$\Pr[W \geq v \mid \hat{S} = s] \leq \Pr\left[\mathrm{Bin}(r, p_\varepsilon) \geq v\right]. \tag{N.8}$$

   The right side does not depend on s, because every guess vector has exactly r non-zero entries. So averaging over s, with weights $\Pr[\hat{S} = s]$, gives Equation 47.10.

If the number of guesses could vary with the output, step 6 would give a binomial with the number of guesses that s makes. The largest possible number of guesses then gives a bound that holds for every s, because a binomial count with more trials is more likely to reach v.

N.1.4. Checking it

Figure N.1 shows the binomial envelope for $r = 100$ guesses at four values of ε. The chapter's worked example observes $v = 75$ correct guesses. The shaded area beyond 75 is the most probability that an ε-DP training run can give to an audit at least this successful. The audit treats each ε as a claim to test. If an ε-DP run would reach 75 correct guesses with probability below $\beta = 0.05$, the audit rejects the claim that the run is ε-DP. Table N.3 lists the tail at each of the four values of ε.

Table N.3.: The binomial envelope for 100 guesses and its probability of 75 or more correct guesses, at four privacy levels.

ε	p_ε	Mean of $\mathrm{Bin}(100, p_\varepsilon)$	$\Pr[\mathrm{Bin}(100, p_\varepsilon) \geq 75]$	Rejected at $\beta = 0.05$?
0.5	0.6225	62.25	0.0048	Yes
1	0.7311	73.11	0.3827	No
$\ln 3$	0.7500	75.00	0.5535	No
2	0.8808	88.08	0.9999	No

The tail grows with ε, and it crosses 0.05 at $\varepsilon = 0.702$. That is the chapter's lower bound, recomputed by this page's script (see Section N.5). The script also reproduces the chapter's ceilings, the largest ε an audit can certify when every guess is right: 3.49 for 100 guesses, 5.81 for 1,000 and 8.11 for 10,000.

The script checks the domination lemma on an adaptive sequence it computes exactly. There are 100 indicators. The first is 1 with probability 0.75, and each later one is 1 with probability 0.75 after a success and 0.6 after a failure, in the spirit of the two-guess example of Table N.2. Their sum has mean 70.64, and its chance of reaching 75 is 0.2363, against 0.5535 for the binomial. Over every v from 0 to 100 its tail never exceeds the binomial's, except by floating-point rounding of 2.1×10^{-14}.

The bound is exact for randomized response, the mechanism that reports each inclusion bit and flips it with probability $1 - p_\varepsilon$. Here the reports play the role of the trained model. Guessing each canary's bit from its report is right with probability exactly p_ε, independently, so W is exactly $\mathrm{Bin}(r, p_\varepsilon)$. The left panel of Figure N.2 simulates 20,000 such audits at $\varepsilon = \ln 3$, each with 100

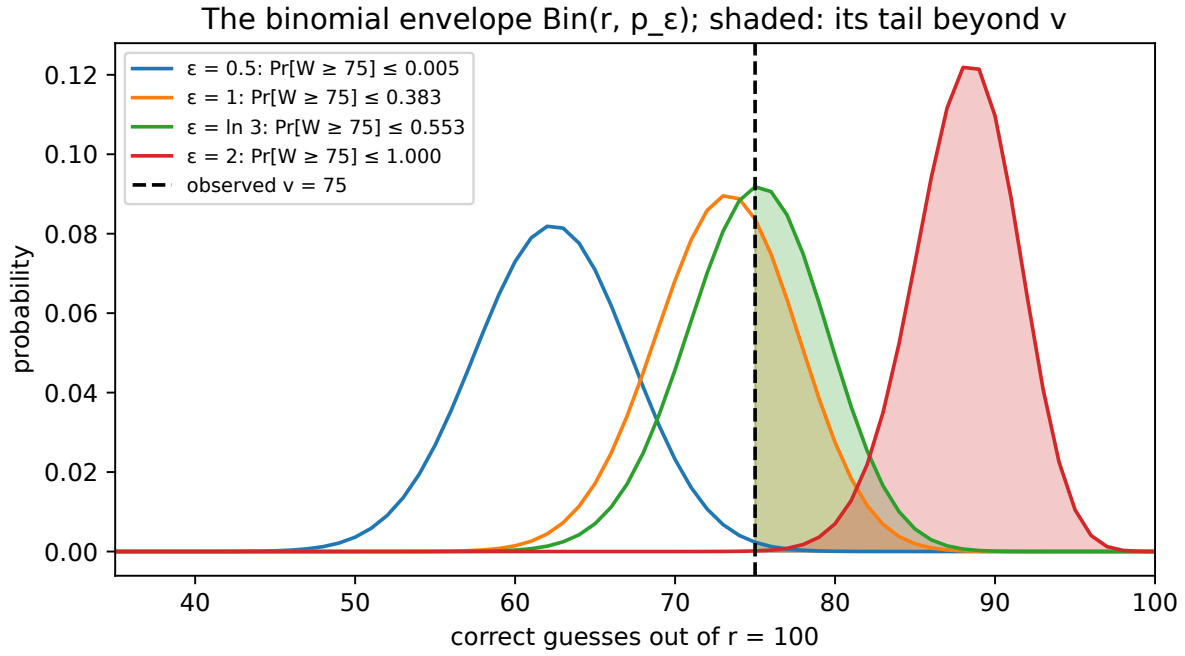

Figure N.1.: The binomial envelope $\mathrm{Bin}(100, p_\varepsilon)$ for $\varepsilon = 0.5$, 1, $\ln 3$ and 2, with the observed count of 75 correct guesses marked and each distribution's probability of 75 or more shaded.

guesses among 1,000 canaries, picked at random among the reports of each sign. The average count is 75.01, and the chance of 75 or more is 0.5544, against 0.5535 for the binomial.

The right panel scores each canary by S_i plus Laplace noise of scale $2/\varepsilon$. Changing S_i moves its score by 2, so this is ε-DP in each bit. Unlike randomized response, these scores differ in how informative they are, so the number of guesses matters. A Laplace density falls by the factor $e^{-x/b}$ over a distance x, where b is its scale. A score of 1 or more is a distance 2 closer to the centre $+1$ than to the centre -1. So it is exactly $e^{2/b} = e^{\varepsilon}$ times as likely when the canary is in as when it is out. A guess on such a confident score is therefore right with probability exactly p_ε, and the binomial is reached.

The simulation confirms this. With 1,000 canaries at $\varepsilon = 1$, where $p_\varepsilon = 0.731$, the average accuracy is 0.730 for 20 guesses and 0.732 for both 100 and 500 guesses. Guessing all 1,000 canaries includes scores near 0, which carry little information. Then the accuracy drops to 0.697. That is the chance that the noise, of scale $b = 2$ at $\varepsilon = 1$, does not move the score across 0, a distance 1 away, which is $1 - \frac{1}{2}e^{-1/2}$. So the auditor should guess only where the scores are confident, as the chapter does.

N.1.5. What it does not cover

The proof needs two things from the audit design. Each canary must be included by its own fair coin, because step 3 uses the prior $\frac{1}{2}$ and step 2 uses the independence of the bits. And the guesses must be computed from the training output alone, so that step 1 can use post-processing.

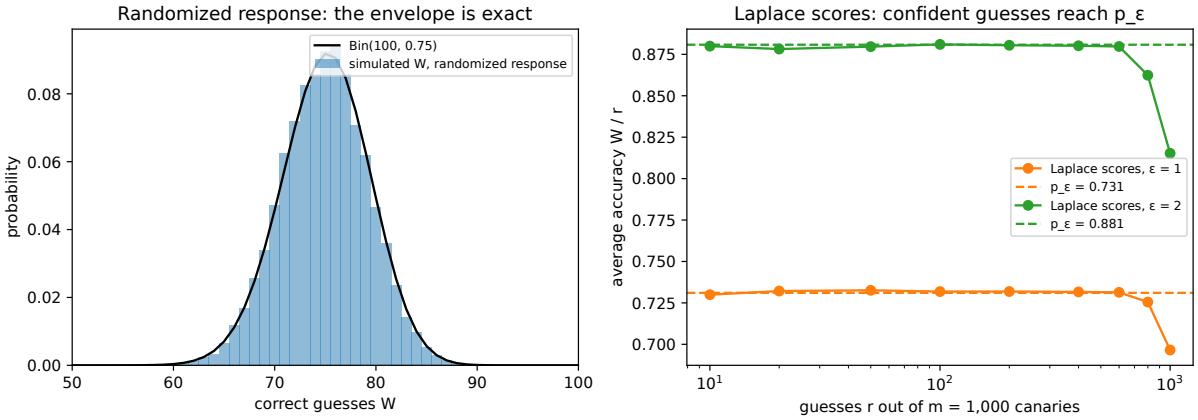

Figure N.2.: Left: the number of correct guesses in 20,000 simulated one-run audits of randomized response at $\varepsilon = \ln 3$, 100 guesses among 1,000 canaries, against the $\mathrm{Bin}(100, 0.75)$ envelope. Right: the average accuracy of one-run audits of Laplace scores against the number of guesses, at $\varepsilon = 1$ and 2, with p_ε dashed.

The proof covers pure DP only. Under (ε, δ)-DP, step 1 picks up an additive δ, and the slack can pile up across the guesses. Steinke, Nasr & Jagielski (2023) control it with a longer induction over the guesses, which gives the correction term of Equation 47.11. That argument is several pages long, so it stays cited.

N.2. Private answers stay accurate with high probability

N.2.1. What the chapter uses

The adaptive data analysis chapter proves the transfer theorem in expectation (Equation 48.15). A mechanism M answers k statistical queries that an analyst chooses one at a time, each from the earlier answers. A **statistical query** q maps one record to a number in $[0, 1]$. Its empirical value $q(D)$ is its average over the dataset D, a sample of n records drawn independently from a distribution $\mathcal{D}$. Its population value $q(\mathcal{D})$ is its average over $\mathcal{D}$. The answer to query q_j is a_j. If the whole interaction is (ε, δ)-DP in the sample, under the replace relation, and the answers are accurate on the sample on average, then they are accurate on the population on average.

Section 48.6 then states a high-probability version with citations and no proof. It credits the result to Bassily, Nissim, Smith, Steinke, Stemmer & Ullman (2016), and says that Jung, Ligett, Neel, Roth, Sharifi-Malvajerdi & Shenfeld (2020) give a shorter proof with explicit constants. This section gives that shorter proof. Call the answers (α, β)**-accurate on the sample** when, with probability at least $1 - \beta$, every answer is within α of its empirical value, so that $\max_j |a_j - q_j(D)| \le \alpha$. The theorem proved here is the following.

> **High-probability transfer theorem.** Suppose the interaction is (ε, δ)-DP in the sample under the replace relation, every answer lies in $[0, 1]$, and the answers are (α, β)-accurate on the sample. Then for every $c > 0$ and $d > 0$,
>
> $$\Pr\left[\max_{j \le k} |a_j - q_j(\mathcal{D})| > \alpha + c + e^{\varepsilon} - 1 + d\right] \le \frac{\beta}{c} + \frac{\delta}{d}. \tag{N.9}$$

The two free numbers c and d trade error for failure probability. The chapter's own statement keeps the failure probability of the order of β. This form instead divides β by c, which costs only a logarithm for Gaussian answers, as the end of the derivation shows.

N.2.2. The idea

The proof introduces one object, the **posterior** Q_π. Picture an observer who knows the distribution $\mathcal{D}$, the mechanism and the analyst's strategy, and who sees the whole transcript π of queries and answers, but not the sample. Ask that observer to describe a record picked at random from the sample. Their answer is a distribution over records, and that distribution is Q_π. Then a query's value under the posterior, $q(Q_\pi)$, is the observer's best guess of the query's empirical value. The proof compares each answer with the population in two hops, through the posterior. First, answers that are close to the sample are close to the observer's guess of the sample, because the observer's guess is an average over the samples that could have produced the transcript. Second, the observer's guess cannot be far from the population, because DP limits how much the transcript reveals about any one record. So the observer cannot believe that the sample's records are very different from fresh ones.

A small case makes the second hop concrete. Take $n = 20$ coin records, each 1 with probability $p = 0.3$, and one query, the average. The mechanism answers it with Laplace noise of scale $1/(n\varepsilon)$, which is ε-DP because one record moves the average by at most $1/n$. Figure N.3 plots the posterior mean of a sample record, $q(Q_\pi)$, against the observed answer a. With $\varepsilon = 4$ the answer is nearly exact, and the posterior follows it: after seeing $a = 0.6$, the observer believes the sample's records are 1 with probability 0.5973. With $\varepsilon = 1$ the observer believes 0.4989, and with $\varepsilon = 0.25$ only 0.3539, close to the population's 0.3. However strange the answer, the posterior cannot leave a band around the population value, and the band narrows as ε shrinks.

N.2.3. Derivation

The randomness is the sample, the mechanism's coins and the analyst's coins. The analyst's strategy and the distribution $\mathcal{D}$ are fixed and known to the proof, and they are not part of the private input. The transcript π lists every query and every answer, so each q_j and each a_j is a function of π. For simplicity the records take countably many values, so that the posterior is a list of probabilities. With densities, every sum below becomes an integral.

1. **The posterior and the resampling identity.** Pick an index I uniformly from $1, \dots, n$, independently of everything else, and define the posterior as the conditional distribution of the record x_I given the transcript:

$$Q_\pi(x) = \Pr[x_I = x \mid \pi] = \frac{1}{n} \sum_{i=1}^{n} \Pr[x_i = x \mid \pi]. \tag{N.10}$$

   For any query q that is a function of π, the empirical value $q(D)$ is the average of $q(x_i)$ over the records, so its conditional expectation is the average of q under the posterior:

$$\mathbb{E}[q(D) \mid \pi] = \frac{1}{n} \sum_{i=1}^{n} \mathbb{E}[q(x_i) \mid \pi] = \sum_{x} q(x)\, Q_\pi(x) = q(Q_\pi). \tag{N.11}$$

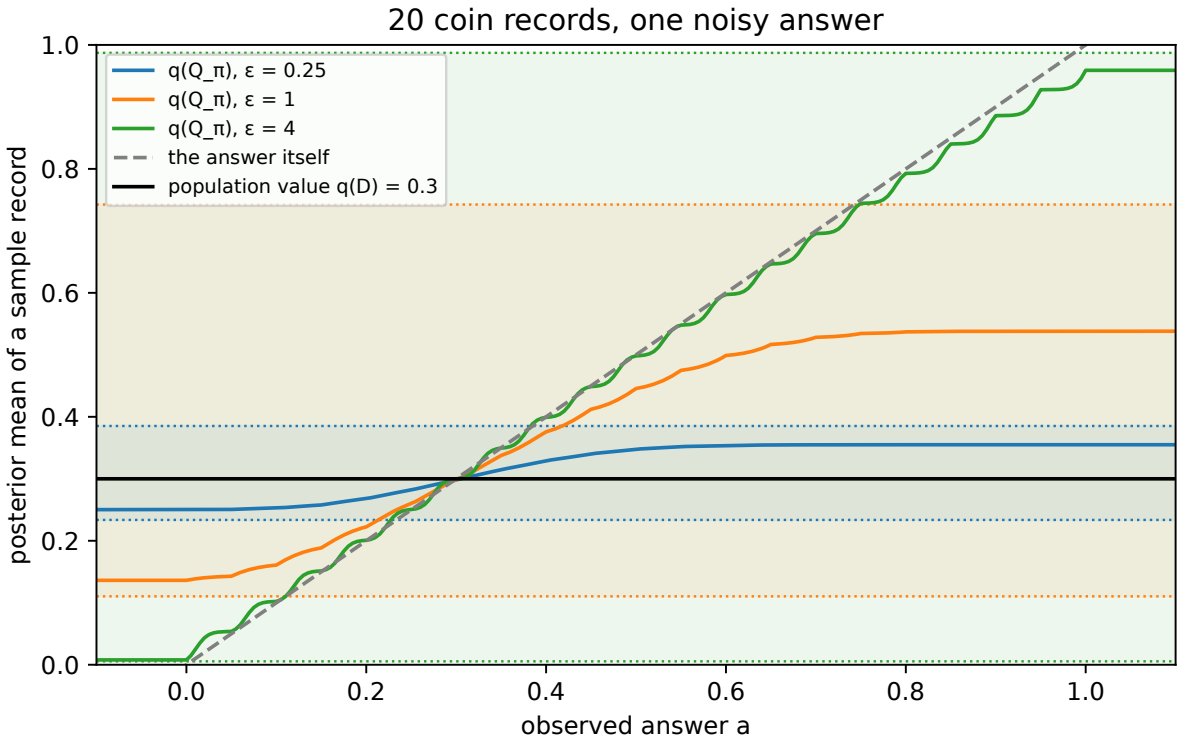

Figure N.3.: The posterior mean of a randomly chosen sample record, $q(Q_\pi)$, against the observed noisy answer a, for 20 coin records with mean 0.3 and Laplace noise at $\varepsilon = 0.25$, 1 and 4. Shaded with dotted edges: the band that pure DP allows, in the matching colour. The dashed diagonal is the answer itself and the black line the population value.

In words, the observer's best guess of a query's empirical value is the query's value under the posterior.

2. **Accuracy on the sample gives accuracy against the posterior.** Write F for the failure event $\max_j |a_j - q_j(D)| > \alpha$, which has probability at most β. The answer a_j is fixed by π, so by Equation N.11, $a_j - q_j(Q_\pi) = \mathbb{E}[a_j - q_j(D) \mid \pi]$. Outside F the gap $|a_j - q_j(D)|$ is at most α. Inside F it is at most 1, because both a_j and $q_j(D)$ lie in $[0, 1]$. So

$$\left|a_j - q_j(Q_\pi)\right| \le \mathbb{E}[|a_j - q_j(D)| \mid \pi] \le \alpha + \Pr[F \mid \pi]. \tag{N.12}$$

3. **The conditional failure probability is rarely large.** The conditional failure probability $\Pr[F \mid \pi]$ is a non-negative quantity whose average over transcripts is $\Pr[F] \le \beta$. Markov's inequality, which says that a non-negative quantity exceeds c with probability at most its average divided by c, gives

$$\Pr_\pi\left[\Pr[F \mid \pi] > c\right] \le \frac{\beta}{c}. \tag{N.13}$$

So, except with probability at most β/c, every answer is within $\alpha + c$ of its posterior value.

4. **Under pure DP, the posterior is never far from the population.** This warm-up is the case $\delta = 0$, and it explains the bands of Figure N.3. Fix a record i, a value x and a transcript π. Bayes' rule writes the observer's belief about record i through the chance of the transcript:

$$\Pr[x_i = x \mid \pi] = \frac{\Pr[\pi \mid x_i = x]\, \mathcal{D}(x)}{\Pr[\pi]}. \tag{N.14}$$

Replacing x_i by another value x' multiplies the chance of the transcript by at most e^ε, whatever the other records are. So it does so after averaging over the other records too, and $\Pr[\pi \mid x_i = x] \le e^\varepsilon \Pr[\pi \mid x_i = x']$. Averaging the right side over x' drawn from $\mathcal{D}$ gives $e^\varepsilon \Pr[\pi]$, because that is how x_i is drawn. Substituting into Bayes' rule, and then averaging over the record i, gives

$$\Pr[x_i = x \mid \pi] \le e^\varepsilon\, \mathcal{D}(x), \qquad Q_\pi(x) \le e^\varepsilon\, \mathcal{D}(x). \tag{N.15}$$

The same argument with x and x' swapped gives $Q_\pi(x) \ge e^{-\varepsilon}\mathcal{D}(x)$. Now average a query q with values in $[0, 1]$ against these two bounds, and do the same for $1 - q$:

$$e^{-\varepsilon} q(\mathcal{D}) \le q(Q_\pi) \le e^\varepsilon q(\mathcal{D}), \qquad e^{-\varepsilon}(1 - q(\mathcal{D})) \le 1 - q(Q_\pi) \le e^\varepsilon (1 - q(\mathcal{D})). \tag{N.16}$$

These confine $q(Q_\pi)$ to a band around $q(\mathcal{D})$. The upper bound of the first pair puts the band's top at most $(e^\varepsilon - 1)q(\mathcal{D})$ above the population value. The upper bound of the second pair puts its bottom at most $(e^\varepsilon - 1)(1 - q(\mathcal{D}))$ below it. Both distances are at most $e^\varepsilon - 1$.

5. **Under (ε, δ)-DP, the posterior is far from the population only rarely.** With $\delta > 0$ the pointwise bound of step 4 fails, so the proof bounds a probability instead. The tool is the one-sided transfer lemma that the chapter proves in Section 48.5. It says that if an (ε, δ)-DP mechanism M' reads the dataset and outputs a query $q_{M'}$, then the query's expected empirical value is not much larger than its expected population value:

$$\mathbb{E}[q_{M'}(D)] \le e^\varepsilon\, \mathbb{E}[q_{M'}(\mathcal{D})] + \delta. \tag{N.17}$$

The reason, in short, is a swap. The population value of a query is its value on a fresh record x_i' that the algorithm never saw. Swapping x_i' with the sample's record x_i leaves

the joint distribution unchanged, so it equals the value on x_i of a query chosen from a sample without x_i. And DP says that choosing from the sample with x_i instead of without it raises the average of any $[0,1]$-valued function of the choice by at most the factor e^{ε} plus δ (Equation 48.5).

Apply the lemma to a query built from the transcript. Among the $2k$ queries q_j and $1-q_j$, let q_π^* be the one with the largest gap $q(Q_\pi) - q(\mathcal{D})$. Adding the complements makes this largest signed gap equal to the largest absolute gap $\max_j |q_j(Q_\pi) - q_j(\mathcal{D})|$, because the complement $1-q$ has the same gap with the opposite sign. Fix a threshold τ, and let E be the event that this gap exceeds τ. Define the query

$$h_\pi(x) = q_\pi^*(x)\,\mathbf{1}[\pi \in E], \tag{N.18}$$

which is q_π^* on transcripts in E and the zero query elsewhere. The algorithm that outputs h_π computes it from the transcript and from the fixed $\mathcal{D}$, so it is post-processing of the interaction and is (ε,δ)-DP. The lemma applied to it, with $h_\pi(D) = q_\pi^*(D)\mathbf{1}[E]$ and $h_\pi(\mathcal{D}) = q_\pi^*(\mathcal{D})\mathbf{1}[E]$, gives

$$\mathbb{E}\big[q_\pi^*(D)\,\mathbf{1}[E]\big] \le e^{\varepsilon}\,\mathbb{E}\big[q_\pi^*(\mathcal{D})\,\mathbf{1}[E]\big] + \delta. \tag{N.19}$$

Both q_π^* and $\mathbf{1}[E]$ are fixed by π, so the resampling identity Equation N.11 turns the left side into $\mathbb{E}[q_\pi^*(Q_\pi)\mathbf{1}[E]]$. Subtract $\mathbb{E}[q_\pi^*(\mathcal{D})\mathbf{1}[E]]$ from both sides. On E the gap exceeds τ, which gives the left inequality below. On the right, $(e^{\varepsilon}-1)\mathbb{E}[q_\pi^*(\mathcal{D})\mathbf{1}[E]] \le (e^{\varepsilon}-1)\Pr[E]$ because $q_\pi^*(\mathcal{D}) \le 1$. So

$$\tau \Pr[E] \le \mathbb{E}\Big[(q_\pi^*(Q_\pi) - q_\pi^*(\mathcal{D}))\mathbf{1}[E]\Big] \le (e^{\varepsilon}-1)\Pr[E] + \delta. \tag{N.20}$$

Choose $\tau = e^{\varepsilon} - 1 + d$ and solve for $\Pr[E]$:

$$\Pr\Big[\max_j \big|q_j(Q_\pi) - q_j(\mathcal{D})\big| > e^{\varepsilon} - 1 + d\Big] \le \frac{\delta}{d}. \tag{N.21}$$

With $\delta = 0$ the right side is 0 for every d, which agrees with step 4.

6. **Combine.** Outside the two bad events of steps 3 and 5, which together have probability at most $\beta/c + \delta/d$ by the union bound, every answer satisfies

$$\big|a_j - q_j(\mathcal{D})\big| \le \big|a_j - q_j(Q_\pi)\big| + \big|q_j(Q_\pi) - q_j(\mathcal{D})\big| \le (\alpha + c) + (e^{\varepsilon} - 1 + d). \tag{N.22}$$

This is Equation N.9.

Gaussian answers. Now apply the theorem to the mechanism of Section 48.6. It answers query j with $q_j(D) + \xi_j$, where the noise ξ_j is normal with mean 0 and standard deviation σ, independently for each query. Here the answer is also clipped, that is, moved into $[0,1]$ if it falls outside. Clipping is post-processing, and it never moves an answer away from $q_j(D)$, which lies in $[0,1]$.

The privacy comes from step 1 of the chapter's derivation in Section 48.6. Zero-concentrated differential privacy (zCDP) measures privacy by one number ρ, a bound on the Rényi divergence of every order divided by the order. Gaussian noise of standard deviation σ on a value whose sensitivity is Δ gives $\rho = \Delta^2/(2\sigma^2)$. One record moves an average of n values in $[0,1]$ by at most

$1/n$, so each answer is zCDP with $\rho_1 = 1/(2n^2\sigma^2)$. Composition adds these to $\rho = k/(2n^2\sigma^2)$, and Equation 48.7 converts the total to (ε, δ)-DP with

$$\varepsilon = \rho + 2\sqrt{\rho \ln(1/\delta)}. \tag{N.23}$$

The sample accuracy comes from the normal tail. Each noise exceeds t in absolute value with probability at most $2e^{-t^2/(2\sigma^2)}$. So a union bound over the k answers gives, for any failure probability β',

$$\Pr\Big[\max_j |\xi_j| > \sigma\sqrt{2\ln(2k/\beta')}\Big] \le \beta'. \tag{N.24}$$

In other words, the answers are $(\sigma\sqrt{2\ln(2k/\beta')}, \beta')$-accurate on the sample.

Now fix a target total error α and failure probability β; here α is the total, not the sample-accuracy term of the theorem. The four error terms of Equation N.9 are the noise level $\sigma\sqrt{2\ln(2k/\beta')}$, then c, then $e^{\varepsilon} - 1$, then d. Give each a quarter of α, so $c = d = \alpha/4$. Split the failure probability equally too, with $\beta' = \delta = \alpha\beta/8$, so that β'/c and δ/d are both $\beta/2$. The noise term is then at most $\alpha/4$ when

$$\sigma = \frac{\alpha}{4\sqrt{2\ln\left(16k/(\alpha\beta)\right)}}. \tag{N.25}$$

For the transfer term, $e^{\varepsilon} - 1 \approx \varepsilon$ when ε is small, and step 4 of the chapter's derivation notes that for small ρ the privacy level is about $\varepsilon \approx \sqrt{2k\ln(1/\delta)}/(n\sigma)$. Setting this to $\alpha/4$ gives $n \approx 4\sqrt{2k\ln(1/\delta)}/(\alpha\sigma)$. Substituting the σ above and $\ln(1/\delta) = \ln(8/(\alpha\beta))$ gives

$$n \approx \frac{32\sqrt{k\,\ln\left(8/(\alpha\beta)\right)\,\ln\left(16k/(\alpha\beta)\right)}}{\alpha^2} = \tilde{O}\Big(\frac{\sqrt{k}}{\alpha^2}\Big), \tag{N.26}$$

where $\tilde{O}$ hides factors that are logarithmic in the number of queries and in $1/\alpha$ and $1/\beta$. This is the chapter's high-probability rate. It needs ε of order α and δ of order $\alpha\beta$, the same conditions the chapter quotes. The failure probability enters only through logarithms, so dividing it by c costs little.

N.2.4. Checking it

The pure-DP band of step 4 holds in the coin example. The script computes the posterior exactly on a grid of answers from -0.2 to 1.2, and Table N.4 compares the range of the posterior mean with the band.

Table N.4.: The posterior mean of a sample record in the coin example, with 20 records of mean 0.3 and one Laplace-noised answer, against the band of step 4.

ε	Posterior mean at $a = 0.6$	Range of the posterior mean	Band allowed by pure DP
0.25	0.3539	$[0.2502, 0.3550]$	$[0.2336, 0.3852]$
1	0.4989	$[0.1362, 0.5381]$	$[0.1104, 0.7425]$
4	0.5973	$[0.0078, 0.9590]$	$[0.0055, 0.9872]$

The posterior stays inside the band at every ε, but it does not fill it, because a single noisy average reveals too little about the records to push the posterior to the band's edge.

Table N.5 solves both bounds for the smallest number of records that brings the largest error down to $\alpha = 0.05$. The expectation column is the chapter's Table 48.5, recomputed. The high-probability column chooses the noise level σ and the numbers c and d. It also chooses how to split $\beta = 0.05$ between the two failure terms. It makes these choices with a numerical search, so it is accurate to about three digits and is rounded to three.

Table N.5.: Records that Gaussian answering needs for a largest error of 0.05, on average and with probability 0.95.

Queries k	Records, expected error Equation 48.18	Records, error with probability 0.95, Equation N.9	Ratio
1	7,300	38,400	5.3
100	201,800	455,000	2.3
1,000	764,337	1,530,000	2.0
1,000,000	33,393,779	56,500,000	1.7

The high-probability guarantee costs a factor of about 2 for a thousand queries, and the factor shrinks as k grows. At the optimum for $k = 1{,}000$ the noise term is 0.0243 and the transfer term $e^{\varepsilon} - 1$ is 0.0240. The slack terms are tiny, with $c = 0.0006$ and $d = 0.0012$, so the optimizer asks for $\delta = 3.89 \times 10^{-5}$ and a sample failure probability of 1.11×10^{-5}. This shows the logarithmic price at work: it is cheaper to make both failure probabilities very small than to give up error.

Figure N.4 runs the chapter's boosting analyst against Gaussian answers. Each record is a point with a label, and the labels are fair coins. A submission is a labelling of the points, and its query asks "does the submission agree with this record's label?", so its value is an accuracy. A fresh label is independent of every submission, so every query has population value exactly $\frac{1}{2}$. The analyst submits 99 random labellings and then the majority vote of those whose answer was above $\frac{1}{2}$. With $n = 10{,}000$ records, $k = 100$ queries and the noise level that minimizes the expectation bound, $\sigma = 0.0319$, the largest population error averages 0.0888 over 400 runs, and 95% of runs stay below 0.1125. The expectation bound is 0.2141, and the high-probability bound at the same σ is 0.3218. So the bounds are valid here, and loose by a factor of about 2.4 on average and about 2.9 at the 95% level. Part of the slack is the analyst, which is far from the worst case. The rest is the transfer step, which charges $e^{\varepsilon} - 1$ to every query.

N.2.5. What it does not cover

The theorem needs the answers to lie in $[0, 1]$, which clipping provides. It also needs the guarantee to hold under the replace relation, because the transfer lemma swaps a record for a fresh one. A mechanism that is (ε, δ)-DP for adding or removing a record is $(2\varepsilon, (1 + e^{\varepsilon})\delta)$-DP for replacing one. The form proved here divides the sample failure probability by c. Bassily et al. (2016) prove a form in which a failure probability β on the sample gives a failure probability of order β on the population, with a different argument, a "monitor" that picks the worst of many independent runs of the interaction. That form stays cited. For mechanisms whose accuracy depends on β only through $\ln(1/\beta)$, such as Gaussian noise, the two forms give the same rate.

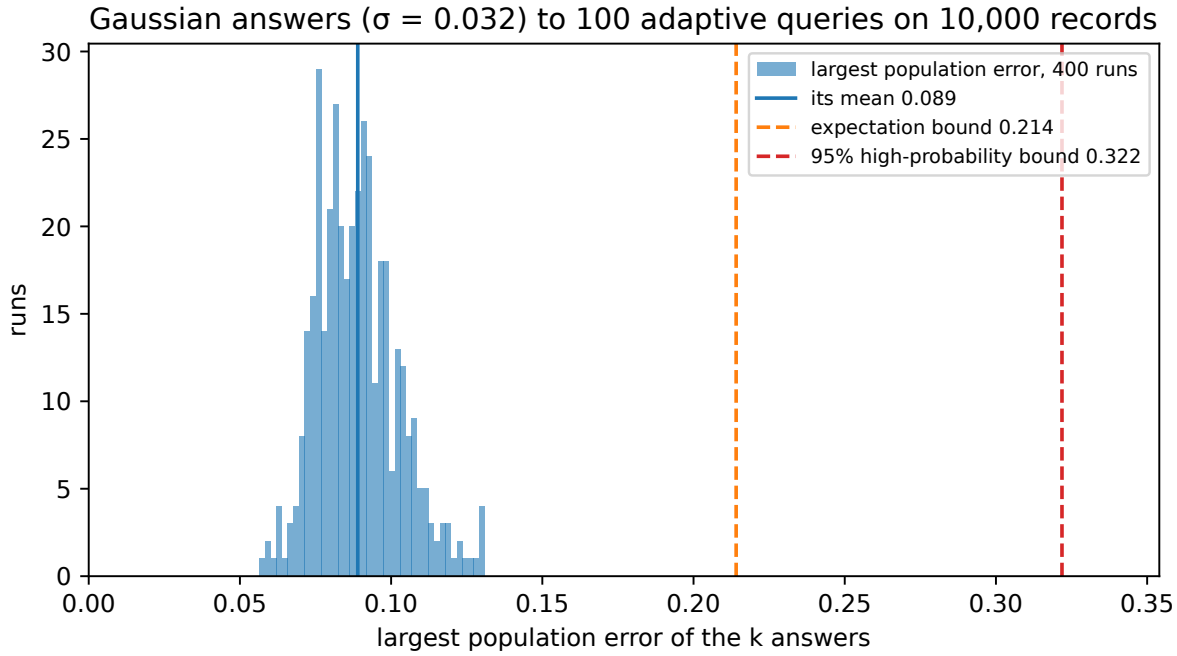

Figure N.4.: The largest population error of Gaussian answers to 100 adaptively chosen queries on 10,000 records, over 400 runs of the boosting analyst, with its mean, the expectation bound Equation 48.18 and the high-probability bound Equation N.9 at failure probability 0.05.

N.3. The Ladder: a leaderboard that rarely changes cannot be overfitted

N.3.1. What the chapter uses

Rule 5 of Section 48.8 says that the **Ladder** of Blum & Hardt (2015) keeps a competition leaderboard accurate against any analyst. The Ladder reports a new score only when a submission beats the best so far by a margin, rounded to that margin. The chapter states that its error against the population is of order $n^{-1/3}$, times a factor that grows like the cube root of $\ln(kn)$, where n is the size of the holdout set and k the number of submissions. It cites the paper and gives only the idea that a leaderboard that changes rarely reveals few bits.

To state the result, write the score as a loss in $[0, 1]$, where lower is better. For a classifier f, the empirical loss $\mathcal{L}(f; D)$ is its average loss on the n records of the holdout set D, and the population loss $\mathcal{L}_{\mathcal{D}}(f)$ is its average over the distribution. With the margin $\nu = 1/J$ for a whole number J, the Ladder releases values $R_0, R_1, \dots, R_k$ as follows.

- Start with $R_0 = 1$.
- When submission f_t arrives, compute $\mathcal{L}(f_t; D)$. If $\mathcal{L}(f_t; D) < R_{t-1} - \nu$, release R_t as $\mathcal{L}(f_t; D)$ rounded to the nearest multiple of ν. Otherwise, release $R_t = R_{t-1}$ again.

The leaderboard should show the best population loss among the submissions so far, so the **leaderboard error** is the largest gap $\max_t |R_t - \min_{i \le t} \mathcal{L}_{\mathcal{D}}(f_i)|$. The result proved here is the following.

> **Ladder bound.** Against any analyst, who may choose each submission from the values released so far, with probability at least $1 - \beta$ the leaderboard error is at most
>
> $$\nu + \sqrt{\frac{\ln(2k/\beta) + \ln \binom{k+J}{J}}{2n}} \;\le\; 3\Big(\frac{\ln(k+1)}{8n}\Big)^{1/3} + \sqrt{\frac{\ln(2k/\beta)}{2n}}, \qquad \text{(N.27)}$$
>
> where the right side holds at the best step $\nu = (\ln(k+1)/(8n))^{1/3}$, ignoring that $1/\nu$ must be a whole number.

The leading term is of order $(\ln k/n)^{1/3}$, and $\ln k \le \ln(kn)$, so this gives the chapter's rate.

N.3.2. The idea

An analyst overfits a holdout set by learning which submissions happen to do well on it and then combining them. To learn that, it must read the scores. The Ladder releases very little. Its released value moves at most $1/\nu$ times, because each move lowers it by at least ν and it starts at 1. Each move happens at one of k submissions and lands on one of $1/\nu$ rounded values. So the whole sequence of released values is one of a modest number of possible sequences, even though the analyst may react to it in any way it likes.

Once the analyst's own coins are fixed, it is a deterministic machine. Each submission is a function of the values released before it. So the set of every classifier it *could* submit, over all possible released sequences, is fixed before the holdout set is drawn, and it is not too large. A fixed set of classifiers is exactly what Hoeffding's inequality and a union bound handle, as in the fixed-query bound of Section 48.3. The adaptivity has been paid for by counting. The rounding to ν is the

price of keeping that count small, so the best ν balances rounding error against the logarithm of the count.

N.3.3. Derivation

1. **The released value falls by at least ν at each move.** All released values are multiples of ν, because $R_0 = 1 = J\nu$ and every new value is rounded to a multiple of ν. A move happens only if $\mathcal{L}(f_t; D) < R_{t-1} - \nu$. Rounding adds at most $\nu/2$, so $R_t < R_{t-1} - \nu/2$. Two multiples of ν that differ by more than $\nu/2$ differ by at least ν, so $R_t \le R_{t-1} - \nu$. The values stay at or above 0, since the loss does. So there are at most $J = 1/\nu$ moves.

2. **The number of possible released sequences.** A released sequence is fixed by the times of its moves and the values it moves to. With u moves, the times are u of the k submissions, and the values are u distinct multiples of ν among $0, \nu, \dots, (J-1)\nu$, which must appear in decreasing order. So the number of sequences is

$$N = \sum_{u=0}^{J} \binom{k}{u}\binom{J}{u} = \binom{k+J}{J} \le (k+1)^J. \tag{N.28}$$

   The middle step is Vandermonde's identity: choosing J items from $k+J$ is the same as choosing u from the first k and $J-u$ from the last J, summed over u, and $\binom{J}{J-u} = \binom{J}{u}$. The last step holds because $\binom{k+J}{J}$ is the product of the ratios $(k+i)/i$ for $i = 1, \dots, J$, and each ratio is at most $k+1$.

3. **The classifiers the analyst could submit.** Fix the analyst's coins, which are independent of the holdout set. Submission t is then a function of the values $R_1, \dots, R_{t-1}$. Those are the first $t-1$ entries of a released sequence, so they take at most N values. Let $\mathcal{F}$ be the set of all classifiers the analyst would submit at some time t after some possible history. It has at most kN members, and it is fixed before the holdout set is drawn, because it depends only on the analyst's strategy and coins.

4. **Every classifier in the set is accurate.** For one fixed classifier, the empirical loss is an average of n independent losses in $[0, 1]$. Hoeffding's inequality bounds the chance that it is more than γ from its mean by $2e^{-2n\gamma^2}$. The union bound over the at most kN members of $\mathcal{F}$ bounds the chance that any of them is off by more than γ by $2kNe^{-2n\gamma^2}$. Setting this to β and solving for γ shows that, with probability at least $1-\beta$,

$$\left|\mathcal{L}(f; D) - \mathcal{L}_{\mathcal{D}}(f)\right| \le \gamma = \sqrt{\frac{\ln(2kN/\beta)}{2n}} \qquad \text{for every } f \in \mathcal{F}. \tag{N.29}$$

   The analyst's actual submissions all belong to $\mathcal{F}$, whatever the holdout set turns out to be.

5. **The released value tracks the best empirical loss.** Write $m_t = \min_{i \le t} \mathcal{L}(f_i; D)$ for the best empirical loss so far. If the leaderboard has not moved by time t, then $R_t = 1$ and every submission had $\mathcal{L}(f_i; D) \ge 1 - \nu$, so $R_t - \nu \le m_t \le R_t$. Otherwise, let $t_0 \le t$ be the time of the last move. Then $R_t = R_{t_0}$ is within $\nu/2$ of $\mathcal{L}(f_{t_0}; D)$, so $m_t \le R_t + \nu/2$. For the other side, take any $i \le t$. If submission i moved the leaderboard, $\mathcal{L}(f_i; D) \ge R_i - \nu/2 \ge R_t - \nu/2$, because the released values never go up. If it did not, $\mathcal{L}(f_i; D) \ge R_{i-1} - \nu \ge R_t - \nu$. So

$$R_t - \nu \le m_t \le R_t + \frac{\nu}{2}. \tag{N.30}$$

6. **Combine.** On the event of step 4, each empirical loss is within γ of the population loss, so the smallest empirical loss so far is within γ of the smallest population loss so far. Together with step 5, $|R_t - \min_{i \le t} \mathcal{L}_{\mathcal{D}}(f_i)| \le \nu + \gamma$ for every t. Substituting $N = \binom{k+J}{J}$ gives the first form of Equation N.27. If the analyst's coins are random, the bound holds for each value of the coins, and so it holds on average over them too.

7. **The best step.** For a closed form, bound the number of histories by $\ln N \le J \ln(k+1) = \ln(k+1)/\nu$, and split the square root with $\sqrt{x+y} \le \sqrt{x} + \sqrt{y}$. Write $\kappa = \ln(k+1)/(2n)$ for short. Then the bound becomes

$$\nu + \sqrt{\frac{\kappa}{\nu}} + \sqrt{\frac{\ln(2k/\beta)}{2n}}. \tag{N.31}$$

   The first two terms trade off. Their derivative in ν is $1 - \frac{1}{2}\sqrt{\kappa}\,\nu^{-3/2}$, which is zero at $\nu^3 = \kappa/4$. There $\sqrt{\kappa/\nu} = 2\nu$, so the two terms add up to $3\nu = 3(\kappa/4)^{1/3} = 3(\ln(k+1)/(8n))^{1/3}$, which is the second form of Equation N.27.

N.3.4. Checking it

Figure N.5 plots the first form of the bound against ν for $n = 10{,}000$ records and $k = 1{,}000$ submissions, at $\beta = 0.05$. A large step makes the rounding term large, while a small one allows more moves, and so more possible histories and a larger union-bound term. The sum is smallest at $\nu = 1/32$, where it is 0.118. The closed form is looser, because it replaces $\binom{k+J}{J}$ by $(k+1)^J$. It puts the best step at 0.0442 and the bound at 0.1556. The closed form's step must be rounded to the form $1/J$. At $\nu = 1/23$, the nearest such step to 0.0442, the first form gives $0.0435 + 0.0769 = 0.1203$.

The script also runs the chapter's boosting attack against both kinds of leaderboard, with $n = 1{,}000$ coin labels and $k = 1{,}000$ submissions, over 20 runs. Every submission has population loss exactly $\frac{1}{2}$. Against a leaderboard that shows each submission's exact loss, the attacker keeps the submissions that scored below $\frac{1}{2}$, and its final majority vote makes the best shown loss wrong by 0.2207 on average. Against the Ladder with $\nu = 1/11$, the attacker sees only when the released value moves. The first submission moves the leaderboard from 1 to its loss near $\frac{1}{2}$, rounded to 5/11 or 6/11, both $1/22 = 0.0455$ away from $\frac{1}{2}$. Later random submissions almost never beat that by ν, so the attacker learns almost nothing, and the error stays at 0.0455, the rounding of that first move. The bound for these sizes is 0.2768 at $\nu = 1/11$, so it is loose by a factor of about 6 here.

N.3.5. What it does not cover

The proof needs the losses to lie in $[0, 1]$ and the holdout records to be independent draws, for Hoeffding's inequality. It controls the best score so far, which is what a leaderboard shows, not the score of every submission. Blum & Hardt (2015) also give a parameter-free variant that sets the margin from the data, which stays cited.

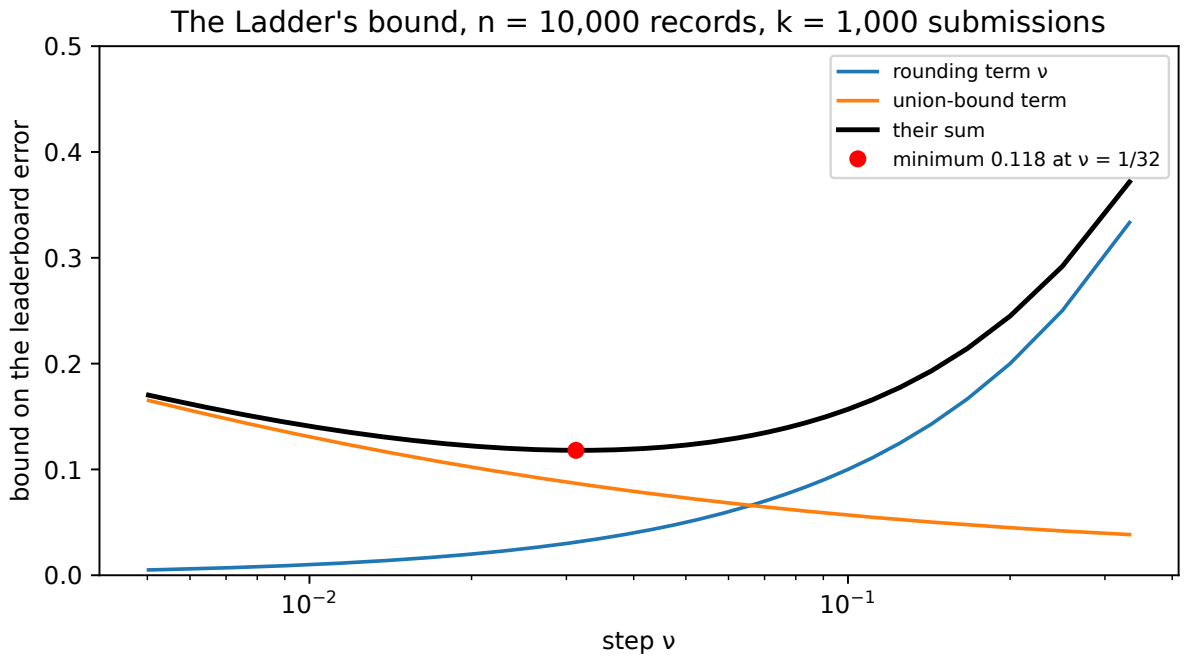

Figure N.5.: The Ladder's bound on the leaderboard error against the step ν, for $n = 10{,}000$ holdout records and $k = 1{,}000$ submissions at $\beta = 0.05$: the rounding term ν, the union-bound term, and their sum, with its minimum marked.

N.4. Unbiased reconstruction has a floor set by Rényi DP of order 2

N.4.1. What the chapter uses

Section 46.6 mentions a bound of Guo, Karrer, Chaudhuri & van der Maaten (2022) in one sentence. It says that under Rényi differential privacy (RDP) of order 2 at level ε, the expected mean squared error of any reconstruction is at least of order $1/(e^{\varepsilon} - 1)$. It adds that Fisher information gives a tighter, data-dependent bound for unbiased reconstructions. The chapter gives no proof. This section proves the first bound, and it has to correct the chapter's wording, because the bound holds for *unbiased* reconstructions, as in Guo et al., and not for every reconstruction.

The setting is a target record whose value is a number x in an interval of width w. The rest of the training data is fixed. The training run releases an output Y whose distribution P_x depends on x. The **Rényi divergence of order 2** between two distributions P and Q is

$$D_2(P\|Q) = \ln \mathbb{E}_Q\left[\left(\frac{dP}{dQ}\right)^2\right], \tag{N.32}$$

where dP/dQ is the likelihood ratio, the density of P divided by the density of Q. Training is $(2, \varepsilon)$-RDP when $D_2(P_{x'}\|P_x) \le \varepsilon$ for every pair of target values x and x', since changing the target is replacing one record. A reconstruction is a function $\hat{x}(Y)$ of the output. It is **unbiased** when its average equals the true value whatever that value is, $\mathbb{E}_x[\hat{x}] = x$ for every x. The result is

$$\mathbb{E}_x[(\hat{x} - x)^2] \ge \frac{w^2}{4(e^{\varepsilon} - 1)} \qquad \text{for every } x. \tag{N.33}$$

A target with several coordinates, coordinate ℓ in its own interval of width w_ℓ, gives the sum of these bounds, $\sum_\ell w_\ell^2/(4(e^\varepsilon-1))$.

N.4.2. The idea

An unbiased reconstruction must move its average by exactly $x'-x$ when the target moves from x to x'. The only thing that changes between the two cases is the distribution of the output, and under RDP that distribution changes little. So the reconstruction must amplify small differences in the output into a large difference in its average, and amplifying noise makes the reconstruction vary a lot. An inequality of Hammersley, Chapman and Robbins makes this precise. Moving the target reweights each output by the likelihood ratio, so the change in the reconstruction's average is a covariance between the reconstruction and that ratio. A covariance is at most the product of two spreads, by the Cauchy–Schwarz inequality. One spread is the reconstruction's error. The other is the spread of the likelihood ratio, which is called the χ^2 divergence and is set by RDP of order 2.

A concrete case is the Gaussian mechanism, which releases $Y = x + Z$ with Z normal of standard deviation σ and $x \in [0,1]$. The natural reconstruction is Y itself. It is unbiased, and its mean squared error is σ^2. Between two normals with the same σ and means a distance h apart, the order-2 divergence is h^2/σ^2, by completing the square in $\mathbb{E}[(dP/dQ)^2]$. Between targets 0 and 1 it is $1/\sigma^2$, so the mechanism is $(2,\varepsilon)$-RDP with $\varepsilon = 1/\sigma^2$, and its error is $1/\varepsilon$. At $\varepsilon = 1$ the error is 1, and the bound Equation N.33 is $1/(4(e-1)) = 0.1455$.

N.4.3. Derivation

Fix two target values x and x' in the interval, and write $\Lambda = dP_{x'}/dP_x$ for the likelihood ratio of the output. The divergence $D_2(P_{x'}\|P_x)$ is finite, so $P_{x'}$ gives no probability to outputs that P_x never produces, and the ratio is well defined.

1. **Change of measure.** An average under $P_{x'}$ is an average under P_x weighted by the likelihood ratio, $\mathbb{E}_{x'}[\hat{x}] = \mathbb{E}_x[\hat{x}\Lambda]$. The weights average to 1, $\mathbb{E}_x[\Lambda] = 1$, because the density of $P_{x'}$ integrates to 1.

2. **Write the change of the average as a covariance.** By unbiasedness, $\mathbb{E}_{x'}[\hat{x}] - \mathbb{E}_x[\hat{x}] = x'-x$. By step 1 the left side is $\mathbb{E}_x[\hat{x}(\Lambda-1)]$. Since $\mathbb{E}_x[\Lambda-1] = 0$, subtracting the constant x from $\hat{x}$ changes nothing, so

$$x' - x = \mathbb{E}_x\big[(\hat{x}-x)(\Lambda-1)\big]. \tag{N.34}$$

3. **Cauchy–Schwarz.** The average of a product is at most the square root of the product of the averages of the squares, so

$$(x'-x)^2 \le \mathbb{E}_x\big[(\hat{x}-x)^2\big]\cdot\mathbb{E}_x\big[(\Lambda-1)^2\big]. \tag{N.35}$$

   The first factor is the mean squared error at x. The second is the χ^2 **divergence** $\chi^2(P_{x'}\|P_x)$. This is the Hammersley–Chapman–Robbins inequality.

4. **The χ^2 divergence is set by order-2 RDP.** Expanding the square, $\mathbb{E}_x[(\Lambda-1)^2] = \mathbb{E}_x[\Lambda^2] - 2\mathbb{E}_x[\Lambda] + 1 = \mathbb{E}_x[\Lambda^2] - 1$. By the definition of D_2, $\mathbb{E}_x[\Lambda^2] = e^{D_2(P_{x'}\|P_x)}$, so

$$\chi^2(P_{x'}\|P_x) = e^{D_2(P_{x'}\|P_x)} - 1 \le e^{\varepsilon} - 1. \tag{N.36}$$

   Dividing step 3 by this gives, for every x' in the interval,

$$\mathbb{E}_x\big[(\hat{x}-x)^2\big] \ge \frac{(x'-x)^2}{e^{\varepsilon}-1}. \tag{N.37}$$

5. **Choose the farthest x'.** The bound holds for every x', so take the one farthest from x, which is an end of the interval. Wherever x lies, one of the two ends is at least $w/2$ away, so $(x'-x)^2 \ge w^2/4$, and Equation N.33 follows. At an end of the interval the other end is w away, and the bound is four times larger, $w^2/(e^{\varepsilon}-1)$.

6. **Several coordinates.** If the target has several coordinates, each in its own interval, apply steps 1 to 5 to each coordinate of $\hat{x}$, with x' differing from x in that coordinate only. Changing one coordinate is still a change of one record, so the RDP bound applies. The squared error is the sum of the coordinates' squared errors, so the bounds add.

N.4.4. Checking it

Table N.6 compares the bound with two unbiased mechanisms for a target in $[0,1]$, so $w=1$. The Gaussian mechanism has error $1/\varepsilon$, as above. The Laplace mechanism releases $x+Z$ with Laplace noise of scale b, whose error is $2b^2$. Its order-2 divergence between targets 0 and 1 is $\ln\left(\frac{2}{3}e^{1/b} + \frac{1}{3}e^{-2/b}\right)$ (Mironov 2017), which the script also checks by numerical integration at $b=1$, getting 0.619124 both ways. The script solves for the b that makes this equal to ε.

Table N.6.: The mean squared error of unbiased reconstructions of a target in $[0,1]$ from the Gaussian and Laplace mechanisms, against the bound Equation N.33, at the same RDP of order 2.

RDP level ε	Bound $1/(4(e^{\varepsilon}-1))$	Gaussian error $1/\varepsilon$	Laplace error $2b^2$	Gaussian over bound
0.1	2.377	10	17.36	4.21
0.5	0.3854	2	2.647	5.19
1	0.1455	1	1.023	6.87
2	0.03913	0.5	0.3458	12.8
4	0.004664	0.25	0.103	53.6
8	8.389×10^{-5}	0.125	0.02831	1,490

Both mechanisms stay above the bound, as they must. For small ε the Gaussian's error is about 4 times the bound. For large ε the gap grows without limit, because the bound falls like $e^{-\varepsilon}$ and the Gaussian's error only like $1/\varepsilon$. The left panel of Figure N.6 shows this on a log scale.

The right panel shows where the slack comes from, at $\varepsilon = 1$, so $\sigma = 1$. For the Gaussian, the true χ^2 divergence between targets a distance h apart is $e^{h^2/\sigma^2} - 1$, from the order-2 divergence above, so Equation N.37 with the mechanism's own pair gives $h^2/(e^{h^2/\sigma^2}-1)$. That rises to the

exact error σ^2 as h shrinks to 0. This limit is the Cramér–Rao bound, which uses the Fisher information, the rate at which the output distribution changes with the target. The RDP bound instead uses the worst-case χ^2, that of targets a full width apart, for every pair. At $h = \frac{1}{2}$, the page's choice for a target in the middle, the true divergence of that pair is $e^{1/4} - 1$, but the bound uses $e - 1$. So the slack comes from summarizing the mechanism by its worst pair.

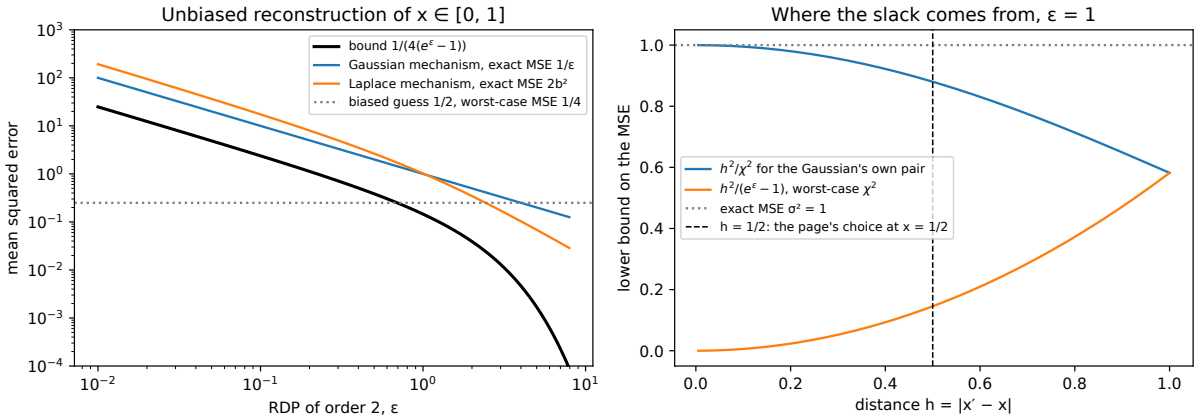

Figure N.6.: Left: the bound $1/(4(e^{\varepsilon}-1))$ on the mean squared error of an unbiased reconstruction of a target in $[0, 1]$, against the exact error of the Gaussian and Laplace mechanisms at the same RDP of order 2, and the worst-case error $\frac{1}{4}$ of the biased guess $\frac{1}{2}$. Right: at $\varepsilon = 1$, the Hammersley–Chapman–Robbins bound h^2/χ^2 against the distance h between the two targets, with the Gaussian's own χ^2 and with the worst-case $e^{\varepsilon} - 1$.

N.4.5. What it does not cover

The bound needs unbiasedness. Step 2 uses it at both x and x'. Without it, the bound fails. For example, the reconstruction that ignores the output and always answers $\frac{1}{2}$ has squared error at most $\frac{1}{4}$ for every target in $[0, 1]$. But Equation N.33 exceeds $\frac{1}{4}$ whenever $e^{\varepsilon} - 1 < 1$, that is, for $\varepsilon < \ln 2 = 0.693$. At $\varepsilon = 0.1$ the "bound" is 2.377, and the constant guess beats it by a factor of almost 10. So for small ε no such bound can hold for every reconstruction, and the chapter states it for unbiased ones.

A biased reconstruction still obeys a weaker statement. Steps 1 to 4 go through if, in step 2, the targets x and x' on the left are replaced by the averages $\mathbb{E}_x[\hat{x}]$ and $\mathbb{E}_{x'}[\hat{x}]$. The x inside the expectation is replaced by $\mathbb{E}_x[\hat{x}]$ too, which turns the squared error into the variance. They give

$$\left(\mathbb{E}_{x'}[\hat{x}] - \mathbb{E}_x[\hat{x}]\right)^2 \le \mathrm{Var}_x(\hat{x})\,(e^{\varepsilon} - 1), \tag{N.38}$$

where Var_x is the variance at x. In words, a reconstruction whose average follows the target closely must vary a lot, and one that varies little cannot follow the target. Guo et al. (2022) state their bound for unbiased reconstructions, and they also give the Fisher-information refinement for them, which is the limit of Equation N.37 as x' approaches x. That refinement needs the output distribution to change smoothly with the target, and it uses how fast the trained model's output distribution moves with the target rather than the RDP level, so it stays cited.

N.5. Code

The script code/appendix-derivations/apx_auditing.py computes every number on this page and draws its figures. It computes binomial tails exactly, solves for the one-run audit's ε bound, and computes the law of an adaptive sum exactly to check the domination lemma. It simulates one-run audits of randomized response and of Laplace scores. It computes the posterior of the coin example exactly, solves the expectation and high-probability bounds for the records that Gaussian answering needs, and simulates Gaussian answers to the boosting analyst. It evaluates the Ladder's bound, runs the boosting attack against an exact leaderboard and against the Ladder, and compares the reconstruction bound with the exact error of the Gaussian and Laplace mechanisms. From the repository root:

```
uv run python code/appendix-derivations/apx_auditing.py
```

Output (seed 0), summarized in Table N.7:

Table N.7.: Summary of the script's output.

Check	Result
One-run audit, $r = 100$, $v = 75$	$\varepsilon \geq 0.702$ at 95% confidence; tails 0.0048, 0.3827, 0.5535 and 0.9999 at $\varepsilon = 0.5$, 1, $\ln 3$ and 2
Domination lemma, adaptive sum of 100	$\Pr[X \geq 75] = 0.2363$ against 0.5535; never above the binomial
Randomized response, $\varepsilon = \ln 3$, 20,000 runs	Mean 75.01 correct; $\Pr[W \geq 75] = 0.5544$ against 0.5535
Laplace scores, $\varepsilon = 1$	Accuracy 0.730 to 0.732 for 20 to 500 guesses, against $p_\varepsilon = 0.731$; 0.697 for all 1,000
Coin posterior, $n = 20$	Inside the pure-DP band at $\varepsilon = 0.25$, 1 and 4
Records for error 0.05, $k = 1{,}000$	764,337 on average; about 1,530,000 with probability 0.95
Gaussian answers, $n = 10{,}000$, $k = 100$	Mean largest error 0.0888, 95% quantile 0.1125; bounds 0.2141 and 0.3218
Ladder, $n = 10{,}000$, $k = 1{,}000$	Best bound 0.118 at $\nu = 1/32$; closed form 0.1556
Boosting attack, $n = k = 1{,}000$	Error 0.2207 against an exact leaderboard, 0.0455 against the Ladder
Reconstruction, $\varepsilon = 1$	Bound 0.1455; Gaussian 1, Laplace 1.023

tests/test_appendix_auditing.py checks that the output still matches the numbers on this page.

What to take from it. The binomial envelope is exact for randomized response and for confident Laplace scores, and an adaptive guesser can only fall below it. The high-probability transfer theorem costs about a factor of 2 in records over the expectation version, because the failure probabilities enter only through logarithms. The Ladder stops the boosting attack almost

completely, while its worst-case bound is loose by a factor of about 6. The reconstruction bound is valid for unbiased reconstructions only, and it is loose by at least a factor of 4 for the Gaussian mechanism, because it charges every pair of targets the worst pair's divergence.

O. Glossary

Acronyms used in the book and the pages that use them.

AI Artificial intelligence. Used in Choosing ε.

API Application programming interface. Used in Threat models and privacy games, Choosing ε.

AUC Area under the curve. Used in Hypothesis testing, Threat models and attacks, Membership inference, Private prediction: PATE and in-context learning.

CDF Cumulative distribution function. Used in Probability distributions, Hypothesis testing, Threat models and privacy games, Syntactic anonymity and how it breaks, The Laplace and Gaussian mechanisms, Selection: exponential mechanism, report-noisy-max, sparse vector, Discrete and floating-point-safe mechanisms, Sums, limits and counting.

CDP Concentrated differential privacy. Used in Concentrated differential privacy.

CLT Central limit theorem. Used in Probability distributions, Concentration inequalities, f-DP and Gaussian differential privacy, Numerical accounting with privacy loss distributions, Choosing an accountant, Choosing ε, Auditing private training, Sums, limits and counting, Composition of trade-off functions.

CPA Chosen-plaintext attack. Used in Cryptography basics.

DLG Deep Leakage from Gradients. Used in Gradient inversion.

DNA Deoxyribonucleic acid. Used in Reconstruction attacks, Lower bounds: what privacy costs.

DP Differential privacy. Used in Differential privacy foundations, The definition of differential privacy, Post-processing, group privacy and composition, The Laplace and Gaussian mechanisms, Advanced and optimal composition, Selection: exponential mechanism, report-noisy-max, sparse vector, Query release and private multiplicative weights, Beyond global sensitivity, Discrete and floating-point-safe mechanisms, Local, shuffle and distributed trust models, Lower bounds: what privacy costs, Private mean estimation, Privacy accounting, Rényi differential privacy, From Rényi DP to (ε, δ) and to tests, Concentrated differential privacy, f-DP and Gaussian differential privacy, Amplification by subsampling, Numerical accounting with privacy loss distributions, Amplification by shuffling and by iteration, Adaptive composition: filters, odometers and individual accounting, Choosing an accountant, Differential privacy in machine learning, Private empirical risk minimization, DP-SGD, Hyperparameter tuning and private selection, DP-FTRL and matrix factorization, Private prediction: PATE and in-context learning, Public data and private fine-tuning, User-level differential privacy, Disparate impact, Choosing ε, Auditing private training, Adaptive data analysis, How much noise to add, Composing private releases, Accounting for DP-SGD, What ε means, and converting between definitions, Random matrices and factorizations, Mechanisms and their limits, Composition of trade-off functions, Subsampling, shuffling and iteration, Private learning and tuning, Auditing, reconstruction and adaptive analysis.

DPI Data processing inequality. Used in Divergences, Reconstruction attacks, Post-processing, group privacy and composition.

EMD Earth mover's distance. Used in Syntactic anonymity and how it breaks.

ERM Empirical risk minimization. Used in Optimization, Algorithmic stability and generalization, Differential privacy in machine learning, Private empirical risk minimization, Public data and private fine-tuning, Private learning and tuning.

FL Federated learning. Used in Gradient inversion.

FNR False negative rate. Used in The definition of differential privacy, Auditing private training, What ε means, and converting between definitions.

FPR False positive rate. Used in Hypothesis testing, Threat models and attacks, Threat models and privacy games, Membership inference, Attribute inference and model inversion, Property inference, The definition of differential privacy, Lower bounds: what privacy costs, Choosing ε, Auditing private training, What ε means, and converting between definitions.

FTRL Follow the regularized leader. Used in Query release and private multiplicative weights, Differential privacy in machine learning, DP-FTRL and matrix factorization, Choosing ε, Random matrices and factorizations.

GAN Generative adversarial network. Used in Divergences, Private prediction: PATE and in-context learning.

GD Gradient descent. Used in Optimization, Amplification by shuffling and by iteration, Optimization and estimation.

GDP Gaussian differential privacy. Used in Concentrated differential privacy, f-DP and Gaussian differential privacy, Numerical accounting with privacy loss distributions, Amplification by shuffling and by iteration, Choosing an accountant, Differential privacy in machine learning, Private empirical risk minimization, DP-FTRL and matrix factorization, Private prediction: PATE and in-context learning, Choosing ε, Auditing private training, What ε means, and converting between definitions, Random matrices and factorizations, Composition of trade-off functions.

GPU Graphics processing unit. Used in Threat models and attacks, Membership inference, Differential privacy in machine learning.

HIV Human immunodeficiency virus. Used in Syntactic anonymity and how it breaks.

HMAC Hash-based message authentication code. Used in Cryptography basics.

IND Indistinguishability, as in IND-CPA. Used in Cryptography basics.

IP Internet Protocol, as in IP address. Used in Choosing ε.

KL Kullback–Leibler. Used in Prerequisites, Divergences, Hypothesis testing, Information theory, Advanced and optimal composition, Local, shuffle and distributed trust models, Rényi differential privacy, Concentrated differential privacy, Sums, limits and counting, Tail bounds, tests and divergences.

LLM Large language model. Used in Private prediction: PATE and in-context learning.

LP Linear programming. Used in Reconstruction attacks.

LR Likelihood ratio. Used in Hypothesis testing.

LWE Learning with errors. Used in Cryptography basics, Pseudorandom functions and learning with errors.

MAP Maximum a posteriori. Used in Information theory, Attribute inference and model inversion, Linkage and re-identification.

MGF Moment generating function. Used in Probability distributions, Concentration inequalities, Divergences, Rényi differential privacy, From Rényi DP to (ε, δ) and to tests, Concentrated differential privacy, Accounting for DP-SGD, What ε means, and converting between definitions, Sums, limits and counting, Tail bounds, tests and divergences, Private learning and tuning.

MIA Membership inference attack. Used in Private prediction: PATE and in-context learning.

ML Machine learning. Used in Cryptography basics, Membership inference, Choosing an accoun-

tant, DP-SGD, Hyperparameter tuning and private selection, Choosing ε, Accounting for DP-SGD.

MWEM Multiplicative weights exponential mechanism. Used in Query release and private multiplicative weights.

NN Nearest neighbour. Used in Algorithmic stability and generalization, Optimization and estimation.

NYC New York City. Used in Linkage and re-identification.

PAC Probably approximately correct. Used in Selection: exponential mechanism, report-noisy-max, sparse vector.

PATE Private aggregation of teacher ensembles. Used in Differential privacy in machine learning, Private prediction: PATE and in-context learning, Private learning and tuning.

PCP Probabilistically checkable proof. Used in Query release and private multiplicative weights.

PIN Personal identification number. Used in Information theory, Tail bounds, tests and divergences.

PLD Privacy loss distribution. Used in f-DP and Gaussian differential privacy, Numerical accounting with privacy loss distributions, Choosing an accountant, Choosing ε, Composing private releases, Accounting for DP-SGD, Composition of trade-off functions, Private learning and tuning.

PMF Probability mass function. Used in Probability distributions, Discrete and floating-point-safe mechanisms.

PPT Probabilistic polynomial time. Used in Cryptography basics.

PRF Pseudorandom function. Used in Cryptography basics, Pseudorandom functions and learning with errors.

PRG Pseudorandom generator. Used in Cryptography basics, Pseudorandom functions and learning with errors.

PRP Pseudorandom permutation. Used in Cryptography basics.

PRV Privacy loss random variable. Used in From Rényi DP to (ε, δ) and to tests, f-DP and Gaussian differential privacy, Numerical accounting with privacy loss distributions, Choosing an accountant.

RDP Rényi differential privacy. Used in Privacy accounting, Rényi differential privacy, From Rényi DP to (ε, δ) and to tests, Concentrated differential privacy, f-DP and Gaussian differential privacy, Amplification by subsampling, Numerical accounting with privacy loss distributions, Amplification by shuffling and by iteration, Adaptive composition: filters, odometers and individual accounting, Choosing an accountant, Differential privacy in machine learning, DP-SGD, Hyperparameter tuning and private selection, DP-FTRL and matrix factorization, Private prediction: PATE and in-context learning, User-level differential privacy, Choosing ε, Auditing private training, Composing private releases, Accounting for DP-SGD, What ε means, and converting between definitions, Tail bounds, tests and divergences, Subsampling, shuffling and iteration, Private learning and tuning, Auditing, reconstruction and adaptive analysis.

RMSE Root-mean-square error. Used in Private mean estimation, Random matrices and factorizations.

ROC Receiver operating characteristic. Used in Hypothesis testing, Threat models and attacks, Threat models and privacy games, Membership inference.

SGD Stochastic gradient descent. Used in Optimization, Algorithmic stability and generalization, Gradient inversion, Privacy accounting, Rényi differential privacy, From Rényi DP to (ε, δ) and to tests, Concentrated differential privacy, f-DP and Gaussian differential privacy, Amplification by subsampling, Numerical accounting with privacy loss distributions,

Amplification by shuffling and by iteration, Adaptive composition: filters, odometers and individual accounting, Choosing an accountant, Differential privacy in machine learning, Private empirical risk minimization, DP-SGD, Hyperparameter tuning and private selection, DP-FTRL and matrix factorization, Private prediction: PATE and in-context learning, Public data and private fine-tuning, User-level differential privacy, Disparate impact, Choosing ε, Auditing private training, Composing private releases, Accounting for DP-SGD, What ε means, and converting between definitions, Optimization and estimation, Random matrices and factorizations, Composition of trade-off functions, Subsampling, shuffling and iteration, Private learning and tuning.

SQL Structured Query Language. Used in Reconstruction attacks.

SVM Support vector machine. Used in Private empirical risk minimization.

TPR True positive rate. Used in Hypothesis testing, Threat models and attacks, Threat models and privacy games, Membership inference, Attribute inference and model inversion, Property inference, The definition of differential privacy, Lower bounds: what privacy costs, Choosing ε, Auditing private training, What ε means, and converting between definitions.

TV Total variation. Used in Divergences, Hypothesis testing, Cryptography basics, Threat models and privacy games, Property inference, Syntactic anonymity and how it breaks, The definition of differential privacy, The Laplace and Gaussian mechanisms, Discrete and floating-point-safe mechanisms, Local, shuffle and distributed trust models, Lower bounds: what privacy costs, f-DP and Gaussian differential privacy, Sums, limits and counting.

XOR Exclusive or. Used in Cryptography basics.

ZIP Zone Improvement Plan code, the US postal code. Used in Linkage and re-identification, Syntactic anonymity and how it breaks, Lower bounds: what privacy costs.
